Professor L. Fernández-Cruz

Ten patients who had undergone whole-organ pancreas transplantation and pancreatoduodenocystostomy from a total of 60 simultaneous cadaveric kidney–pancreas transplants met the criteria for graft pancreatitis. This condition is clearly different from acute rejection on the basis of marked hyperamylasaemia and significant local findings over the allograft. Graft rejection was the cause of graft loss in one of the patients; eight are alive, seven with a functioning graft 61, 30, 27, 25, 21, 18 and 14 months after transplantation. Two patients died: one from severe graft pancreatitis and the other from cytomegalovirus infection. Bladder drainage with or without antibiotics has been the most common therapy, based on the theory that damage is caused by duodenal content and infected urine reflux. To prevent graft loss, antiviral treatment should be given when pancreatitis due to cytomegalovirus is suspected or diagnosed. Two patients with native pancreatitis are also described; the disease was severe and surgery was required in both cases. The pancreas grafts have now been functioning for 2 years 7 months and 2 years 10 months respectively.

According to the International Pancreas Transplant Registry[1] the results of pancreatic graft survival have shown a progressive improvement, comparable to that obtained for transplantation of other solid organs. Failure of a pancreatic allograft can be attributed to immunological or non-immunological causes. Mechanisms of non-immunological graft loss include thrombosis, infection and pancreatitis.

Pancreatitis constitutes an infrequent cause of graft loss[2]. This complication can present early in the postoperative course in association with preservation damage, or late, often occurring months after transplantation. Differentiation between graft pancreatitis and rejection can be difficult in some patients, but graft pancreatitis is clearly distinguishable from acute inflammation of the native pancreas. Acute native pancreatitis is a rare complication after renal transplantation, and can also occur following simultaneous renal–pancreas transplantation.

The purpose of this study was twofold: first, to determine the factors that predispose to late graft pancreatitis to establish the optimal treatment and, second, to document experience of acute native pancreatitis and its management.

Patients and methods

Between February 1983 and July 1992, 60 primary cadaveric simultaneous kidney and pancreas transplants were performed in adults with type I diabetes mellitus. Only one patient had a segmental graft occluded with prolamine. In the other patients, exocrine pancreatic graft secretions were drained to the urinary tract using techniques described previously[3,4]: to the renal pelvis in four patients, to the ureter in five and to the bladder (duodenocystostomy technique) in 50.

There were 45 men and 15 women. The mean age of patients was 36·4 (range 25–51) years. The mean duration of insulin-dependent diabetes mellitus (IDDM) was 20·4 (range 12–33) years. The pancreas was preserved under cold storage conditions with Collins' solution ($n = 24$) and, more recently, with University of Wisconsin solution ($n = 36$). Postoperative immunosuppression consisted of azathioprine and prednisone (five patients), prednisone and cyclosporin (12) or quadruple therapy with cyclosporin, prednisone, azathioprine and prophylactic antilymphoblast globulin (43). Episodes of rejection were treated with pulsed corticosteroids or OKT3.

All patient records were reviewed retrospectively for episodes of abdominal pain associated with hyperamylasaemia. Ten patients (eight men), with a mean(s.d.) age of 39·4(7·6) years and IDDM for a mean(s.d.) of 19·7(5·3) years, had clinical criteria compatible with the definition of allograft pancreatitis: an inflammatory process of the pancreas allograft with rapid onset of symptoms and usually presenting with lower abdominal pain and raised levels of pancreatic enzymes in the blood. The condition is usually associated with stable renal allograft function and minimal organ disturbance. Serum glucose (normal value 80–110 mg/dl), lipase (normal < 200 units/l), amylase (normal < 400 units/l) and urinary amylase levels were determined regularly, and intravenous and oral glucose tolerance tests carried out serially at 1-year or shorter intervals in all patients suspected of graft pancreatitis.

In all patients with clinical suspicion of graft pancreatitis, duplex Doppler ultrasonography was performed. Pancreatic size, echostructure and perigraft–intra-abdominal fluid were evaluated by real-time ultrasonography. A pulsed Doppler study was performed thereafter to assess the permeability of the vascular pedicle at the hilum. Venous and arterial Doppler spectra were also obtained of graft parenchyma (head, body, tail). The arterial pulsed Doppler spectrum was quantified by the resistive index (RI):

$$\mathrm{RI} = \frac{\text{peak systolic velocity} - \text{end diastolic velocity}}{\text{peak systolic velocity}}$$

Three consecutive waveforms were obtained at each parenchymal level and the final RI derived from the mean of these values. Patients were also checked for lower urinary tract infection. Cystography was performed when bladder or duodenal perforation was suspected.

Diagnosis of cytomegalovirus (CMV) infection was performed by CMV serology and/or histological examination. Serological testing for CMV-specific immunoglobulin (Ig) G and IgM antibodies was carried out by complement fixation. Seroconversion for IgG and/or IgM was required for the diagnosis of primary CMV infection. Reactivated infection was diagnosed by an increase in CMV-specific IgG level to four times the previous value. Histological diagnosis of CMV infection was made when a pancreatic graft biopsy showed inclusion bodies in the acinar cells.

Two patients had native acute pancreatitis (acute inflammation of their own pancreas) and are considered separately.

Results

Graft pancreatitis

Ten patients met the criteria for graft pancreatitis. All had undergone whole-organ pancreas transplantation with duodenocystostomy. The total number of episodes was 22 with a mean(s.d.) of 2·2(0·4) (range 1–5) episodes per patient. The

0007-1323/93/111429-04 © 1993 Butterworth-Heinemann Ltd

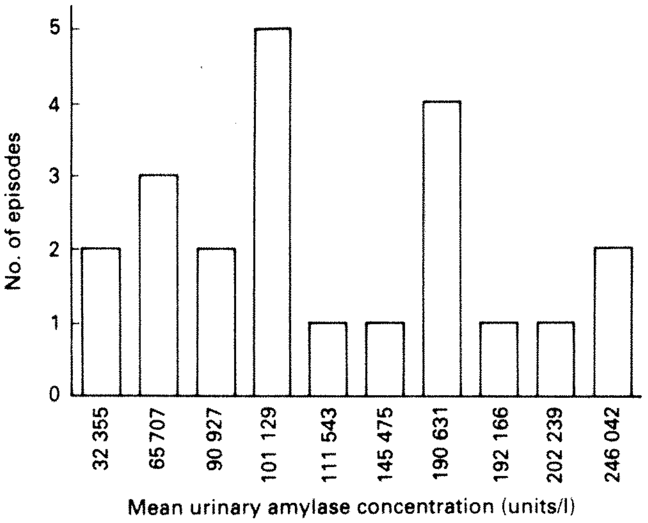

Figure 1 *Relationship between urinary amylase level and number of episodes of pancreatitis for each patient*

mean(s.d.) time of occurrence was 341(76) days after transplantation. Abdominal pain was present in all patients. Other symptoms, such as fever (ten patients), dysuria (eight), haemorrhagic cystitis (one), paralytic ileus (four) and shock (one), were also observed. Physical findings were characterized by tenderness of the lower abdomen (22 episodes), abdominal distension (22) and ascites (one). All patients had marked hyperamylasaemia (mean(s.d.) level 1620(182) units/l) and hyperlipasaemia (mean(s.d.) level 1415(417) units/l). Endocrine graft function remained normal (mean(s.d.) serum glucose level 107(10) mg/dl) in all patients during the episodes of graft pancreatitis.

As shown in *Figure 1*, there was great variability in the mean urinary amylase level of patients with pancreatitis. Those with graft pancreatitis had the same number of rejection episodes (one or two) as those without inflammation of the graft.

Duplex Doppler ultrasonography of normal grafts showed a homogeneous structure without pancreatic duct dilatation (<2 mm), and the graft size did not exceed the expected dimensions of a normal pancreas. On pulsed Doppler examination, the venous spectrum showed continuous flow. Quantification of the arterial Doppler spectrum in stable grafts (>2 months after grafting) showed a mean(s.d.) RI of 0·62(0·01). Results with duplex Doppler ultrasonography in the follow-up of pancreatic grafts and in graft rejection episodes have been partially reported previously[5,6] and are summarized in *Table 1*. The most common abnormalities seen on ultrasonography in graft pancreatitis were perigraft fluid and graft hypoechogenicity. The pulsed Doppler RI could differentiate between graft pancreatitis and rejection (75 per cent sensitivity, 95 per cent specificity). The latter is characterized by a significant increase (mean(s.d.) 0·79(0·14)) compared with the RI value obtained before rejection (0·62(0·05)). However, the RI in graft pancreatitis (0·61(0·04)) is similar to that measured before episodes of pancreatitis (0·63(0·01)).

Twelve episodes were clearly associated with bladder outlet obstruction resulting in urine retention or stasis secondary to a large bladder. Urinary infection was encountered in 19 of 22 episodes of graft pancreatitis (*Staphylococcus epidermidis*, nine patients; group D enterococcus and *Staphylococcus epidermidis*, three; *Pseudomonas* species, six; other Gram-positive organisms, one). Three episodes of CMV graft pancreatitis were documented in two patients: one died from multiple organ failure 2 months after grafting, and pancreatic graft biopsy showed inclusion bodies in acinar cells; the other suffered two episodes of graft pancreatitis during which seroconversion for CMV-specific IgG antibodies (titre 1/128) was detected. By 2 months later these titres were negative but the patient developed irreversible rejection resulting in graft failure.

Indwelling bladder drainage was the most frequent therapy for episodes of graft pancreatitis (22 episodes), and antibiotics were also given when urinary infection was documented (19). Other treatments used were bowel rest (18 episodes), oral pancreas extract (two), somatostatin (three), total parenteral nutrition (one) and anti-CMV therapy (two). Bladder irrigation with saline and the protease inhibitor aprotinin was successfully used in one patient with haemorrhagic cystitis. The mean(s.d.) time for resolution of the hyperamylasaemia and abdominal pain was 7·2(1·8) (range 2–41) days.

Three patients developed local complications. One graft duodenocolic fistula was managed conservatively; there were two bladder fistulas, in one complicated by peritoneal ascites which healed spontaneously; in the other surgical repair was required.

Severe graft pancreatitis associated with organ failure was observed in one patient after conversion of the graft from bladder to intestinal drainage, with cessation of endocrine and exocrine pancreatic function and progressive deterioration leading to death 10 days after conversion.

Eight patients are still alive. Pancreatic graft rejection led to graft failure in one patient. In the other seven, both kidney and pancreas are currently functioning and the patients do not require insulin 61, 30, 27, 25, 21, 18 and 14 months after transplantation.

Native pancreatitis

Patient 1. A 29-year-old man underwent combined cadaveric renal–pancreas transplantation in November 1989. Both grafts functioned immediately after transplantation. Immunosuppression consisted of cyclosporin, azathioprine and prednisone. The pancreas was drained via a duodenocystostomy. Rejection of the kidney and pancreas was treated 1 month after transplantation with pulsed doses of corticosteroids and OKT3, and 6 weeks later with bolus steroids. At 10 days after treatment the patient developed CMV infection with neurological signs of rhomboencephalitis, and was treated with antiviral therapy. Some 4 months after this episode and 6 months after transplantation he presented with repeated episodes of right hypochondrial and epigastric pain for 7 days, followed by sudden collapse. At laparotomy there was peripancreatic and splenic haematoma; splenectomy and peripancreatic debridement were performed. Peripancreatic drains were placed for lavage for 10 days. The postoperative course was uneventful.

This patient is currently well with both kidney and pancreas functioning (insulin-free) for 2 years 7 months.

The exact mechanism of native pancreatitis in this patient is unknown but CMV infection and the previous potent antirejection treatment may have contributed.

Patient 2. A 36-year-old man underwent combined renal–pancreas transplantation in January 1990. The pancreas was drained via a duodenocystostomy. Both grafts functioned immediately after transplantation. At 6 months there was rejection of both organs, which was successfully treated with pulsed doses of corticosteroids. Some 3 weeks later the patient experienced an episode of graft pancreatitis and dysuria, managed with a urinary Foley catheter for 3 days. At 12 months after transplantation, renal function deteriorated as a sign of ongoing chronic rejection despite good endocrine and exocrine pancreatic graft function. Haemodialysis was instituted 16 months after transplantation. The patient underwent renal retransplantation 2 years after primary transplantation and the kidney graft was placed in an orthotopic position. The graft functioned immediately, with no change in the triple immunosuppression therapy. However, 2 weeks later he developed abdominal pain with a marked rise in the serum amylase level (mean 1142 (range 1059–1237) units/l) and clinical evidence of sepsis. Endocrine pancreatic graft function remained normal.

Ultrasonography showed that both kidney and pancreas grafts were of normal size. However, a fluid collection was detected near the head of the native pancreas in the subhepatic region. Percutaneous, then surgical, drainage revealed 300 ml pus containing group D enterococcus and *Pseudomonas* species. Some 6 weeks later a 6-cm pseudocyst was detected in the body of the pancreas. Cystogastrostomy was performed with complete resolution of the clinical symptoms. This patient has to date had both kidney and pancreas functioning (insulin-free) for 2 years 10 months.

The native pancreatitis in this case may have been related to intraoperative injury to the gland at the time of kidney graft placement in the orthotopic position.

Discussion

Graft pancreatitis can be differentiated from acute rejection on the basis of marked hyperamylasaemia and significant local findings over the allograft, both of which are not characteristic of acute rejection. Stratta *et al.*[7] have reported that only 17·7 per cent of rejection episodes are associated with hyperamylasaemia. In the present group of ten patients, eight had had nine previous rejection episodes but hyperamylasaemia was observed in only one episode. Furthermore, endocrine pancreatic function was not affected; all the patients maintained normoglycaemia and good exocrine function with little or no modification of urinary amylase levels from the baseline. In addition, the absence of changes in renal function over time and the improvement in hyperamylasaemia without changes in immunosuppressive therapy are against isolated pancreatic rejection.

No correlation was observed between levels of urinary amylase and the frequency of episodes of graft pancreatitis, showing that the amount of exocrine secretion is not predictive of the occurrence of inflammatory responses in the graft. Patients without graft pancreatitis with stable functioning grafts also show great variability in the level of urinary amylase. However, urinary amylase monitoring is reliable[8,9] in the diagnosis of graft rejection when the level of urinary amylase in an individual patient falls by 50 per cent.

Late graft pancreatitis was thought to be unique to the bladder drainage technique but it has been associated with enteric diversion[10]. Stratta *et al.*[7] reported 43 episodes in 19 patients with bladder drainage. Concomitant urinary tract infection was documented in 64 per cent of patients and short-term Foley catheter drainage plus antibiotic therapy successfully reversed 39 of the 43 episodes. See and Smith[11] demonstrated that active proteolytic enzymes are present in the urine of many patients with a duodenocystostomy. These observations may be related to the mechanisms of graft pancreatitis. Urinary retention and stasis facilitate the activation of proteolytic enzymes, which leads to the breakdown of the normal bladder and duodenal mucosal barrier and facilitates colonization by bacteria. The reflux of bladder–duodenal content with active trypsin and infected urine may damage the ductal mucosal barrier, resulting in intrapancreatic activation of enzymes[12]. Another possibility could be increased pressure in the pancreatic duct secondary to the increased pressure in the bladder associated with urethral or bladder obstruction. It is noteworthy that bladder drainage with or without antibiotics resulted in resolution of the majority of episodes of pancreatitis; however, recurrent episodes were common. Another explanation could be occlusion of the sphincter of Oddi secondary to rejection. This process could cause ductal occlusion as a result of local mucosal swelling, impaired blood flow and necrosis leading to ductal stenosis. In a series of 124 pancreatic grafts, Backman *et al.*[13] reported eight patients with pancreatitis associated with ongoing CMV infection; five developed intrapancreatic abscesses and four of the grafts were lost. To prevent graft loss, antiviral treatment should be given when CMV pancreatitis is suspected or diagnosed[14].

The occurrence of graft pancreatitis does not lead to graft loss. Of ten of the present patients, seven still retain a functioning graft. Graft rejection led to graft loss in one patient. Two patients died, one from severe graft pancreatitis and one from CMV infection.

Acute pancreatitis is an infrequent but severe complication of renal transplantation[15]. A number of aetiological factors may contribute to pancreatitis. Possible explanations for the development of native pancreatitis following combined renal–pancreas transplantation and renal transplantation alone are the intensive immunosuppressive regimen used, the development of CMV infection and pancreatic injury in cases of orthotopic renal transplantation using the splenic vessels of the recipient for revascularization. The differential diagnosis between native and graft pancreatitis is usually not difficult. Graft pancreatitis is frequently associated with fever, graft tenderness, lower abdominal pain and abdominal distension. In native pancreatitis the physical findings are upper abdominal pain and the systemic manifestations are more severe.

Intestinal obstruction following laparoscopic inguinal hernia repair

C. W. Hendrickse and D. S. Evans

Department of Surgery, The Royal Shrewsbury Hospital, Shrewsbury SY3 8XF, UK
Correspondence to: Mr D. S. Evans

Following the success of laparoscopic cholecystectomy, the list of procedures that have been attempted laparoscopically is expanding rapidly[1]. For laparoscopic inguinal herniorrhaphy the goal is to reduce the recurrence rate, decrease postoperative morbidity and reduce the time off work compared with the open operation. The complications associated with this new technique are at present unclear, but should now include intestinal obstruction.

Case report

A 20-year-old man was admitted for repair of a right inguinal hernia. Laparoscopic preperitoneal mesh herniorrhaphy was performed. After transverse incision of the peritoneum above the hernial defect and dissection of the preperitoneal space, the sac was reduced and a Marlex mesh (C. R. Bard, Billerica, Massachusetts, USA) cut to the required size and fixed into place with staples. Peritoneal closure over the repair was by staples and sutures; the total operating time was 60 min. The patient made an uncomplicated recovery and was discharged home the next morning.

Some 4 days after operation the patient was readmitted with a 1-day history of colicky central abdominal pain, vomiting and constipation. He also complained of pain in the right groin radiating to the upper medial thigh. On examination the man had mild abdominal distension, obstructive bowel sounds and tenderness over the right iliac fossa. Plain radiography confirmed the impression of small bowel obstruction. The patient was treated conservatively by nasogastric aspiration and intravenous fluid administration. The intestinal obstruction and groin pain settled, and 4 days later he went home.

The patient was readmitted 7 days later with the same clinical and radiological picture of small bowel obstruction with reduced pin-prick sensation in the upper medial aspect of the right thigh. After rehydration, laparotomy revealed that the peritoneal repair covering the mesh had separated at its lateral extent. A loop of distal ileum had herniated through the defect, was adherent to the Marlex mesh and obstructed at this point. Gentle blunt dissection freed the adherent obstructed segment of distal ileum and, apart from repair of the peritoneal defect, no further procedure was required. The postoperative recovery was uneventful; the patient was discharged home 6 days after operation and 1 month later was asymptomatic.

Discussion

This paper describes a predictable and major complication following laparoscopic preperitoneal mesh repair of an inguinal hernia. The cause of failure of the peritoneal repair over the mesh is unclear, but probably related to a tight repair with failure of the staples and sutures to hold the peritoneum, thus allowing adherence of small bowel to the mesh.

An intraperitoneal onlay mesh technique of laparoscopic herniorrhaphy has recently been described[2]. There are obvious concerns regarding this method because of the possibility of bowel adherence to the uncovered mesh. The pain and diminished sensation in the right thigh of the present patient were probably related to oedema around the femoral branch of the genitofemoral nerve rather than to stapling of the nerve since symptoms settled after laparotomy.

A recent review of laparoscopic hernia repair in several centres[3] reported a complication rate of less than 10 per cent including anterior thigh and testicular pain, haematoma formation and bladder injury; the short-term recurrence rate was low (under 0·8 per cent). No other case reports describing the complication encountered here, following laparoscopic preperitoneal mesh repair, have been found in the literature. Assessment as to whether laparoscopic herniorrhaphy could replace conventional repair as the method of choice for inguinal hernia awaits properly organized prospective studies.

Liver resection for recurrent hilar cholangiocarcinoma

E. M. Targarona, G. Zografos and N. A. Habib

Department of Surgery, Royal Postgraduate Medical School, Hammersmith Hospital, Du Cane Road, London W12 0NN, UK

Correspondence to: Mr N. A. Habib

Hilar cholangiocarcinoma is a rare lesion that accounts for less than 2 per cent of all tumours and 10 per cent of liver cancers[1]. It carries a poor prognosis, and surgical resection offers the only chance of cure[2]. Because of the anatomical location of the tumour, carcinoma cells spread via the lymphatics to the caudate lobe. This pattern of spread may increase the possibility of tumour recurrence after local resection if the hilum is resected without concomitant hepatectomy[3]. However, long-term survival has been achieved in a small percentage of patients managed by hilar resection alone[3,4]. The treatment of local recurrence usually consists of percutaneous external biliary drainage or surgical bypass procedures.

A case is reported of hilar cholangiocarcinoma treated with local resection. The tumour recurred and was subsequently treated successfully with a repeat resection including extended right hepatectomy.

Case report

A 56-year-old man underwent operation in June 1991 for hilar cholangiocarcinoma causing obstructive jaundice. The tumour was located at the biliary convergence and local resection was performed. Biliary continuity was established by bilateral hepatojejunostomy using a Roux-en-Y jejunal loop. Histopathological examination confirmed the presence of well differentiated cholangiocarcinoma, with infiltration of the proximal resection margin. The patient made a smooth recovery and was discharged without further therapy. At 10 months the man developed several episodes of acute cholangitis. Percutaneous transhepatic cholangiography showed a short tight stricture affecting the right anterior and posterior sector ducts, suggesting tumour recurrence (*Figure 1*). Retrograde filling of the left duct from the jejunal loop showed this anastomosis to be normal. An external–internal drain was inserted to relieve the cholangitis. Visceral angiography revealed no arterial or portal vascular encasement. Computed tomography (CT) excluded secondaries in the hepatic parenchyma. No attempt was made at this stage to obtain a tissue diagnosis.

Because of the good general condition of the patient and his motivation, a decision was taken to operate and resect the hilar recurrence in May 1992. At laparotomy there was no evidence of peritoneal seeding or lymphadenopathy. Tumour recurrence was confirmed by frozen-section examination. The liver was mobilized and the hilar tumour resected in continuity with an extended right hepatectomy. The tumour was adherent to but not invading the portal vein. During the dissection the jejunal loop was mobilized, but the left hepatojejunostomy was left undisturbed. The patient had an uncomplicated postoperative recovery and was discharged home on day 10. The pathology report on the resected tumour showed features of well differentiated cholangiocarcinoma without involvement of the resection margin, so no adjuvant therapy was given. Some 10 months later the man remains well with normal carcinoembryonic antigen levels and no sign of tumour recurrence on CT.

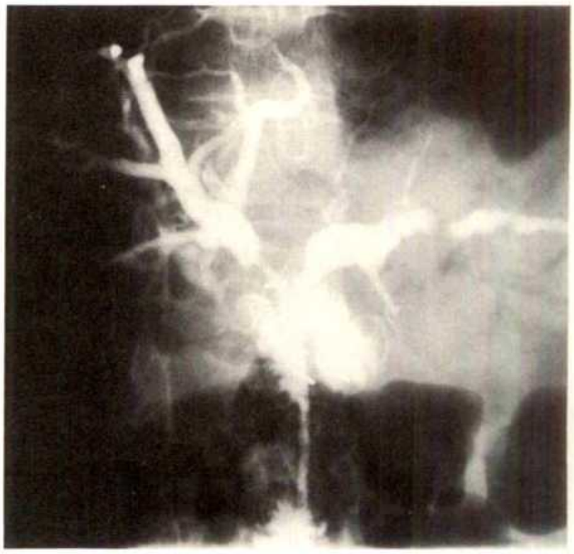

Figure 1 *Percutaneous transhepatic cholangiogram showing a short stricture affecting the right anterior and posterior sector ducts consistent with recurrent cholangiocarcinoma*

Discussion

Surgical resection is the only curative treatment for hilar cholangiocarcinoma. The role of repeat operation and liver resection for treatment of recurrent hilar cholangiocarcinoma is not well documented[2,3]. Most patients develop local recurrence at the anastomosis after resection for hilar cholangiocarcinoma. Usually, previous surgery and the spread of the tumour preclude re-resection, and patients are treated by percutaneous external drainage. Analysis of several large series published in recent years does not provide information on the feasibility of this therapeutic option[1–5]. In the patient presented, recurrence was confined to the right hepatojejunal anastomosis and major liver resection was undertaken with satisfactory results.

Radical extended resection of cholangiocarcinoma is a more complex surgical procedure than localized hilar resection and hence is associated with a high mortality rate, although it gives the best survival figures[2]. The main rationale for operative treatment in the era of interventional radiology is to aim for prolonged survival. This goal is better achieved by radical than local palliative resection[3].

Mr O. J. Garden

A series of 107 patients with cholangiocarcinoma diagnosed between January 1980 and December 1991 is reported. Changing patterns of investigation and treatment in the periods 1980–1985 and 1986–1991 are analysed. There was a decrease in the use of percutaneous transhepatic cholangiography in the second period (86 versus *51 per cent of patients) but increased use of endoscopic retrograde cholangiography (19* versus *71 per cent) and computed tomography (8* versus *59 per cent). The overall resectability rate (17 per cent) was similar to those of other reported series but greater in the second period (8* versus *21 per cent). Palliation by endoscopic and percutaneous stenting was associated with a high incidence of recurrent cholangitis (55 per cent) and jaundice (35 per cent). During the second 6-year period, more effective palliation was achieved by segment III cholangiojejunostomy with a lower incidence of recurrent cholangitis (19 per cent) and jaundice (19 per cent). Overall prognosis for patients with this condition is grim and efforts must usually be aimed at providing the most appropriate palliation.*

Carcinoma involving the extrahepatic bile ducts carries a poor prognosis, with fewer than 30 per cent of patients surviving for more than 5 years even in selected groups[1,2]. The tumour is frequently diffuse and sclerotic in nature, tending to invade locally and involve the hilum of the liver. As a consequence, resectability rates under 20 per cent are common[3–6] and efforts are more often aimed at the relief of obstructive jaundice. In recent years, wider application of new imaging techniques has led to improved diagnosis of the cause of the bile duct obstruction. However, investigations such as percutaneous transhepatic cholangiography (PTC) and endoscopic retrograde cholangiography (ERC) are invasive and the complications that may follow their use can compromise further management. A 12-year experience in the management of patients with cholangiocarcinoma of the extrahepatic bile ducts has been reviewed in an attempt to improve future management of the condition.

Patients and methods

The case records of 107 patients with extrahepatic bile duct carcinoma diagnosed between January 1980 and December 1991 were identified from unit discharge summaries and operation notes. All patients had been admitted under the care of two consultant surgeons in the University Department of Surgery at Glasgow Royal Infirmary (January 1980 to September 1988) or the University Department of Surgery at the Royal Infirmary, Edinburgh (October 1988 to December 1991). No change in approach to the diagnosis and treatment of these tumours was apparent following the authors' move to Edinburgh.

The extent and type of investigations undertaken in patients referred from other hospitals and before transfer varied. Before 1985, ultrasonography was used to confirm the presence of an obstructed biliary tree and PTC to define the level and nature of the obstruction. Patients with tumours not amenable to resection underwent palliation by surgical insertion of a U tube or by jejunal anastomosis to the common hepatic duct. From 1985, ERC was used to demonstrate the site of obstruction of the biliary tree and PTC reserved for patients in whom endoscopic evaluation was unsuccessful or unsatisfactory. Patients considered unfit for surgery underwent stenting by endoscopic or percutaneous means, or by a combination of both techniques. Computed tomography (CT) and angiography were used to assess suitability for resection. Patients who were fit for surgery but with an irresectable tumour underwent segment III cholangiojejunostomy. Tumours were considered irresectable when metastases were present in the liver or extrahepatic disease was seen on CT. Extensive bile duct involvement on one side of the liver with vascular involvement on the other, evidence of encasement of the common hepatic artery and involvement of the main portal vein on angiography were also taken as signs of irresectability. Liver resection was deemed necessary where there was involvement of the biliary tree beyond the second bifurcation. To demonstrate the changing trends in management, the 37 patients treated before January 1986 were compared with the 70 managed from January 1986 to December 1991.

Clinical presentation, radiological investigation and pathology results were reviewed retrospectively from case records. In addition, the site of tumour, form of treatment and resulting complications were noted. Tumours were classified using the method described by Longmire[7]: 'upper' third tumours involved the common hepatic duct above the level of the cystic duct, 'middle' third lesions affected the supraduodenal portion of the common bile duct and 'lower' third tumours involved the retroduodenal and intrapancreatic portions of the common duct. 'Diffuse' tumours were those involving more than one-third of the extrahepatic bile ducts. Long-term morbidity and mortality were documented from outpatient and inpatient attendance, and by questionnaires completed by the patient's general practitioner when hospital follow-up was not possible.

Operative mortality was defined as that within 30 days of surgery. The following postoperative complications were documented: cholangitis (rising serum bilirubin level above normal laboratory range in association with pyrexia, rigors and upper abdominal pain), acute pancreatitis (serum amylase level above 1000 units/l), an intra-abdominal collection (abdominal pain, pyrexia and collection seen on ultrasonography), biliary peritonitis (clinical signs of peritonism associated with tachycardia, pyrexia and confirmed at autopsy in one case), septicaemia (general deterioration in clinical state associated with pyrexia, tachycardia, hypotension and growth of one organism on repeat blood culture), chest infection (pyrexia, purulent sputum, clinical and radiological evidence of acute pulmonary consolidation), wound infection (erythema with production of pus from the wound), superficial wound dehiscence (breakdown of skin apposition in the healing wound), cardiac failure (dyspnoea, orthopnoea, pitting peripheral oedema with radiological confirmation), myocardial infarction (chest pain, serial electrocardiographic changes, acute rise in serum cardiac enzyme levels), cardiac arrest (clinical and electrocardiographic evidence of disruption of normal cardiac rhythm), pulmonary embolus (chest pain, dyspnoea, central cyanosis, tachycardia and collapse with confirmation at autopsy), cerebrovascular accident (deterioration in conscious state, development of neurological signs lasting more than 24 h), bleeding peptic ulcer (lesion seen at endoscopy following haematemesis), urinary

tract infection (dysuria, frequency and growth of bacteria on culture) and acute renal failure (urine output less than 400 ml per day associated with rising urea and creatinine levels).

The χ^2 test was used to examine changing trends in diagnosis and treatment and to compare the incidence of cholangitis between groups. The log rank test was used for comparison of survival curves, which were prepared from Kaplan–Meier life-tables.

Results

A total of 107 patients (63 men, 44 women) with a diagnosis of cholangiocarcinoma were identified. The mean age at diagnosis was 65 (range 35–90) years. Sixteen patients were admitted directly to the surgical unit, eight transferred from medical wards within the hospital and 83 transferred from other hospitals.

Fourteen patients had undergone a procedure involving the biliary tract before admission: four had received cholecystojejunostomy, two choledochojejunostomy, four operative placement of a stent and three non-operative stent insertion. Another patient had undergone cholecystectomy, open biopsy of cholangiocarcinoma situated in the common hepatic duct and placement of a T tube.

The time from first admission to the authors' unit until definitive treatment ranged from 0 to 47 (mean 9) days. The length of stay in the unit ranged from 4 to 101 (mean 23) days.

A diagnosis of cholangiocarcinoma was confirmed histologically or cytologically in 67 per cent of cases. In 53 of the 57 patients from whom material was obtained for histological evaluation, the diagnosis of cholangiocarcinoma was confirmed. Malignant cells were seen in fine-needle aspirates in 15 of the 23 patients from whom material was obtained for cytological evaluation. Six patients had the diagnosis confirmed at post-mortem examination. Patients who did not have positive pathological confirmation of cholangiocarcinoma had typical radiological features on cholangiography and the subsequent clinical course was consistent with a primary bile duct tumour.

Table 1 *Investigations used in the management of patients with cholangiocarcinoma*

	1980–1985 ($n=37$)	1986–1991 ($n=70$)	Total ($n=107$)

Jaundice was a presenting feature in all but one patient. The highest bilirubin level for each patient in the week before surgery (or in the first week after admission if no operation was performed) varied between 7 and 785 (mean(s.d.) 346(218)) μmol/l.

The investigations performed before and after referral are shown in *Table 1*. Although 64 per cent of patients underwent PTC, this procedure was used less frequently in the period 1986–1991. The use of ERC increased after 1985 and CT was employed much more frequently in the second period under review. The change in use of all three of these investigations was significant ($P<0{\cdot}001$). Angiography was also used more frequently after 1985 ($P<0{\cdot}01$).

Sixty-nine tumours (64 per cent) involved the upper third of the extrahepatic biliary tree, eight (7 per cent) the middle third, ten (9 per cent) the lower third and 20 lesions (19 per cent) were diffuse. Of the 20 patients with diffuse cholangiocarcinoma, only two had tumours that did not involve the upper third of the biliary tree and seven had tumours that involved the upper, middle and lower thirds. There was a clear predominance of tumours involving the upper biliary tract (81 per cent), reflecting the high proportion of tertiary referrals (85 per cent).

The number of patients who received no treatment or underwent laparotomy only decreased in the period 1986–1991 (*Table 2*). There was a reduction in the number of extrahepatic bypass procedures performed and the number of operative stents inserted after 1985, while only one segment III cholangiojejunostomy was performed before 1986. The trend was significant for all three of these treatment groups ($P<0{\cdot}01$).

In the period 1980–1985, three bile duct resections were undertaken and consisted of excision of tumour involving the confluence of the right and left hepatic ducts. In the years 1986–1991, six such local resections were performed, six hemihepatectomies undertaken (because of local hepatic invasion of hilar tumour) and three pancreatoduodenectomies performed for tumours of the lower biliary tree with local pancreatic invasion. This increase in the resectability rate from 8 to 21 per cent was not, however, significant ($P>0{\cdot}05$).

Biliary stenting was not employed before 1986 but thereafter its use increased significantly ($P<0{\cdot}001$). Twenty-seven patients had non-operative stent insertion: 14 at ERC, nine by a combination of ERC and PTC, and four by PTC alone.

The incidence of postoperative or postintervention complications is shown in *Tables 3* and *4*. Six patients experienced cholangitis within 7 days of treatment: operative extrahepatic bypass (one), segment III bypass (one), resection (one) and ERC–PTC stenting (three). Another patient developed acute pancreatitis following ERC stenting and required pancreatic necrosectomy at the time of resection of a hilar bile duct tumour with left hemihepatectomy. Two patients developed anastomotic leakage and an intra-abdominal collection following

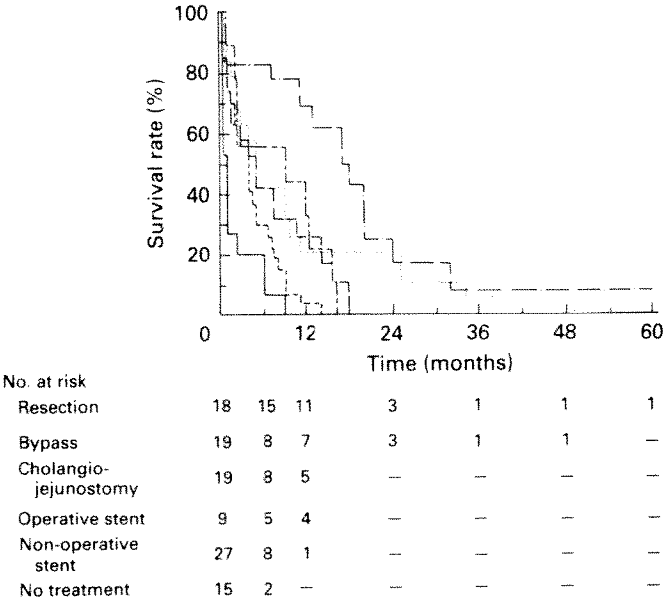

Figure 1 *Kaplan–Meier survival curves for six treatment groups of patients with cholangiocarcinoma. ——, No treatment; – – –, segment III cholangiojejunostomy; -----, endoscopic and/or percutaneous stent insertion; — – —, operative stent insertion; —·—, resection; ·····, extrahepatic bypass. Eight patients are still alive: extrahepatic bypass, one at 16 months; segment III cholangiojejunostomy, one at 14 months; and resection, six at 7, 8, 14, 15, 18 and 19 months*

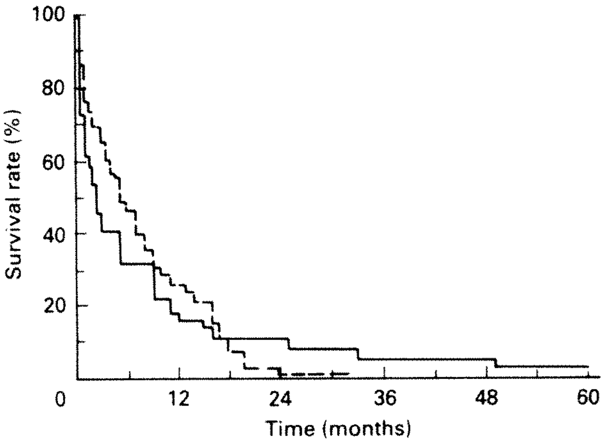
resection of a hilar tumour, while two cases of biliary peritonitis and one of septicaemia followed non-operative stenting. Another patient suffered a fatal cerebrovascular attack 6 days after an extrahepatic bypass procedure. Two patients were found to have an endoscopically confirmed bleeding peptic ulcer in the immediate postoperative period; one gastric ulcer followed hemihepatectomy and the bleeding responded to injection sclerotherapy, and the other followed a segment III bypass and the bleeding point was under-run at operation. One patient died from a pulmonary embolus following surgical placement of a stent. Three patients were treated for cardiac failure (laparotomy only, extrahepatic bypass, segment III bypass) and another was resuscitated from a cardiac arrest during attempted extrahepatic bypass and so underwent laparotomy only. Antibiotics were used for one urinary tract infection (extrahepatic bypass) and two patients required medical management of acute renal failure (operative stent insertion, segment III bypass). The remaining complications were chest infection (14), wound infection (seven) or dehiscence (two), and fatal myocardial infarction following resection (one).

Ten patients died within 30 days of attempted resection or surgical palliation (*Tables 3* and *4*), with an operative mortality rate of 15 per cent. In addition, four of the seven patients undergoing laparotomy only and seven of the 27 undergoing non-operative stent insertion died within 30 days. The 30-day mortality rate for all patients with cholangiocarcinoma was 26 per cent. The operative mortality rate for each of the four surgical treatments was similar. The number of patients developing complications in each of these groups was also similar (*Table 3*).

The operative mortality rate for patients undergoing resection was 17 per cent overall, and 10 per cent for those with tumours involving the upper third of the biliary tract. Sixteen of the 18 resections were performed with macroscopically clear resection margins at laparotomy. Ten of these 16 patients also had clear resection margins on histological examination. The presence of clear margins has not significantly prolonged survival but six patients are alive to date. Two of the 18 patients who underwent resection died from postoperative sepsis. One patient died from local recurrence of tumour, four died with liver metastases and five died with widespread metastatic disease associated with local recurrence in two.

Recurrent symptoms in patients who survived more than 30 days are shown in *Tables 5* and *6*. Patients who underwent surgical bypass or resection of tumour and who survived to leave hospital had a significantly lower incidence of recurrent cholangitis (seven of 47) than those undergoing non-operative (11 of 20; $P<0·001$) or operative (six of eight; $P<0·001$) stent insertion. All patients who developed recurrent cholangitis following surgical bypass of the tumour had undergone PTC or ERC before operation. After successful segment III bypass one patient developed multiple abscesses in the right hemiliver



No. at risk

1986–1991	70	34	18	2	–	–	–

Figure 2 *Kaplan–Meier survival curves for patients with cholangiocarcinoma in the periods 1980–1985 (——) and 1986–1991 (– – –). Eight patients treated in 1986–1991 are still alive at 7, 8, 14, 14, 15, 16, 18 and 19 months*

while another developed a cholecystoduodenal fistula. Six of the 11 patients who developed cholangitis following non-operative stenting had the prosthesis changed but two died as a consequence of the complication. Three patients required more than one change of stent. In total, 36 prostheses were used for 27 patients, although the number of stents used in each patient did not affect long-term survival.

Long-term survival following the different forms of treatment for all patients is shown in *Tables 3* and *4*. Patients who underwent resection had the longest duration of survival ($P < 0{\cdot}03$). There was no difference in long-term survival between patients having other forms of surgical palliation and, although survival in all these groups was longer than that in patients undergoing non-operative stenting, the difference was not significant. *Figure 1* shows the survival curves for each of the six treatment groups. Two patients were still alive after extrahepatic and segment III bypass at 16 and 14 months respectively. Six patients were still alive after resection at 7, 8, 14, 15, 18 and 19 months. *Figure 2* compares the survival curves for the two periods under review. The median survival period for 1980–1985 was 2·5 (range 0–114) months and for 1986–1991 5 (range 0–32) months, but eight patients are still alive in the second interval under review. There was no significant difference in duration of survival between the two time periods.

Discussion

Primary carcinoma of the biliary tract is an uncommon cause of obstructive jaundice but carries a poor prognosis. The majority of patients die within 6–12 months of diagnosis[8,9] and, although some series have reported survival rates of up to 30 per cent at 5 years in those undergoing attempted curative resection[1,2], the overall 5-year survival rate has previously been reported[3,10] as less than 10 per cent.

Jaundice is absent in 2–10 per cent of cases at the time of diagnosis of bile duct cancer[3,11,12] since incomplete obstruction may occur involving only the right or left hepatic duct[13]. Many patients admit to long-standing abdominal pain or dyspepsia; the one anicteric patient in the present series presented with upper abdominal pain and deranged liver function test results.

Ultrasonography is accepted as the initial imaging procedure in jaundiced patients. It may demonstrate bile duct dilatation and give an indication of tumour extent or even resectability[4,14,15]. It has been suggested that Doppler ultrasonography may, in experienced hands, yield clinically useful information about vascular invasion and obviate the need for angiography in the assessment of resectability[16].

More detailed information on the level of obstruction can be obtained by percutaneous or endoscopic cholangiography. It has been stated that PTC allows preoperative determination of the proximal extension of the tumour into the liver, but the procedure is not without significant risk and may introduce infection into an obstructed biliary tree. ERC is also associated with considerable morbidity[17–19] as a large volume of contrast medium has to be injected through the obstruction if the distended proximal biliary tree is to be visualized, and the proximal extent of the tumour cannot always be determined. This procedure does permit the option of stenting, but we believe that its use should be restricted to palliation in unfit patients with irresectable low bile duct tumours.

Good-quality CT may obviate the need for PTC or ERC by demonstrating the level of obstruction and involvement of the caudate lobe[15]. It may determine the presence of metastatic invasion of the liver and exclude left hepatic lobe atrophy, which would prevent useful decompression via the segment III duct. Arteriography and portography have also proved useful in assessing resectability. Vascular involvement of one side of the liver with extensive bile duct involvement on the other side, or involvement of both main branches or the main trunk of the portal vein, are taken as signs of irresectability[20]. Several authors[21–24] have suggested diagnostic strategies in jaundice, and the formulation of an ordered use of radiological investigations would be of clear benefit in selecting appropriate treatment.

There is considerable debate as to whether preoperative biliary drainage diminishes postoperative morbidity and reduces the operative mortality rate in patients submitted to surgery for obstructive jaundice. However, prospective controlled studies have not shown a reduced surgical morbidity rate in patients undergoing preoperative external drainage[25,26] and there is a significant incidence of complications related to the drainage procedure itself[27]. Czerniak and Blumgart[4] concluded that preoperative external drainage in obstructive jaundice is not indicated except in patients with cholangitis who have developed sepsis. Furthermore, the present authors' experience has demonstrated that attempted drainage of the right system may compromise the option of using a segment III duct should the tumour prove irresectable.

The resectability rate for hilar cholangiocarcinoma remains low at 15–20 per cent, even in specialized centres with an interest in the condition[3–6,28]. The degree of ductal involvement and evidence of vascular invasion will influence the extent of resection required. Involvement of the biliary tree beyond secondary bifurcations usually indicates the need for hepatic resection[5,29]. Caudate lobe involvement may be discovered only at laparotomy and will influence the decision to proceed to resection[5,30], but some would now advocate routine removal of this lobe when resection is contemplated[31]. In recent years, intraoperative ultrasonography has been of value in assessing the extent of local invasion and in determining whether radical resection with excision of the caudate lobe or segment III cholangiojejunostomy should be undertaken[32].

Resection of hilar tumours carries considerable morbidity[33], which is often related to leakage of bile at the anastomosis. Reports of hospital mortality rates vary from 0 to 27 per cent in large series[3,8,28,34]. Of the 18 patients who underwent resection in the present series, three died within 30 days of operation, although only one operative death occurred since 1985. Eleven of the patients undergoing resection died within 3 years, although one-third of patients are still alive. Czerniak and Blumgart[4] reviewed a number of series which reported that resection of hilar cholangiocarcinoma was associated with a survival rate of 30 per cent at 3 years and of 12 per cent at 5 years. More recent series have reported a 5-year survival rate of up to 30 per cent for patients undergoing resection[1,2] and a median survival period of between 6 and 24 months[28,35–37]. The present median survival time of 18 months for the nine patients with upper third cholangiocarcinoma treated by resection and surviving to leave hospital is similar. If long-term survival is to be improved, resection must be associated with tumour-free margins on histological examination. The present series does not show significantly prolonged survival in such patients but others have reported an improved survival rate when histologically tumour-free resection margins have been achieved[28]. Although some support a more radical surgical approach to the treatment of cholangiocarcinoma, this has not been associated with an obvious increase in curative resection or survival rates[35]. None the less, excision of tumour offers the only prospect of cure, and in the present series resection provided the most effective form of palliation. The unchanged long-term survival in the two consecutive 6-year periods (*Figure 2*) underlines the need for successful and long-lasting palliation in most of these patients.

When resection is not feasible, biliary decompression may be achieved by one of several methods of surgical bypass[6,8]; evidence[20,29,38] suggests that drainage of only part of the liver suffices to relieve jaundice and pruritus, provided the undrained remnant is not infected and the drained liver not atrophic. Approaching the left hepatic duct through the umbilical fissure (segment III cholangiojejunostomy) has become popular by achieving satisfactory results with a low operative morbidity rate[39,40]. The 30-day mortality rate associated with this procedure in the present series was 16 per cent; this value is in keeping with those in other reports[4,5,8,41], where the 30-day mortality rate ranged between 0 and 31 per cent. Alternative surgical procedures such as the Longmire approach have not been widely taken up. In the authors' experience, bypass procedures with anastomosis to the extrahepatic biliary tract do not provide adequate palliation as there is a high risk of recurrent cholangitis and jaundice owing to the proximity of the anastomosis to the tumour. Terblanche and colleagues[42] have popularized the use of surgically placed catheters for drainage, and various modifications have subsequently been described[8], but we have been disappointed by the quality of palliation with these U tubes. Advances in radiological and endoscopic intubation have reduced the need for these procedures in patients who are not suitable for segment III bypass or who are unfit for surgery.

There is considerable debate as to whether bypass surgery is superior to non-operative stenting[43]. A number of authors[5,44,45] strongly support surgical palliation because of the apparent improvement in duration and quality of survival, despite conclusions by others[46,47] in favour of endoprostheses. There are no controlled data to support either view in the management of hilar cholangiocarcinoma but, in the present series, patients were more likely to suffer cholangitis following non-operative stenting. One advantage of managing patients by an operative approach is the ease with which tissue may be obtained for histological examination. The lack of tissue diagnosis in one-third of the present patients is disconcerting but similar to findings of previous reports[48]. Thirty-five of the present patients did not undergo laparotomy and obtaining pathological confirmation of diagnosis in these is notoriously difficult[49]. In other series, confirmation of diagnosis has been better when patients have been managed surgically[20]. In addition, a number of other conditions such as lymphoma and metastatic breast carcinoma may mimic cholangiocarcinoma, and their treatment and subsequent prognosis are quite different.

Endoprostheses may be inserted endoscopically or percutaneously. Quality of life with endoprostheses appears to be superior to that with external drains, although their exchange is less easy. External drains may lead to metabolic derangement, may become infected and require daily care. Hilar tumours may be more difficult to traverse with the endoscopic technique, and the authors have found a combined percutaneous and endoscopic approach[50] useful. In 13 of 27 patients undergoing non-operative stenting of a high hilar lesion, it was not possible to insert the prosthesis by endoscopic means alone. There is a significant risk of septicaemia or pancreatitis associated with ERC[18,19]. Percutaneously or endoscopically inserted stents may become blocked or infected, necessitating repeated hospital admission for the patient. The complication and 30-day mortality rates observed in the present series (41 and 26 per cent respectively) are marginally higher than those of 10–30 per cent and 20–30 per cent reported by others[8,46,51,52].

Patients with irresectable tumours have a poor long-term prognosis and, until recently, treatment has been aimed at palliation of symptoms. However, radical resection combined with liver transplantation has been proposed as an option for patients without distant metastases. Although initial outcome has been disappointing[53–55], careful patient selection may lead to more favourable results[56].

The search for better palliation of bile duct cancer has prompted the use of radiotherapy in several centres. External radiation alone proved unsatisfactory and techniques involving the use of iridium-192 wire, inserted either percutaneously or endoscopically, have been developed[57–59]. In addition, the combination of palliative surgery, intraoperative and postoperative radiotherapy has been proposed for advanced tumours[60]. Small numbers of patients, in addition to lack of cytological or histological proof of diagnosis in long-term survivors, make it difficult to draw firm conclusions. Further assessment of long-term benefit is required but such treatment offers some hope in the management of this difficult condition.

The effectiveness and long-term results of percutaneous cholecystostomy for acute acalculous cholecystitis are evaluated. Fifteen patients with acute acalculous cholecystitis were treated prospectively by this procedure, using a pigtail catheter successfully placed under ultrasonographic and fluoroscopic guidance. Prompt relief of the signs and symptoms of cholecystitis was achieved in 14 patients. One required emergency cholecystectomy for uncontrolled bleeding after drainage. Another patient underwent prophylactic cholecystectomy before further chemotherapy for leukaemia. The remaining 13 patients required no further surgery. Morbidity and mortality rates were 13 per cent and nil respectively. Long-term follow-up showed no recurrence of cholecystitis after removal of the catheter. Percutaneous cholecystostomy is a safe, effective and usually definitive procedure for the treatment of acute acalculous cholecystitis.

Acute acalculous cholecystitis is a serious condition occurring in critically ill patients. The first case was reported[1] in 1844 and the incidence is increasing[2,3]. Risk factors include severe trauma or burns, major surgery, long-term fasting with or without total parenteral nutrition, sepsis, diabetes mellitus, atherosclerotic vascular disease, systemic vasculitis and acquired immune deficiency syndrome[4–14].

Many surgeons recommend early cholecystectomy or early surgical cholecystostomy[2,3,5–7,9,15,16], while some advocate percutaneous cholecystostomy for critically ill patients with acute cholecystitis[14,17–26]. However, the number of patients with acute acalculous cholecystitis treated by percutaneous drainage is too small (eight or fewer in each series[14,18,19,21,22,24]) to clarify the merits and demerits of the procedure. Moreover, long-term follow-up after removal of the percutaneous catheter has not been reported.

Experience of percutaneous transhepatic cholecystostomy in a large series of 15 patients with acute acalculous cholecystitis is reported. The aims were to evaluate the early safety and efficacy and long-term results of percutaneous drainage.

Patients and methods

Between 1982 and 1991 a total of 511 patients with benign biliary disease were treated in this department. During this period, 15 patients (2·9 per cent) with acute acalculous cholecystitis were treated, all of whom are included in this study.

Diagnosis of acute acalculous cholecystitis was made by physical examination and abdominal ultrasonography. Biliary scintigraphy was not performed. Findings suggesting acute cholecystitis on physical examination included right hypochondrial pain, tenderness and/or muscular rigidity located in the right upper quadrant and a palpable distended gallbladder with localized tenderness. Ultrasonographic findings suggesting acute cholecystitis included gallbladder distension, sludge formation, a thickened gallbladder wall (thickness 3 mm or greater), sonographic localization of gallbladder tenderness and a sonolucent layer in the gallbladder wall. Acute acalculous cholecystitis was diagnosed if one or more physical findings and two or more sonographic signs were present in the absence of gallstones. The diagnosis of acalculous cholecystitis was confirmed when no gallstones were identified in imaging studies including postdrainage cholangiography and in the resected gallbladder (two cases). Non-specific physical findings associated with acalculous cholecystitis included nausea, vomiting, abdominal distension, fever (temperature 37°C or greater), and leucocytosis (white cell count over 10^{10}/l).

A prospective protocol of management was followed, using percutaneous transhepatic cholecystostomy as the first choice of treatment. Biliary drainage was conducted under both ultrasonographic and fluoroscopic guidance. A 7- or 8-Fr pigtail cholecystostomy catheter (Niigata University type; Hanako Medical, Tokyo, Japan) was placed by a two-step method with guidewire exchange. The catheters are 280 mm in length and contain an end hole and four side holes on the inner border of the curved tip to avoid obstruction during drainage. A right intercostal transhepatic approach was used for all drainage procedures; this reduces the risk of catheter dislodgement and decreases intraperitoneal leakage of bile. Aspirated bile was sent for anaerobic and aerobic culture. The position of the catheter was adjusted as necessary during cholecystography at the time of drainage. Definitive cholangiography was performed several days later, after the resolution of acute cholecystitis, to detect any abnormality, including gallstones in the biliary tract.

Results

Patients

The 15 patients comprised 11 men and four women of mean age 56·1 (range 34–75) years. Acute acalculous cholecystitis followed major abdominal surgery in six patients and cardiovascular procedures in four; it developed during intensive medical treatment in five patients (for leukaemia in two, irresectable endometrial cancer in one, sepsis in one, systemic lupus erythematosus in one).

Diagnosis

The clinical manifestations and ultrasonographic findings of acute acalculous cholecystitis are shown in *Table 1*. Signs and symptoms were often difficult to assess in comatose or severely ill patients. Although gallbladder distension and sludge formation were present in all cases, other ultrasonographic findings were not consistent.

Immediate effects of percutaneous cholecystostomy

After catheterization, prompt relief of the signs and symptoms of acalculous cholecystitis was achieved in all but one patient. The single non-responder underwent percutaneous cholecystostomy for cholecystitis occurring during steroid therapy for severe systemic lupus erythematosus. Her condition was complicated by systemic sepsis and pneumonia at the time of drainage. Catheter insertion was followed by immediate arterial bleeding from the gallbladder wall. Blood was aspirated from the catheter. The bleeding could not be managed conservatively and emergency cholecystectomy was performed. Gross examination of the gallbladder revealed gangrenous cholecystitis and bleeding from an eroded branch of the cystic artery.

Table 1 *Incidence of clinical and ultrasonographic findings in 15 patients*

	Incidence
Clinical examination	
Right hypochondrial pain	14
Localized tenderness	13
Localized muscular rigidity	7
Palpable enlarged gallbladder	5
Nausea and/or vomiting	5
Fever (temperature ≥37°C)	14
Leucocytosis (white cell count $\geq 10^{10}$/l)	13
Ultrasonography	
Gallbladder distension	15
Sludge formation	15
Thickness of wall ≥3 mm	11
Sonolucent layer	10
Pericholecystic fluid	2
Sonographic localization of gallbladder tenderness	5

Acute gangrenous cholecystitis was confirmed by pathological examination.

Complications developed during percutaneous cholecystostomy in two of the 15 patients. One major complication was described above. A second patient had transient haemobilia that settled spontaneously within several hours. Dislodgement of the catheter or bile peritonitis after insertion did not occur. There were no deaths attributable to percutaneous cholecystostomy. The overall morbidity and mortality rates of the procedure were thus 13 per cent and nil respectively.

Two cholecystectomies were performed after percutaneous drainage: one emergency procedure and one elective operation in a patient who suffered acute acalculous cholecystitis in the course of anticancer chemotherapy for leukaemia. This patient underwent uncomplicated percutaneous cholecystostomy that relieved the signs and symptoms. The gallbladder was removed prophylactically as it represented a possible focus of infection following an additional course of anticancer chemotherapy. In the remaining 13 patients, percutaneous cholecystostomy was the definitive treatment and none has required further surgical intervention.

The bile aspirated initially was thick and black in 11 patients and purulent in three. The characteristics of the bile were not recorded in the remaining patient. Cholecystography at the time of drainage was performed in 14 patients; cystic duct obstruction was demonstrated in all cases. Repeat cholecystography was performed several days later in 14 patients and revealed patent cystic and common bile ducts with no calculi in the biliary tract. The colour and viscosity of draining bile returned to normal within 2 or 3 days. Seven of the 15 patients had positive bile cultures. *Enterococcus* was the most common bacterium, detected in six specimens, although two or more bacterial isolates were identified in five of these. *Escherichia coli* was identified in only one specimen.

Long-term outcome

Eight patients in this series died within 1 year of percutaneous cholecystostomy from causes unrelated to acute acalculous cholecystitis. Four of the ten patients with postoperative cholecystitis died within 1 year: three from recurrent cancer at 4, 9 and 11 months, and one from ongoing sepsis and multiple organ failure at 2 months. Four of the five patients in whom acalculous cholecystitis occurred during intensive medical care died from the underlying disease within 1 year. The remaining seven patients have survived 5–75 months after removal of the percutaneous catheter (six patients) or after elective cholecystectomy (one).

Follow-up results of the 13 patients treated with percutaneous cholecystostomy alone are shown in *Figure 1*. To analyse the effectiveness of percutaneous drainage alone, the two patients who subsequently underwent cholecystectomy were eliminated. Long-term follow-up of more than 5 years was possible in five patients (four surgical, one medical). None of the 13 patients has had recurrent gallbladder disease during the follow-up period.

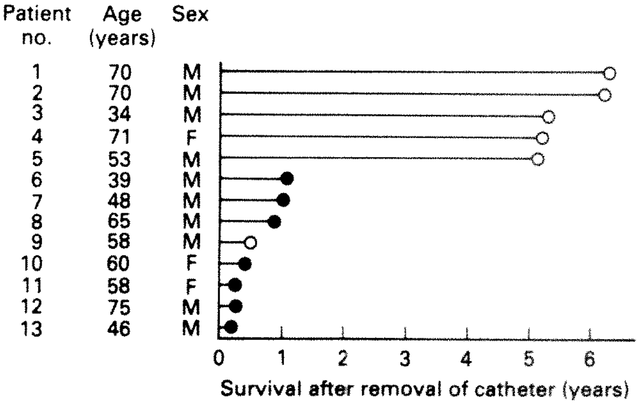

Figure 1 *Outcome in 13 patients treated with percutaneous cholecystostomy alone. ○, Survival without recurrent gallbladder disease at the last follow-up; ●, death from underlying disease. No patient showed recurrence of gallbladder disease during the follow-up period*

Discussion

Many surgeons have advocated early cholecystectomy for acute acalculous cholecystitis because of the rapid progression of the disease[2,3,6,7,9,15,16]. Some have recommended early surgical cholecystostomy for high-risk patients[2,5,9,16]. Percutaneous cholecystostomy has recently been accepted as an alternative to surgery[14,17–26], but the procedure has been limited to critically ill patients. The present authors have adopted percutaneous transhepatic cholecystostomy as the treatment of choice for all patients with acute acalculous cholecystitis.

The patients in this series were predominantly male, consistent with the findings of other authors[5,6,9,14,15,21]. Although Savoca *et al.*[9] showed a preponderance of elderly men with atherosclerotic vascular disease in acalculous cholecystitis, increased incidence was not found in any age group in the present study. Savoca *et al.* found several cases of acalculous cholecystitis in outpatients. In contrast, all those in the present series were inpatients recovering from surgery or under intensive medical care.

Hepatobiliary scintigraphy is thought to be useful in the early detection of cystic duct obstruction[9,27,28]. Ultrasonography can demonstrate pathology of the gallbladder wall, depict the luminal contents and detect pericholecystic lesions[5,7,14,29,30]. Ultrasonography is preferable to cholescintigraphy because it is easily available, it allows detection of concomitant lesions (such as gallstones, abscess or tumour), it is cost–effective, requires a shorter examination time and allows simultaneous therapeutic intervention such as percutaneous drainage[14,18,20,25,26].

Successful catheterization and prompt relief of signs and symptoms were achieved in almost all cases in the present series. These results are similar to those of other reports[14,17–26]. Dislodgement of the catheter is a serious complication of percutaneous cholecystostomy[17,23]. Pearse *et al.*[17] and Klimberg and colleagues[21] recommended use of an accordion catheter to prevent dislodgement. McGahan[23] used a catheter with a Cope-type loop. The present authors use a specially designed pigtail catheter with angulation to prevent dislodgement and have not experienced this complication. Teplick *et al.*[25] reported low morbidity (7·8 per cent) and mortality (0·4 per cent) rates for percutaneous cholecystostomy in a review of 231 patients. The rates of morbidity (including minor complications) and mortality in the present series are similar. Percutaneous cholecystostomy has a lower morbidity and mortality rate[14,19,22,24–26] than surgical cholecystostomy and cholecystectomy[5,9,15], and is therefore advocated as the treatment of choice for acalculous cholecystitis.

The present study confirms previous reports[24,26] that in acute acalculous cholecystitis the aspirated bile is thick and black, and that initial cholecystography demonstrates an obstructed cystic duct, although later repeat cholecystography reveals a patent cystic duct. It may be postulated that the concentrated viscous gallbladder bile with sludge causes pseudo-obstruction of the cystic duct, leading to cholecystitis.

Bile cultures were positive in seven of 15 cases in this series, consistent with several studies which report positive rates ranging from 38 to 100 per cent[5,6,14,15,19,24]. Bile culture may be negative in the early phase of acute acalculous cholecystitis and the overall rate of negative cultures is high. These findings suggest that bacterial infection is secondary in the pathogenesis of such cholecystitis and that negative bile cultures do not exclude the condition. Although *E. coli* has generally been regarded as the most common causative organism of acute acalculous cholecystitis[6,14,15,19], *Enterococcus* was the bacterium most frequently recovered in the present study. Orlando and co-workers[5] and Berger *et al.*[24] also reported the predominance of *Enterococcus* and *Pseudomonas aeruginosa* in critically ill patients. The recovery of these organisms in bile culture suggests that therapies in intensive care may alter the organisms isolated.

The prognosis following percutaneous cholecystostomy for acute acalculous cholecystitis mainly depends on the patient's underlying condition. Long-term results after percutaneous cholecystostomy alone have not been sufficiently reported. The present long-term follow-up data indicate that all patients have been free from recurrent gallbladder disease, including acalculous cholecystitis, during the follow-up period.

Percutaneous cholecystostomy is a safe and effective treatment for acute acalculous cholecystitis. The procedure is usually definitive, requiring no further surgery. Recurrent gallbladder disease, after the removal of the catheter, did not occur in this study population. Percutaneous cholecystostomy is advocated as the treatment of choice for all patients with this condition.

Temporary use of a biliary endoprosthesis for unsuspected bile duct stones found at laparoscopic cholecystectomy

H. Rønning, U. Raundahl and J. Kiil

Department of Surgery, Randers Centralsygehus, DK-8900 Randers, Denmark

Correspondence to: Dr J. Kiil

Preoperative identification of patients with common bile duct (CBD) stones is often possible using the following criteria[1]: history of jaundice or pancreatitis; abnormal liver function test results; or CBD diameter >5 mm. Nevertheless, the incidence of unsuspected CBD stones is 4–10 per cent in studies that include operative cholangiography as a routine procedure at laparoscopic cholecystectomy[2,3]. This creates a dilemma in laparoscopic cholecystectomy as to whether the surgeon should leave the duct stones and rely on postoperative endoscopic sphincterotomy (ES) to solve the problem. ES is usually a straightforward procedure but occasionally fails, necessitating additional open surgery. Alternatively, the surgeon could deal with the stones immediately and prevent bile duct obstruction in the early postoperative period. Although procedures for laparoscopic CBD stone removal have been reported[3–5], they are difficult to perform and have not become common practice. Conversion to open cholecystectomy is not an attractive option at this stage.

This paper reports adaptation of a well known endoscopic procedure for use in conjunction with laparoscopic cholecystectomy, namely insertion of an endoprosthesis with multiple side holes from the CBD across the sphincter to the duodenum. This manoeuvre prevents obstruction of the bile duct from retained stones, with its risk of cystic duct leakage and cholangitis, and greatly facilitates ES. It allows a safe 'precut' along the prosthesis with a needle papillotome before insertion of a conventional papillotome. The technique virtually eliminates the risk of endoscopic failure.

Patients and methods

A total of 60 patients with gallbladder stones were treated by laparoscopic cholecystectomy using a standard technique. A 5-mm trocar was inserted below the costal margin at the site of the fundus of the gallbladder. Operative cholangiography was attempted in each case by the use of Olsen's forceps and a catheter. If stones were found, a 0·28-mm guidewire was passed through the catheter down the cystic duct and CBD into the duodenum, where it was placed as far distal as possible (*Figure 1a*). The cholangiography catheter was then withdrawn and a straight 5-Fr endoprosthesis (Cook Denmark, Karlslunde, Denmark), 6 cm long with multiple side holes and reference marks at both ends, was introduced through the Olsen forceps over the guidewire. Using the cholangiography catheter, the prosthesis was pushed over the guidewire under fluoroscopic control until it lay with its proximal end in the CBD and its distal end in the duodenum (*Figure 1b*).

At a convenient time after operation, ES was performed. A needle papillotome was first used to cut along the endoprosthesis before insertion of an ordinary papillotome to complete the sphincterotomy. Finally, the CBD stones and endoprosthesis were removed.

Results

Unsuspected bile duct stones were found in three patients (5 per cent); insertion of the endoprosthesis was achieved without problems in all three cases. The maximum time for cholangiography and endoprosthesis insertion was 20 min. Antibiotic cover was given.

The postoperative course was uneventful in each patient. ES was carried out on the first day after operation in two patients, while one had the procedure postponed until day 14 and had no symptoms in the meantime. Each patient was discharged home on the following day, after an uneventful recovery.

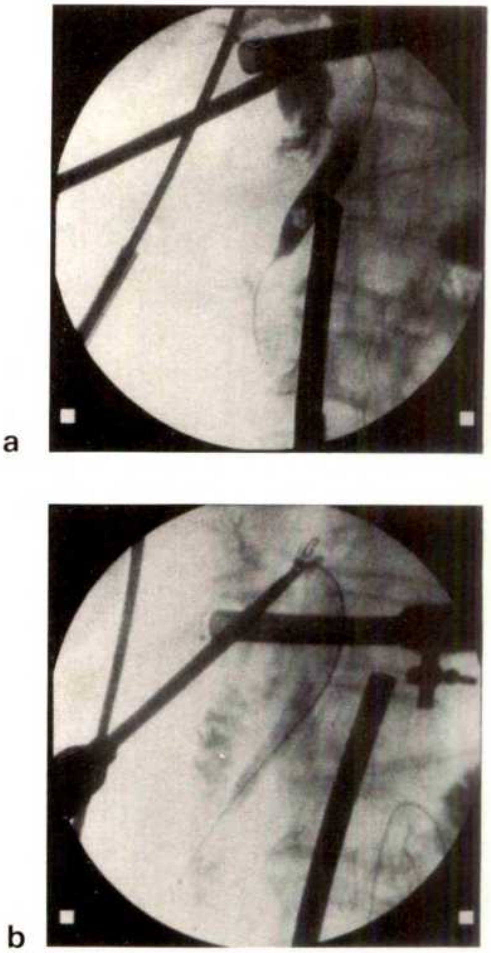

Figure 1 *Plain abdominal radiographs taken during laparoscopic cholecystectomy in a patient with a stone in the common bile duct.* **a** *A guidewire has been passed through the Olsen cholangiography forceps down the common bile duct and into the duodenum.* **b** *A 6-cm 5-Fr endoprosthesis has been passed over the guidewire and placed across the sphincter of Oddi. Note that the guidewire has been passed into the jejunum*

Discussion

During laparoscopic cholecystectomy the introduction of a guidewire with Olsen cholangiography forceps down the bile duct into the duodenum is very simple. Displacement of the guidewire while the endoprosthesis is pushed downwards into the duodenum is effectively prevented by the narrow bile duct, so the time needed is minimal. ES is an accepted treatment for patients with CBD stones and reluctance to use it has vanished with increasing experience. The procedure is safe in skilled hands, and the use of an endoprosthesis as a guide to the CBD enhances this safety.

After more than two decades of the widespread use of ES in the treatment of patients with CBD stones, no serious long-term effects have emerged from the lack of a sphincter

0007-1323/93/111443-02 © 1993 Butterworth-Heinemann Ltd

between the bile duct and duodenum. Nevertheless, most endoscopists restrict the procedure to patients above the age of 40 years. It is among this group of patients that CBD stones are most frequent. Complicating factors such as extreme obesity may justify sphincterotomy for stones at an even younger age.

Laparoscopic ligation of large pedicles

D. R. Andrew and P. S. Veitch

Department of Surgery, Leicester General Hospital, Leicester, UK

Correspondence to: Mr D. R. Andrew, Department of Surgery, The Princess Alexandra Hospital, Royal Air Force Wroughton, Swindon SN4 0QJ, UK

In laparoscopic surgery it is difficult to apply ligatures. Various techniques and devices such as the Roeder knot and the Endoloop (Ethicon, Edinburgh, UK) have been developed. These have limitations in that the Roeder knot is time consuming in application and the Endoloop requires that the structure to be secured has a free end over which the loop can be passed. An alternative method of inserting a strong ligature is described that does not suffer from these disadvantages and which may have important applications.

Surgical technique

Tie-wrap fasteners are widely used in engineering to secure wires together. A tie wrap can be passed down a 10-mm laparoscopy cannula to be applied internally. An applicator 'gun' has been developed that inserts the tie wrap and then secures it.

The tie wrap is mounted in the applicator gun by its locking square and passed tail-first through the laparoscopy cannula to the pedicle or structure to be secured. The tail is picked up with a grasping forceps and passed around the pedicle, then fed into the locking square (*Figure 1*). The tie is tightened by pulling the tail up the applicator gun shaft using a trigger-operated ratchet mechanism. When the ligature has reached the required tension, a guillotine blade cuts off the excess tail which is then removed with the applicator gun (*Figure 2*).

Discussion

The authors have used tie wraps to occlude the oesophagus during thoracoscopic oesophagectomy and found them to be easily applied, strong and secure. A tie manufactured from biodegradable material could be left in the body without fear of late complications. Tie wraps may be suitable for a wide variety of applications, such as ligating vascular pedicles or occluding the cystic duct, appendix, oesophagus or bowel. They can be used in open surgery but their action makes them ideally suitable for the limited access available during laparoscopic procedures.

Mucosal morphology, cell proliferation and faecal bacteriology in acute pouchitis

A study was performed to investigate whether acute reservoir ileitis (pouchitis) is associated with specific changes in mucosal morphology, crypt cell kinetics and faecal bacteriology in the ileal pouch. Forty-six patients were studied (ileal reservoir, 36; end ileostomy, ten) using clinical grading, sigmoidoscopy and biopsy; 24 patients with a reservoir were restudied after therapy for 1 month with metronidazole 400 mg three times daily. An index of villus atrophy and crypt cell production rate (CCPR) were determined in all biopsy material. Faecal bacteriology was assessed in 12 patients with a pouch before and after metronidazole therapy. The mucosa of patients with pouchitis was associated with a lower villus atrophy index ($P = 0{\cdot}052$), a higher CCPR ($P = 0{\cdot}03$) and a higher grade of acute inflammation than that in those without pouchitis. There was no difference in faecal bacterial counts between patients with and without pouchitis. A low atrophy index correlated with a high CCPR ($P < 0{\cdot}001$), worse functional score ($P < 0{\cdot}001$) and more severe pouch mucosal acute inflammation ($P < 0{\cdot}001$), but not with faecal bacteriology. Following metronidazole therapy there was resolution of acute pouch inflammation, increased villus atrophy index ($P = 0{\cdot}049$), decreased CCPR ($P = 0{\cdot}049$) but no differences in faecal bacterial counts apart from Bacteroides *species. These data show that metronidazole therapy does not specifically alter the growth of common faecal bacteria in patients with pouchitis, apart from* Bacteroides *species. However, metronidazole causes resolution of the typical changes in pouch mucosal morphology and crypt cell kinetics associated with pouchitis.*

Restorative proctocolectomy is now a realistic option in the elective surgical management of selected patients with ulcerative colitis and familial adenomatous polyposis[1]. However, changes occur in the ileal mucosa after reservoir construction (villus atrophy and crypt hyperplasia) that render its morphology similar to that of colonic mucosa[2]. Chronic inflammation is found in almost all ileal reservoir biopsies, while the association of an acute inflammatory infiltrate in patients with pouch dysfunction is characteristic of pouchitis[3].

Although the mechanisms of the mucosal morphological changes in ileal reservoirs are unknown, increased numbers of anaerobic bacteria have been found in reservoir effluent compared with those seen in an ileostomy[4]. Villus atrophy is severe in pouchitis[5] but faecal stasis and bacterial overgrowth may not be aetiological factors[6,7]. It is possible that the morphological changes of pouch ileum in pouchitis represent mucosal adaptation to a new luminal bacterial environment[7]. Alternatively, the infrequent reports of pouchitis in patients without a previous history of ulcerative colitis suggest the possibility of reactivation of such colitis in colonic metaplasia, but this hypothesis does not explain the clinical and endoscopic resolution of pouchitis after metronidazole therapy.

This study was designed to investigate whether acute reservoir ileitis is associated with specific changes in mucosal morphology, crypt cell kinetics and faecal bacteriology in the ileal pouch before and after metronidazole therapy.

Patients and methods

Forty-six patients were selected for the study, of whom 36 had an ileal pouch and ten an end ileostomy. Clinical features were matched as closely as possible and no patient had an ileal resection >5 cm. The 36 patients with an ileal pouch underwent a personal interview at which a pro forma was completed. A clinical score was subsequently compiled for each patient, with each of ten items scoring one point: daytime soiling (controlled with one pad), nocturnal soiling, change of pads (for a single soiling episode), daily antidiarrhoeal medication, lack of discrimination between flatus and faeces, profuse soiling (uncontrolled by multiple pad changes), severe urgency (<10 min), daytime frequency of defaecation >7, night-time frequency of defaecation >2, and 24-h frequency of defaecation >9.

Pouch endoscopy was performed by one author (W.A.K.) in all patients using a paediatric sigmoidoscope, and an acute inflammatory grade was recorded: loss of vascular pattern, 1; mucosal granularity, 2; contact haemorrhage, 3; spontaneous haemorrhage, 4; mucosal ulceration, 5; surface mucopus, 6.

Two large biopsies were taken from each pouch and terminal ileum using Officer biopsy forceps. The ileum in the patients with an ileostomy was healthy and uninflamed. Biopsies were taken from specific areas of the pouch and the ileostomy 10 cm from the anal verge or stoma. One biopsy was placed in formalin for histological analysis; the other was halved and used separately to measure crypt cell production rate[8] (CCPR) and villus atrophy index.

The 36 patients with a pouch were subdivided into those with (12) and those without (24) pouchitis. A sigmoidoscopy score ≥3 and an acute histology score (see below) ≥3 was used to define pouchitis. The 24 patients without pouchitis were further grouped into those with a good (12) or a poor (12) functional result from restorative proctocolectomy using a clinical score ≥3 to define a poor result. The four study groups were well matched for age, sex, diagnosis, pouch design and length of follow-up (*Table 1*). Random stool culture in all patients before the start of the study did not reveal any enteropathogenic organism.

Twenty-four patients (12 with pouchitis, 12 with a poor result) underwent a repeat study after therapy for 1 month with metronidazole 400 mg three times daily. Repeat sigmoidoscopy after treatment was performed by an independent observer (R.T.) who was not aware of the initial findings. Concurrent assessment was performed by W.A.K.

Presented to the Surgical Research Society in Southampton, UK, July 1990 and published in abstract form as Br J Surg *1990;* 77: *1417*

and R.T. in 12 of these 24 patients. There was a good correlation between the two observers for sigmoidoscopy score ($\rho = 0{\cdot}97$, $P < 0{\cdot}001$).

All patients provided informed consent and the study was approved by the Central Birmingham Health Authority Ethical Committee.

Bacterial counts

Counts[9,10] of all aerobic and anaerobic bacteria isolated from the pouch were made in 12 of the 24 patients (six with and six without pouchitis) before and after metronidazole therapy. Six other patients with a pouch in the good-function group had pouch samples collected on 3 consecutive days at a specific time in the day, while taking their normal diet, to measure day-to-day variability in bacterial count.

All faecal samples were processed within 5 min of collection. A 1-g sample of faeces was mixed with 9 ml glycerol broth, and 1 ml of this suspension was snap-frozen at −70°C in duplicate for 1 week. The two samples were thawed, pooled and a 0·02-ml drop of dilute faeces used to isolate *Salmonella* and *Shigella* on Selenite and Rappaport media. Serial tenfold dilutions of the faecal suspension were made, from 10^{-1} to 10^{-8}, and two drops inoculated on to a range of aerobic and anaerobic media. Aerobic plates were initially incubated at 37°C for 24 h and, if there was no growth at this stage, reincubated for a further 24 h. Anaerobic plates were incubated in an anaerobic cabinet for 48 h at 37°C and, if negative, reincubated for a further 96 h. All isolated organisms were identified by the morphological appearance of the colonies, by the appearance after Gram staining and by standard biochemical testing[10]. Quantitative results are shown as logarithmic colony-forming units of organisms per gram of ileal stool.

Histology

Each biopsy was oriented under a dissecting microscope and embedded in paraffin so that the mucosa was uppermost. Perpendicular sections from the middle of the block were cut, stained with haematoxylin and eosin, and mounted. Only sections with at least ten villi and an intact muscularis mucosa were retained.

Sections were assessed in random order by a pathologist (H.T.) without access to clinical information. Sections taken before and after therapy with metronidazole were scored as follows: polymorph infiltration – none, 0; mild, 1; moderate plus crypt abscess, 2; severe plus crypt abscess, 3; and surface ulceration – none, 0; <25 per cent, 1; 25–50 per cent, 2; >50 per cent, 3.

Villus atrophy index

Black and white photographs of each section at a magnification range of ×48–75 were taken and used to quantify the degree of villus atrophy by computerized morphometry using the Reichert–Jung Kontron IBAS 1 image analyser (Germany). The computer software was calibrated to account for photograph magnification and initial pixel units converted into millimetres.

Measurements were made of the total mucosal surface length (MS), area of lamina propria (LP) and total crypt area (CA) over at least ten villi. The ratio of MS/(LP − CA) was used as an index of villus atrophy[4,11].

Crypt cell production rate

Fresh biopsy material was incubated in organ culture medium[8]. After 15 h, the medium was replaced with identical fresh medium to which vincristine 0·4 μg/ml had been added. The explants were removed at hourly intervals 1–3 h after reincubation, placed in Carnoy's fixative (six parts ethanol, one part acetic acid, three parts chloroform) for 2–6 h and stored in 70 per cent ethanol.

Crypt microdissection was performed by an independent person (D.Y.) unaware of the clinical outcome. After rehydration and hydrolysis, the biopsy was stained in Schiff's reagent. The number of arrested metaphase figures in ten crypts for each time point were counted and recorded as the mean metaphase number per crypt. Counts from crypts with either anaphase or telophase figures were discarded. The mean number of metaphase figures per crypt was plotted against time and the slope of the line, determined by linear regression, provided the CCPR[12].

Representative tissue explants were prepared for transmission electron microscopy before and after organ culture. The sections were examined by a specialist in electron microscopy.

Statistical analysis

Unless otherwise indicated, grouped data were expressed as the median and approximate 95 per cent confidence interval. Differences between two independent groups were assessed using the two-sample Wilcoxon test and those between more than two independent groups using rank one-way analysis of variance (Kruskal–Wallis test). Differences between paired groups were analysed using the paired Wilcoxon test. Significance was set at a two-tailed value of $P < 0{\cdot}05$.

Linear regression lines were plotted using the method of least squares. The significance of association was measured using the Spearman rank correlation coefficient.

Results

Assessment of tissue viability by transmission electron microscopy showed that after incubation for 15 h the nuclear and cytoplasmic ultrastructure of the brush border glycocalyx and microvillus were well preserved. Crypt cell morphology before incubation in organ culture was normal, with tissue and organelle integrity remaining unaltered after incubation.

Faecal bacteriology

There was no significant day-to-day variation in either total anaerobe ($P = 0{\cdot}355$) or aerobe ($P = 0{\cdot}058$) numbers (*Table 2*), or in individual species counts of *Escherichia coli*, enterococci (*Streptococcus faecalis*) and *Bacteroides*. These three species were the only organisms isolated in all three faecal samples from the six patients studied. Other aerobic isolates found in some but not all samples were: *Proteus* species, non-haemolytic streptococci, *Klebsiella* species and lactobacilli; other anaerobic isolates were *Bifidobacterium*, *Proprionibacterium*, *Clostridium* and *Peptostreptococcus* species[13]. To minimize intraperson variability only total aerobic and anaerobic bacterial counts and individual species counts of *E. coli*, *S. faecalis* and *Bacteroides* were studied further.

There was no significant difference in the total aerobic ($P = 0{\cdot}11$) or anaerobic ($P = 0{\cdot}75$) bacterial counts between the six patients with and the six without pouchitis (*Table 3*). There was also no difference in the numbers of *E. coli* ($P = 0{\cdot}46$), *S. faecalis* ($P = 0{\cdot}20$) or *Bacteroides* species ($P = 0{\cdot}75$) between these two patient groups.

Table 2 *Faecal bacterial validation data over 3 consecutive days*

	Day 1	Day 2	Day 3
Total aerobes ($n = 6$)	4·81–9·40	4·99–8·40	6·18–8·40
Total anaerobes ($n = 6$)	6·98–9·36	4·40–8·54	7·44–9·70
Escherichia coli ($n = 6$)	4·70–7·63	4·43–6·70	4·70–7·40
Streptococcus faecalis ($n = 6$)	4·11–9·40	4·40–8·40	4·81–8·40
Bacteroides ($n = 6$)	6·98–9·11	4·40–8·48	7·40–9·70

Values are ranges in $\log_{10}$ [colony-forming units per g]

Table 3 *Faecal bacterial counts in patients with and without pouchitis*

	Pouchitis	No pouchitis

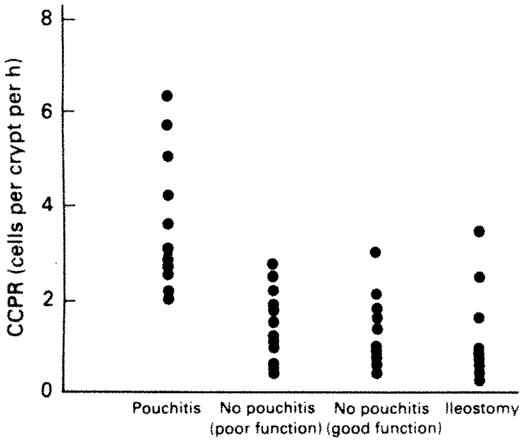

Figure 1 *Crypt cell production rate (CCPR) in patients with and without pouchitis and in those with an ileostomy.* P = *0·03 (Kruskal–Wallis analysis of variance)*

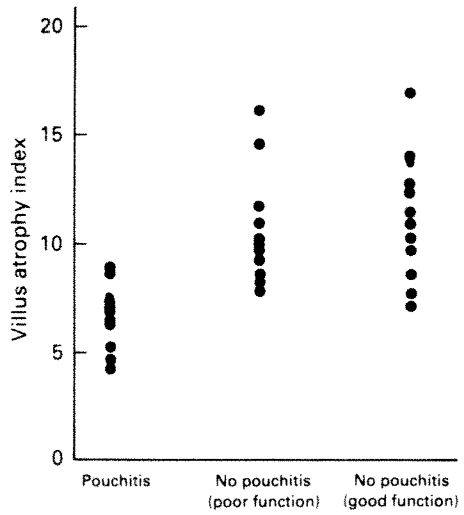

Figure 2 *Villus atrophy index in patients with and without pouchitis.* P = *0·052 (Kruskal–Wallis analysis of variance)*

Pretreatment assessment

There was no significant difference in the median (range) functional score between the 12 patients with and the 12 without pouchitis (5 (5–8) *versus* 4 (3–6) respectively, $P = 0.35$). The median (range) sigmoidoscopy score in patients with pouchitis was significantly higher (4·5 (3–6)) than that in those without (1 (0–2)) ($P = 0.02$). The median (range) histology score in patients with pouchitis (3·5 (3–6)) was significantly higher than in those without (1·5 (0–3)) ($P = 0.046$).

The CCPR was significantly higher in patients with pouchitis than in both those with no pouchitis and those with an ileostomy (median (range) 3·1 (1·8–6·6), 1·4 (0·4–2·8) and 1·1 (0·5–2·9), and 0·8 (0·2–3·4) respectively, $P = 0.03$) (*Figure 1*). The villus atrophy index was lower in patients with pouchitis (signifying a greater degree of atrophy) than in those without (median (range) 6·7 (4·1–8·2) *versus* 9·5 (6·7–17·1) and 11·8 (6·2–17·8), $P = 0.052$). Although this difference was not statistically significant, the distribution of the data suggests a possible type II error (*Figure 2*).

There was a negative correlation between CCPR and villus atrophy index ($\rho = -0.82$, $P < 0.001$). There was also an inverse correlation between the atrophy index and: (1) the functional score ($\rho = -0.59$, $P < 0.001$); (2) the acute histology score ($\rho = -0.64$, $P < 0.001$); and (3) the sigmoidoscopy score ($\rho = -0.69$, $P < 0.0001$). There was no apparent correlation between the villus atrophy index and any bacterial count: total aerobes, $\rho = -0.40$; total anaerobes, $\rho = -0.48$; *E. coli*, $\rho = -0.42$; *S. faecalis*, $\rho = -0.46$; *Bacteroides* species, $\rho = -0.54$.

Longitudinal studies

In the 12 patients with pouchitis, the functional score fell from a median (range) of 5 (5–8) before to 3 (1–4) after metronidazole therapy. The median (range) sigmoidoscopy score fell after metronidazole from 4·5 (3–6) to 2 (1–3) (*Figure 3*) and the histology score also fell from 3·5 (3–6) to 1 (1–3) after metronidazole therapy (*Figure 4*). In contrast, in patients without pouchitis there was no significant change in the median (range) functional score before and after metronidazole therapy (4 (3–6) *versus* 3 (2–4)), sigmoidoscopy score (1 (0–2) *versus* 0·5 (0–2)) or histology score (1·5 (0–3) *versus* 1 (0–3)).

There was a significant decrease in the median (range) CCPR in patients with pouchitis, from 3·1 (1·8–6·6) to 1·1 (0·4–3·0) after therapy for 1 month with metronidazole ($P = 0.049$). In contrast, in the 12 patients without pouchitis there was no significant change in the median (range) CCPR before and after metronidazole therapy (1·4 (0·4–2·8) *versus* 1·2 (0·4–1·8), $P = 0.54$) (*Figure 5*). The villus atrophy index also increased significantly, from 6·7 (4·1–8·2) to 12·1 (6·7–14·3) ($P = 0.049$), in patients with pouchitis following metronidazole

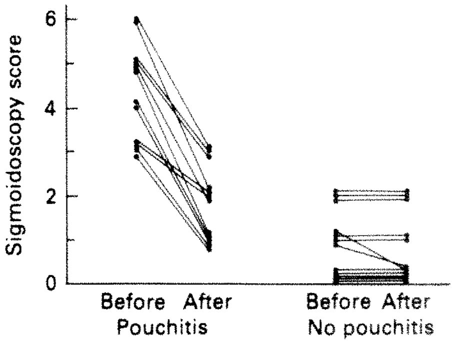

Figure 3 *Sigmoidoscopy score before and after metronidazole therapy in patients with and without pouchitis*

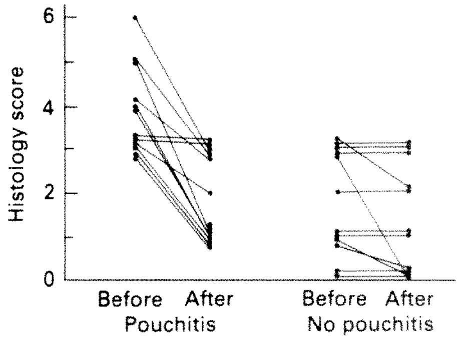

Figure 4 *Histology score before and after metronidazole therapy in patients with and without pouchitis*

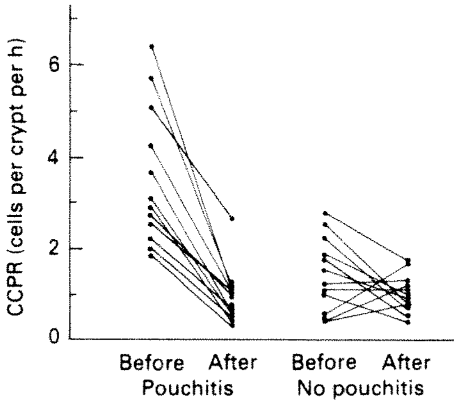

Figure 5 *Crypt cell production rate (CCPR) before and after metronidazole therapy in patients with and without pouchitis*

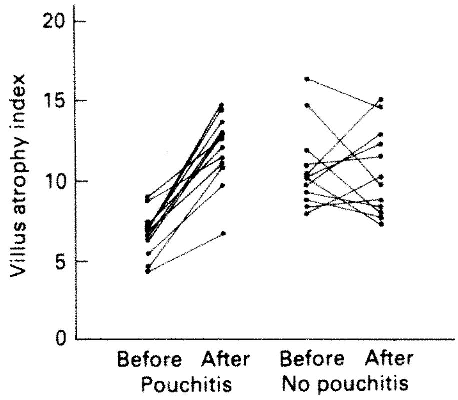

Figure 6 *Villus atrophy index before and after metronidazole therapy in patients with and without pouchitis*

therapy, suggesting that remission of pouchitis is associated with villus regrowth. However, there was no change in atrophy index after metronidazole in patients without pouchitis (9·5 (6·7–17·1) before *versus* 9·4 (6·4–15·8) after therapy, $P = 0{\cdot}17$) (*Figure 6*).

Despite the reduction in CCPR and increase in villus atrophy index following metronidazole therapy in patients with pouchitis, there was no significant difference in total faecal aerobic and anaerobic bacterial counts after metronidazole[13], either in the six patients with or the six without pouchitis. There was also no difference in the counts of *E. coli* and *S. faecalis* in these patient groups following metronidazole administration. As expected, metronidazole had a significant influence on the counts of *Bacteroides* species, which were eliminated by the drug.

Discussion

This study shows that a low villus atrophy index (indicating severe atrophy) and a high CCPR in the ileal pouch mucosa are associated with endoscopic and histological features of pouchitis. These mucosal morphological and cell kinetic changes also occur in active ulcerative colitis[14]. Computer-aided microscopy was used in the present study to minimize observer bias in the measurement of villus atrophy index. This estimate of atrophy has been shown to correlate with other estimates measured morphometrically using linear and eyepiece graticule techniques[11].

Assessment of the rate of cell division[15] provides more dynamic information than does reliance on proliferative state measurement alone. CCPR takes account of the three determinants of cell proliferation, changes in cell cycle time, growth fraction and crypt cell population size[12,14], but is not a sensitive measure of proliferation because large differences are required in linear regression models before significance is obtained[16].

The severe villus atrophy seen in patients with pouchitis confirms the observations of others[7]; also, the negative correlation between atrophy index and CCPR has previously been shown in ileal pouch mucosa. Crypt cell hyperplasia may indicate attempted mucosal regeneration[17,18]. The regrowth of intestinal villi and reduction in CCPR after metronidazole therapy in patients with pouchitis implies that the treatment allows resolution of villus atrophy and normalization of crypt proliferation, as in pouchitis the villi are shed and the crypts hyperactive in an attempt to replace them.

The variable changes in the villus atrophy index and CCPR after metronidazole therapy in patients without pouchitis have three possible explanations. The first is that patient compliance with metronidazole was poor. This explanation is unlikely as *Bacteroides* species were eliminated from the stool in the 12 patients studied following metronidazole treatment. The second interpretation is that quantitative differences exist in bacterial counts to account for the different morphological responses to metronidazole. It has been shown that the total number of bacterial counts and the anaerobe:aerobe ratio in faeces are greater in patients with a continent ileostomy or pelvic ileal pouch[4,19] than in those with an ileostomy[20]. Acute mucosal inflammation has also been shown to be associated with increased faecal bacterial counts in patients with a pelvic ileal pouch and a Kock continent ileostomy by some[21,22] but not by others[4,23].

The present study did not demonstrate any correlation between mucosal morphology and pouch faecal aerobic and anaerobic bacterial counts in patients with and without pouchitis before and after metronidazole therapy. These findings must be interpreted cautiously as faecal bacterial transport and culture provide a very different environment to that of the intestinal lumen. Thus, *in vivo* factors that control bacterial growth may be absent *in vitro*[4]. However, the low numbers in this part of the study raise the possibility of a type II statistical error. These observations do not exclude other qualitative differences in faecal bacteria or their metabolites as important in the aetiology of pouchitis.

The third interpretation of this variable response to therapy postulates that pouchitis is specific to patients with ulcerative colitis. In this setting, metronidazole would act by suppressing cell-mediated immunity rather than by any specific antibacterial mechanism[24]. Although pouchitis is much more common after colectomy for ulcerative colitis, sporadic reports exist of pouchitis following colectomy for familial adenomatous polyposis[25,26]. Furthermore, therapy with metronidazole does not seem to be effective in severe ulcerative colitis[27] and, unlike pouchitis, disease remission in this condition is not associated with either decreased CCPR or mucosal regeneration.

The present study indicates that metronidazole therapy, apart from eliminating *Bacteroides* species, does not specifically alter the growth of other intestinal bacteria in patients with pouchitis. However, metronidazole does result in resolution of the typical changes in pouch mucosal morphology and cell kinetics seen in pouchitis. Although the aetiology of pouchitis remains uncertain, these data suggest that *Bacteroides* species may cause pouchitis in predisposed individuals by an interaction with an as yet unidentified faecal or mucosal factor.

One-layer continuously sutured colonic anastomosis

W. H. F. Thomson and M. H. E. Robinson

Department of Surgery, Gloucestershire Royal Hospital, Great Western Road, Gloucester GL1 3NN, UK
Correspondence to: Mr W. H. F. Thomson

A continuous single-layer suture is rarely used for colonic anastomosis, perhaps both from fear of imperilling perfusion of the cut ends and from anxiety that purse-stringing might occur and cause stricture.

Long experience of the method, however, has reassured the senior author (W.H.F.T.) that neither contingency need be expected. Therefore, when a simple means was appreciated of treating the irksome part of hand-sutured gut union, namely the mesenteric border – particularly when fat laden – and the 'posterior wall' in pelvic anastomosis, it was decided that a prospective assessment should be undertaken. This was started in February 1989 and the 200th anastomosis completed in July 1992. The series was consecutive and unselected, although ten further anastomoses were constructed otherwise by trainees unfamiliar with the technique.

All anastomoses involved the colon but none was extraperitoneal (where other techniques were employed). Preoperative bowel purgation and on-table orthograde colonic lavage were used for left-sided resection. Difficult pelvic anastomoses were protected by wide-bore tube caecostomy.

Table 1 shows the distribution of anastomoses. Operation was performed in 154 patients with carcinoma, 27 with diverticulitis and nine with Crohn's disease. There were ten other miscellaneous colonic lesions. The procedure was classified as urgent in 26 patients: 17 with obstruction (15 carcinoma, two Crohn's disease), four with volvulus, three with

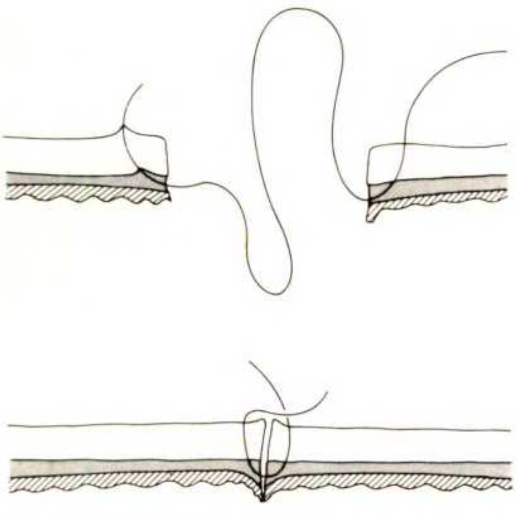

Figure 2 *Extramucosal suture placement*

diverticulitis and one each with caecal carcinoma and caecal diverticulitis. The median age was 68 (range 16–89) years.

Surgical technique

Using a double-ended absorbable monofilament, the stitch starts with a knot on the serosal surface to join the bowel ends midway between mesenteric and antimesenteric borders (*Figure 1a*). Needle 1 passes back through the seromuscular layer to emerge extramucosally at the cut edge of the bowel and on the surgeon's left (*Figure 1b*) to begin the 'back wall' stitch. This can then proceed comfortably, carrying the needle from right to left and towards the surgeon, on the luminal aspect (*Figures 1c–e*) with unimpaired vision along the mesenteric border. When needle 1 has finished on the serosal surface of the right-hand bowel end, needle 2 completes the encirclement, again being passed from right to left and towards the surgeon, although now on the serosal aspect, to finish the anastomosis with a second knot (*Figure 1f*).

The sutures are lightly drawn to appose, but not to crush, the cut ends, and are kept extramucosal so that as the edges are brought together (*Figure 2*) the mucosa is pushed up to create a flutter valve, further enhancing anastomotic security. The submucosa is picked up in the stitch.

Results

Table 1 shows the outcome. Three of the four leaks occurred in extenuating circumstances (resection through an abscess cavity, long-term high-dosage steroid medication, reversal of a low Hartmann's procedure in an infirm, obese, elderly patient). The patient taking steroids died. These three patients were operated on by the consultant surgeon. The fourth, minor, leak followed right hemicolectomy and was the only one generated by a trainee surgeon. No clinical evidence of stricture has occurred.

Discussion

Extramucosal suturing may contribute to anastomotic safety by avoiding transmural puncture and by apposing undamaged vascularized edges, as well as acting as a flutter valve. Matheson *et al.*[1] advocated extramucosal sutures and Halsted[2] showed over 100 years ago the greater importance of the submucosa. Both used interrupted stitches. However, continuous suturing has been found to be as safe as an interrupted procedure in rats[3], and Max and colleagues[4] experienced only a 1 per cent leakage rate in 1000 continuously sutured intestinal anastomoses.

The leak rate in the present study (2 per cent) is acceptable given the greater age of the patients. The method is straightforward to perform and teach, and appropriate to both elective and emergency work. Its speed approaches that of a stapled anastomosis and it is, of course, much cheaper.

Conservative treatment for low rectal carcinoma by local excision with or without radiotherapy

P. Rouanet, B. Saint Aubert, J. M. Fabre, C. Astre, J. Z. Liu, J. B. Dubois, H. Joyeux, C. Solassol and H. Pujol

Centre Val d'Aurelle, 34094 Montpellier, France

Correspondence to:
Dr P. Rouanet

Thirty-seven patients with low rectal carcinoma were treated by transanal resection between January 1979 and December 1988. Adjuvant radiotherapy was used in eight patients before operation, in 13 after operation and six patients had both preoperative and postoperative radiotherapy. The selection criteria for transanal resection were low, superficial tumours treated conservatively with curative intent (group 1, 18 patients) or patients medically unfit for (12) or refusing (seven) abdominoperineal resection (APR) (group 2, 19 patients). In group 1, the local recurrence rate was 11 per cent with an overall 5-year survival rate of 100 per cent. In group 2, the local recurrence rate was 53 per cent with an overall 5-year survival rate of 35 per cent. There was no postoperative mortality and minimal morbidity. Salvage of local failure was by APR in six patients. The survival rate after local recurrence was 70 per cent at 1 year and 30 per cent at 5 years. Transanal resection can be proposed as a curative procedure for selected low, small, minimally infiltrating and well differentiated adenocarcinomas. Local control might be improved by postoperative radiotherapy for Astler–Coller stage B_1 tumours or those above 3 cm in diameter. Further trials should examine the results of high-dose (60 Gy) preoperative radiotherapy so that transanal resection might be employed for favourable post-irradiation stage (0 or A) lesions. This new strategy will benefit from a better evaluation of tumour response after primary radiotherapy and an improved assessment of histological excision margins.

Recent advances in understanding of the natural history of low rectal carcinoma and in the surgical technique of coloanal anastomosis have allowed most patients to be treated by anterior resection[1]. However, a minority still require abdominoperineal resection (APR), which entails a permanent stoma and, not infrequently, urinary and sexual dysfunction. Transanal resection has often been explored as a palliative measure. A combination of careful preoperative digital examination with newer imaging techniques (endoluminal ultrasonography, pelvic computed tomography, magnetic resonance imaging) can allow low rectal carcinoma to be staged and its radiosensitivity to be assessed before operation more accurately than previously[2,3]. It is likely that more suitable lesions will be chosen for local treatment in the future[4]. Experience with transanal resection with or without radiotherapy has been reviewed to assess its potential as a curative measure in selected patients.

Patients and methods

Patient population

Thirty-seven patients with a diagnosis of localized, low, resectable adenocarcinoma of the rectum were treated by transanal resection at the Montpellier Cancer Institute between January 1979 and December 1988. Two groups were identified: group 1 consisted of 18 patients (nine men, nine women; median age 59 (range 27–75) years) with small (diameter less than 3 cm), mobile lesions for whom transanal resection was believed to be the treatment of choice. Group 2 comprised 19 patients (11 men, eight women; median age 67 (range 28–77) years) who were either medically unfit for (12) or refused (seven) APR. The median follow-up was 61 (range 24–144) months. Five patients were lost to follow-up or died from unrelated causes. During the study period, 212 patients underwent APR and 225 anterior resection. The transanal approach represented 7·8 per cent of procedures for low rectal cancer. The treatment of choice for small (less than 3 cm in diameter), polypoid, mobile tumours was primary local excision; for larger lesions preoperative radiotherapy was given and following incomplete surgical removal postoperative radiotherapy was recommended.

Tumour location, size and histology

The height from the anal verge to the inferior margin of the tumour was evaluated by clinical examination and rigid sigmoidoscopy. The median distance was 5·7 (range 1–11) cm. Twenty tumours were in the lower, 15 in the middle and two in the upper third of the rectum. The median tumour diameter was 2·5 (range 0·5–6) cm. All tumours were mobile; 24 involved less than half and 13 more than half of the rectal circumference. No tumour was fully circumferential. All lesions were adenocarcinoma: 22 were well differentiated, four moderately differentiated, one undifferentiated and ten had malignant change (more than 50 per cent involvement by cancer) in a villous adenoma.

Therapeutic procedure

Surgery. Local tumour excision was performed transanally, after the anal sphincter had been dilated. Injection of lignocaine (1 per cent) with adrenaline improved haemostasis and visibility. Tumours were removed with an excision margin of no less than 1 cm. When necessary the full thickness of the rectal wall was excised and the resultant defect closed with interrupted 3/0 polyglactin sutures. The excision margins were examined by frozen section for residual disease. A defunctioning colostomy was not used in any patient at the time of primary excision.

Adjuvant therapy. This was used in 27 patients (group 1, 11; group 2, 16): eight before operation (two in group 1, six in group 2), 13 after surgery (seven in group 1, six in group 2) and six both before and after surgery (two in group 1, four in group 2). The radiation was delivered by 15-MV accelerators at 2·2 Gy per day, usually in 18 fractions over 3 weeks, to a total dose of 39·6 Gy. The whole pelvis was treated with a three-field technique. All fields were treated daily and the dose was prescribed to the isodose line, which covered the target volume at risk. Eighteen patients had a further 15-Gy boost directed to the tumour bed. No patient received chemotherapy.

0007-1323/93/111452-05 © 1993 Butterworth-Heinemann Ltd

Follow-up

During the first 2 years, patients underwent clinical examination and estimation of serum markers every 3 months, liver ultrasonography and lung radiography every 6 months, and colonoscopy once a year. After 2 years of follow-up, patients were seen every 6 months for the next 3 years and annually thereafter. Local recurrence was defined as recurrence in the tumour bed or pelvic lymph nodes and was confirmed by guided biopsy. Metastasis represented distant recurrence.

Statistical analysis

Actuarial survival analysis was performed using the Kaplan–Meier method and rates compared using the log rank test. Differences between proportions were analysed by Fisher's exact test; $P<0.05$ was considered significant.

Results

Pathology

Using the Astler–Coller[5] system, the 37 tumours were staged: A, 18; B_1, 14; and B_2, one. Four patients did not have residual tumour after preoperative radiation therapy. Surgical margins were free from tumour in 34 of the 37 specimens. Nodal involvement could not be evaluated because no sampling was done. The tumour stage in each of the patient groups is shown in *Table 1*. There was no difference between the two groups but preoperative radiotherapy was delivered more often in group 2 (53 *versus* 22 per cent).

Table 1 *Treatment and outcome in patients undergoing transanal resection*

	Group 1 ($n=18$)	Group 2 ($n=19$)
Median (range) age (years)	59 (27–75)	67 (28–77)
Preoperative radiotherapy (%)	22	53
Tumour stage		
A	11	7
B_1	5	9
B_2	0	1
No tumour	2	2
Recurrence		
Local	2	10
Metastasis	0	4
Overall survival rate (%)		
3 years	100	50
5 years	100	35

Mortality and postoperative morbidity

There was no perioperative death. Disruption of the rectal suture line occurred in one-third of sutured cases. One patient developed a rectovaginal fistula, which required repair and a temporary colostomy. Three patients complained of radiation proctitis with mild symptoms only.

Sphincter function

No patient developed faecal incontinence necessitating a permanent colostomy. Two patients developed incontinence to flatus, which reduced within 3 months.

Local recurrence (Table 2)

The overall incidence of local failure was 12 of 37: two of 18 in group 1 and ten of 19 in group 2. The two local recurrences in group 1 occurred 47 and 55 months after primary treatment. Salvage of local failure was by APR in a 31-year-old patient and by radiotherapy alone in a 78-year-old. These two patients were free from further disease after follow-up for 85 and 42 months.

In group 2, three of ten local recurrences occurred after incomplete excision. Adjuvant radiotherapy did not prevent progression of the disease and recurrence occurred at 3, 4 and 35 months. Two of these three patients died from local progression. One 68-year-old woman, who initially refused APR for a middle-third carcinoma, was operated on 4 months after transanal excision by anterior resection and low colorectal anastomosis. Among the seven other patients in group 2 who had local recurrence, three had a large stage A tumour (mean diameter 3·9 cm) and three an advanced lesion (stage B_1 after radiotherapy). APR controlled the disease in three patients. The survival rate after local recurrence (*Figure 1*) was 70 per cent at 1 year, 30 per cent at 2 years and 30 per cent at 5 years.

Three patients did not undergo curative treatment of local recurrence and subsequently died from local progression. In nine cases treatment was attempted with a curative goal. APR

Table 2 *Details of 12 patients with locoregional recurrence*

Patient no.	Age at diagnosis (years)	Indication for transanal resection	Tumour stage	Primary therapy	Time to local recurrence (months)	Treatment for local recurrence	Clinical outcome	Length of follow-up (months)

APR, abdominoperineal resection. *Resection not curative microscopically; †patient refused APR

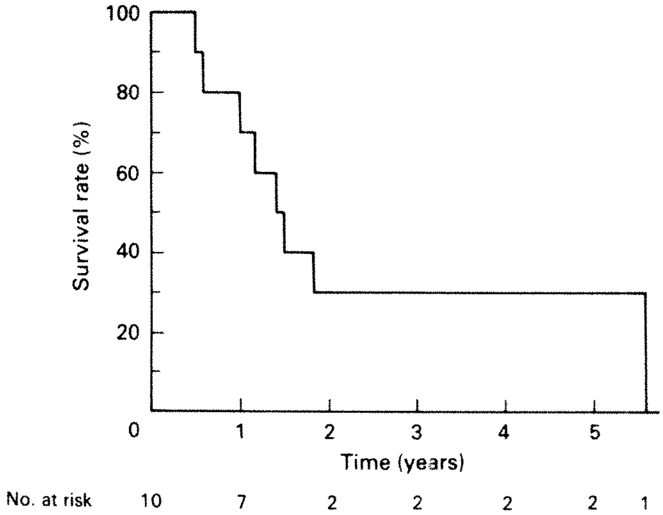

Figure 1 *Survival after locoregional recurrence for patients in group 2*

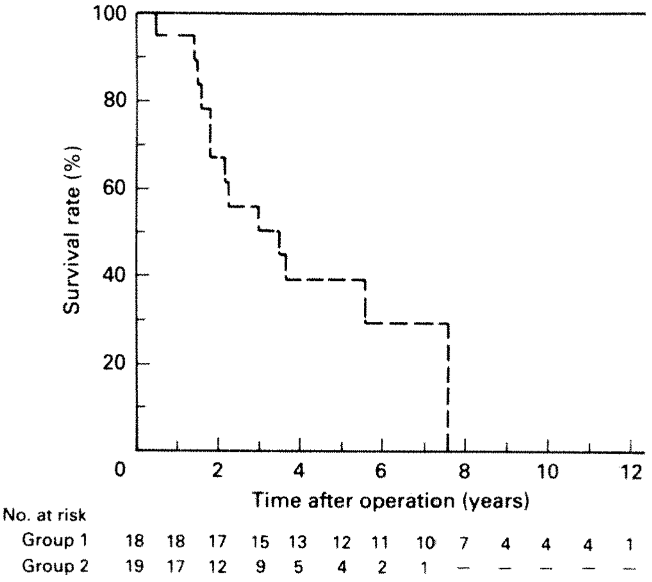

Figure 2 *Overall survival according to the indication for transanal resection:* ——, *group 1 (small tumour);* – – –, *group 2 (abdominoperineal resection contraindicated or refused)*

was performed in six patients; two died, one from local progression at 14 months and one from metastases at 13 months. In patients with stage B_1 and B_2 tumours there was a local recurrence rate of four of nine with 40-Gy adjuvant radiotherapy and five of 18 with 60 Gy. This difference was not statistically significant in such a small number of patients.

Metastases

Metastases occurred only in group 2. The incidence was four of 37; two of these patients had no local recurrence (liver metastases). Only one 28-year-old patient received chemotherapy but did not respond.

Survival

The overall survival rate at 3 years was 74 per cent and at 5 years 68 per cent; the median survival time was greater than 155 months. Survival was significantly ($P<0.001$) better in group 1 than in group 2 (*Figure 2*; *Table 1*). In group 1 the overall 5-year survival rate was 100 per cent, with an 84 per cent disease-free survival rate. In group 2 these values were 35 and 13 per cent respectively. Nine patients died from rectal cancer, giving a rectal cancer-specific mortality rate of 24 per cent: 0 per cent in group 1 and 47 per cent in group 2.

Discussion

Transanal resection for rectal neoplasm aims to restrict the loss of function and to diminish the operative risk. Nevertheless, local tumour excision has to be justified by patient survival rates similar to those achieved by more radical procedures. The reported incidence[6–9] of lesions suitable for transanal resection is variable, ranging from 1·2 to 13 per cent.

Operative deaths after local excision may be avoided, in contrast to reported mortality rates after conventional resection for Dukes' A tumours of 6 per cent[6,8]. In the authors' experience, the length of hospital stay was 23 days for APR, 19·2 days for anterior resection and 9·8 days for transanal excision. Preoperative radiotherapy did not significantly increase this period. In more than 500 patients reported in the literature (*Table 3*), no permanent colostomy for postoperative incontinence was necessary. After transanal resection and postoperative radiotherapy, complications requiring reoperation are infrequent[15,16].

The rate of lymph node metastasis for stage A–B_1 tumours, smaller than 3·0 cm, evaluated after radical resection ranges from 10 to 30 per cent[6,9,10,22,23]. On the other hand, when the tumour invades the perirectal fat, there is nodal involvement in 58 per cent of cases[22,24]. Non-encircling polypoid tumours less than 5 cm in diameter have a lower risk of lymph node involvement, but even tumours confined to the submucosa have lymphatic metastases in 6·5 per cent[6], which is no greater than the operative mortality rate for radical resection in the same series. For small tumours (up to 3·5 cm in size) operated on with radical resection, the incidence of positive lymph nodes rises with increasing tumour penetration[24], high grade[9] or presence of colloid histology[24]. For high-risk patients, excision plus adjuvant pelvic irradiation appears to be a useful form of treatment. Selection criteria for curative local excision must include an assessment of the risk of lymph node involvement.

After local excision, salvage resection has been regarded as a 'back-up' procedure with a reasonable chance of cure. Several authors[11,12,25] have reported that only 50 per cent of local recurrences were operable after curative local excision. Conversely, others have reported satisfactory results after subsequent radical operation[17,26]. In the present authors' experience, APR, whenever possible or accepted by the patient, controlled local progression of the disease in five of six cases. Early diagnosis of local recurrence seems to be the most important criterion for curative resection. For this reason, patients should be followed routinely with frequent clinical examination and endorectal ultrasonography.

It is important that the same type of tumours are being compared. There are good clinical, technical and pathological reasons for making a distinction between malignant polyps treated by endoscopic polypectomy, large sessile adenomas of the rectum containing a focus of invasive carcinoma treated by local excision, and small ulcerating cancers treated by local resection[22]. Recent progress in preoperative staging has shown the value of endorectal ultrasonography[27–29] to study rectal wall involvement and magnetic resonance imaging to assess regional cancer extension[30]. Clinical examination[31] remains important to appreciate tumour fixity and sphincter involvement. After these investigations, two situations can be considered.

The first concerns low tumours that fit the classical indication for transanal resection, that is they are located within the lowest 10 cm of the rectum, with a diameter less than 3 cm, they do not extend through the rectal wall into the perirectal fat and are characterized by well differentiated grading. Many authors report excellent results for local excision of superficial tumours (*Table 3*): a 3–11 per cent local recurrence rate for stage A tumours[6,8,13,14] and 13–18 per cent for stage B_1[1,12,14]. The 5-year survival rate ranges from 100 to 89 per cent for

*All tumours possessed a pedicle or pseudopedicle after the application of traction. †Patients with high-grade tumour or incomplete excision were reoperated on early by anterior resection or rectal excision. ‡High-risk tumours: stage B_2, resection line with tumour or undifferentiated carcinoma. §Systematic postoperative radiotherapy (47 Gy) for B_1 tumours

stage A[6,8,14] and from 90 to 78 per cent for stage B_1[10,14] tumours. Papillon[19,32,33] and Papillon and Berard[20] have reported 312 low rectal cancers treated by intracavitary irradiation (stage A–B_1) with an 8·8 per cent local recurrence rate and a 5-year survival rate of 92 per cent. Sischy and associates[21,34] reported equally good results. However, this technique is available at only very few medical centres and does not permit pathological study of the tumour. Whiteway *et al.*[35] perceived local excision as a 'total biopsy' that allowed confirmation of complete removal of the lesion and analysis of other histological parameters. This biopsy could be followed by radical resection, if prognostic factors suggested the need. The 11 per cent failure rate in the present favourable group 1 patients requires consideration. After local excision alone, similar rates have been reported[6,12,13,36], which underlines the need for adjuvant radiotherapy for selected high-risk patients. In the present study, after excision radiotherapy (60 Gy) was given to seven of the 18 patients with small tumours, with good local control in 90 per cent. Like others[16–18,37] we believe that adjuvant postoperative radiotherapy requires 45–60 Gy. When surgical removal was microscopically inadequate, radiotherapy could not compensate for the presence of tumour at the surgical margin. In the present series, disease in three patients with incomplete resection could not be controlled by adjuvant radiotherapy greater than 55 Gy. Rich *et al.*[37] reported a 56 per cent local recurrence rate in nine patients with residual gross disease who received postoperative radiation. Willett *et al.*[25] are alone in reporting no local failures in six patients with pathologically positive resection margins receiving postoperative radiation therapy in whom boost doses were increased to 65 Gy. On the other hand, radiotherapy may decrease the recurrence rate following local excision of early rectal cancer with occult lymph node metastases and/or microscopically unsuspected tumour at the margins[16,18].

The second situation concerns larger and deeper tumours that would ordinarily be treated by APR. Papillon and Berard reported a 5-year disease-free survival rate of 60 per cent and a pelvic failure rate of 7 per cent for T_2 or T_3 low rectal cancer treated by external and endocavitary irradiation[20,32]. In the present small series, a 44 per cent local recurrence rate was found for large tumours (B_1–B_2) with preoperative irradiation of 40 Gy. A 20-Gy postoperative boost reduced the local recurrence rate to 28 per cent. The importance of high-dose preoperative irradiation was outlined by Marks and coworkers[36,38,39]. They reported a 23 per cent local recurrence rate at 3 years and a 61 per cent survival rate for full-thickness local excision after high-dose preoperative irradiation[39]. Local excision after radiotherapy seems to be better than radiotherapy alone, which produced good temporary palliation and initial tumour regression but poor long-term control of disease. The survival rate was often less than 5 per cent. The same authors[36] reported experience of high-dose radiation therapy (60 Gy) followed by curative radical rectal resection and coloanal anastomosis for low and advanced rectal cancer. For favourable post-irradiation stage (0, A, B_1) the local recurrence rate was 0 per cent, and it was 18·3 per cent for unfavourable post-irradiation stage. These excellent results raise the issue of whether local excision is appropriate for favourable post-irradiation stage (0, A), even for an initially fixed and bulky tumour. It implies that the resection margins should be reassessed after preoperative radiotherapy.

Transanal resection should be considered as a curative procedure for selected low, small, well differentiated adenocarcinomas of the rectum. Local control could be improved by postoperative radiotherapy for stage B_1 tumours larger than 3 cm in diameter or for high-grade lesions. Further trials should examine the results of high-dose preoperative radiotherapy to define the role of transanal excision for favourable post-irradiation stages. Curative APR for early local recurrence after transanal resection seems possible when careful follow-up is undertaken.

Local excision of early rectal tumours is an attractive proposition, avoiding the morbidity and mortality of major resection and possible permanent stoma. This study was designed to investigate the incidence of lymph node metastases associated with tumours that are locally confined to the bowel wall. A total of 454 rectal excision specimens were reviewed. Twenty-two (20 per cent) of 109 patients with tumours locally confined to the bowel wall had metastases in local lymph nodes, although 14 of these had only one or two involved nodes. Three of 27 patients with tumours that did not penetrate through the submucosa had lymph node metastases. Less well differentiated tumours were more likely to have metastasized but there was no significant difference in the height or size of tumours or in the depth of invasion between patients with or without lymph node metastases.

The ideal surgical treatment for potentially curable cancer is removal of all viable tumour cells in a manner that causes the least mortality and morbidity. The usual procedure for rectal cancer is segmental excision of the bowel together with the adjacent mesorectum.

Local removal of carcinoma has been recommended[1–3] as a definitive procedure for early rectal cancer confined to the bowel wall. However, this procedure does not remove local lymph nodes in the mesorectum and thus does not allow full staging of the tumour; nor does it offer the prospect of cure to patients with involved nodes.

This study was designed to define the incidence of metastatic lymph node spread in rectal carcinoma confined locally to the bowel wall and to investigate whether features of the primary tumour may be used to predict nodal involvement. This may allow selection of patients suitable for local excision.

Patients and methods

The histological findings of two consecutive series totalling 454 patients in whom the rectum was removed for cancer were reviewed. These patients were under the care of two surgeons with an interest in colorectal cancer over a 10-year period. In each case the tumour was removed by either a radical anterior approach involving wide mesorectal clearance or by abdominoperineal resection. Patients in whom the local tumour did not penetrate the full thickness of the bowel wall were identified and the presence and number of lymph node metastases sought.

Routine histological preparation was carried out in the hospital laboratory. In one hospital, lymph nodes were identified by a fat clearance technique[4]. In the other hospital, lymph nodes were identified by careful dissection in an attempt to find at least 13 nodes in each specimen. Blocks were not routinely subjected to serial sectioning.

The height of the primary tumour, its diameter, the degree of cellular differentiation and the depth of tumour penetration were studied to determine whether these could be used to predict lymph node metastases. Differentiation was recorded by the reporting pathologist as the least well differentiated area along the invasion margin, assessed by tubule formation, mitotic rate and pleomorphism. Mucoid carcinoma was always classified as poorly differentiated.

Statistical comparison was made between the groups by χ^2 analysis or Student's t test as appropriate. $P < 0.05$ was considered significant.

Results

The 454 tumours in the series comprised 193 (43 per cent) Dukes' C, 174 (38 per cent) Dukes' B and 87 (19 per cent) Dukes' A. The Dukes' A tumours included those from two rectums removed after previous peranal excision of carcinoma confined to the bowel wall in which no further tumour was found in the specimen. There were 109 tumours in which the primary lesion did not extend through the bowel wall. In 22 (20 per cent) of these, metastases were present in local lymph nodes. In the majority (14 of 22) there were only one or two lymph node metastases present, and in only five specimens were more than three nodes involved (*Figure 1*). The tumour in the 22 cases associated with lymph node metastasis extended to the submucosa in three and to the muscularis propria in 19. The depth of invasion and degree of differentiation of tumours that

were locally confined to the bowel wall both in patients with and without lymph node metastasis are shown in *Table 1*. Only the degree of tumour differentiation showed a statistically significant difference between the two groups.

The height of the tumour above the anal margin did not differ between the two groups (mean(s.d.) 7·0(3·4) cm for the node-positive *versus* 7·6(3·9) cm for the node-negative group).

Similarly, the diameter of the primary tumour did not differ significantly between the two groups (mean(s.d.) 3·9(1·7) cm for node-positive *versus* 4·2(1·4) cm for node-negative patients).

Discussion

Rectal cancers may be considered in three groups. Tumours penetrating the full thickness of the bowel wall require radical surgery with removal of all local lymph nodes. At the other extreme is a group of tumours that are found in polypectomy specimens, in which the lesion does not involve the base of the stalk, is not poorly differentiated and is not large; in these local removal is probably adequate. This leaves an intermediate group that is considered in this study. The optimum treatment for these tumours is not clear, partly because it is not possible to predict the presence of tumour within local lymph nodes accurately[5,6].

Patients with lymph node metastases and local tumour confined to the bowel wall form a relatively small subgroup (5 per cent in this series) of all those with rectal cancer. This number is comparable to that previously reported by Jass and Love[7]. This group is, however, important as it makes up a significant proportion of patients who may be considered for local removal of cancer and in whom the presence or absence of involved nodes is of crucial importance. Furthermore, the routine techniques used in this study may have underestimated the numbers of involved lymph nodes.

Local removal of rectal tumour is an attractive proposition. The surgery involved is relatively minor with correspondingly low mortality and morbidity rates, and may avoid a temporary or permanent stoma. The technique does not, however, remove mesorectal lymph nodes. Histological examination of these nodes allows staging and an estimation of prognosis. More importantly, removal of metastatic tumour in these nodes in continuity with the primary lesion can frequently be curative, with survival figures[8,9] of over 50 per cent. Furthermore, there is evidence[7] to suggest that patients with Dukes' C tumours in whom the primary lesion does not penetrate the bowel wall have a better prognosis than those with Dukes' C tumours as a whole. Wolmark *et al.*[10] reported fewer involved nodes (mean 2·5 *versus* 4) and more patients with only one involved node (47 *versus* 15 per cent). Copeland *et al.*[11] reported a 47 per cent 5-year mortality rate for this group as opposed to 80 per cent when the tumour penetrated the wall. The operative mortality rate for patients aged less than 70 years undergoing radical surgery is approximately 1 per cent[8]. Clearly, when the involved lymph nodes are left behind, surgery cannot be expected to be curative.

Selection of patients for local removal of tumours of the lower rectum would be easier if it were possible to predict clinically the presence of lymph node metastases. Digital rectal examination has been shown[5] to be an unreliable guide to the presence of local lymph node involvement. Computed tomography is useful in determining the local depth of invasion and the presence of distant metastases, but disappointing in its ability to predict local lymph node involvement[6,12], and little better than digital examination[5]. Transrectal echosonography may prove to be a more useful investigation for the detection of nodal metastases. Beynon *et al.*[12] reported a series of 49 patients with positive nodes with five false-negative investigations. However, the procedure relies on a high degree of expertise and general results are likely to be less satisfactory.

In the present series, lymph node metastases in local lymph nodes were demonstrated in 22 (20 per cent) of 109 tumours locally confined to the bowel wall and in three of 27 when the primary lesion was confined to the submucosa. This is in broad agreement with the results of others. Morson[13] found that 12·1 per cent of patients with tumours that did not penetrate the full thickness of the bowel wall had lymph node metastases, and 10·9 per cent when the tumour was confined to the submucosa.

Small tumour size has been suggested as a criterion for local resection[14]. However, in the present series, when only tumours confined to the bowel wall were investigated, there was no difference in the mean size of tumour with or without associated metastases, and this has also been found by others[11,15]. Larger tumours are, however, more likely to have penetrated the bowel wall. Although poor cellular differentiation was associated with lymph node metastasis, this feature was not determined independently of knowledge of lymph node metastasis, so the possibility of observer bias exists. In any case, the clinical utility of this association is doubtful, as ten of the 17 patients with poorly differentiated tumours did not have nodal metastasis.

Present methods of investigation do not allow accurate prediction of patients who have metastasis to local lymph nodes. Features of the local tumour may provide a guide but are unreliable in the specific case. An early lesion is curable in the majority of cases by adequate surgery. Almost one-fifth of patients will have lymph node metastases and the risks of conservative surgery must be appreciated and taken into account in the planning of optimal treatment for each patient.

Surgical Research Society Abstracts

Br. J. Surg. 1993, Vol. 80, November, 1459–1485

The following abstracts were presented at the 78th meeting of the Surgical Research Society, with Professor L. E. Hughes in the chair. The meeting was held on 8–9 July 1993 at Ninewells Hospital and Medical School, Dundee. One hundred and fifteen papers were presented during the scientific sessions, which were preceded by a symposium entitled 'Tumour biology'. The Patey Prize was awarded to Mr C. Cunningham for his paper entitled 'Deletion mapping in colorectal cancer: sublocalization of a putative tumour suppressor gene on chromosome 8p'.

Tumour blood flow is related to cytotoxic drug uptake

M.J. Dworkin, J. Zweit*, B. Deehan*, P. Carnochan* and T.G. Allen-Mersh, *Department of Surgery, Chelsea and Westminster Hospital, London and *Department of Physics, Institute of Cancer Research, Sutton, UK*

Vasoactive manipulation to enhance cytotoxic uptake into tumours has been proposed but the underlying assumption that tumour flow correlates with drug uptake has never been tested. This was examined in the present study, which also determined whether angiotensin-induced alteration in blood flow correlates with alteration in 5-fluorouracil (5-FU) uptake.

Nineteen Chester Beatty Hooded rats bearing 183 hooded sarcoma N hepatic tumours underwent a 30-min hepatic artery infusion of saline (nine animals) or angiotensin II (ten). After 25 min a blood flow tracer (copper(II)-pyruvaldehyde *bis*(*n*-4-methylthiosemicarbazone) and tritiated 5-FU were infused. All liver and tumour tissues were counted in γ and liquid scintillation counters to establish blood flow and the 5-FU tumour:liver ratios.

In the saline (control) group there was a high correlation ($r = 0{\cdot}93$, $P < 0{\cdot}0001$) between individual tumour:liver blood flow and 5-FU uptake ratios. Although angiotensin significantly ($P < 0{\cdot}01$) increased the tumour:liver blood flow ratio (median saline 0·13, angiotensin 0·22), there was no significant change in the 5-FU uptake ratio (median saline 0·23, angiotensin 0·27).

Individual tumour variation in blood flow does correlate with 5-FU uptake. However, this relationship does not apply to angiotensin-induced changes in blood flow. This suggests that tumour-related factors are involved in the relationship between tumour blood flow and drug uptake.

Bombesin as a mitogen in human gastric cancer

S.R. Preston, L.F. Woodhouse and J.N. Primrose, *Academic Unit of Surgery, St James's University Hospital, Leeds, UK*

Receptors for the mammalian bombesin-like peptides gastrin-releasing peptide (GRP) and neuromedin B (NMB) are found throughout the gastrointestinal tract in the submucosal and myenteric plexuses. They have been demonstrated in human gastric cancer cell lines, but human tumour tissue has not been studied.

The aim of the study was to screen membrane preparations from snap-frozen human gastric cancers and macroscopically uninvolved adjacent mucosa for the presence of bombesin receptors using a standard radioligand displacement assay. ^{125}I-labelled Tyr^4-bombesin was used as radioligand and unlabelled bombesin, GRP and NMB as competitors.

Of 23 gastric cancers, 13 were positive for bombesin receptors whereas no 'normal' gastric mucosa expressed receptors. One patient with Ménétrièr's disease, a recognized premalignant condition, had a bombesin receptor-positive early gastric cancer and bombesin receptor-positive mucosa. Of eight gastric cancers in which the receptor has been subtyped, all expressed the GRP-preferring subtype of the bombesin receptor.

In conclusion, GRP receptors have been demonstrated in 57 per cent of human gastric cancers but not in normal mucosa. The only receptor-positive mucosa was from a patient with disordered mucosal growth. Expression of GRP receptors may be important in the neoplastic transformation of human gastric mucosa. Currently available stable bombesin antagonists may provide a new therapeutic approach to this common human cancer.

Torsion of the testis: a new twist

N. Brindley, T. Creagh, J. Dolan, M. Leader, S. Monkhouse, A. Qureshi and D. Bouchier-Hayes, *Departments of Surgery and Anatomy, Royal College of Surgeons in Ireland, Beaumont Hospital, Dublin, Ireland*

Torsion of the testis is a urological emergency. The reported salvage rate is approximately 60 per cent, but as many as two-thirds of these testes subsequently atrophy. Reperfusion injury may explain this delayed testicular loss. The effect of ischaemia and reperfusion on testicular function and structure and the potential protective roles of hypothermia and the anti-ischaemic drug trimetazidine were examined in a rodent model of testicular torsion.

Fifty testes undergoing 3 h of torsion (720°) were divided among seven experimental groups: group 1 ($n = 6$), no reperfusion; group 2 ($n = 6$), 1 h reperfusion; group 3 ($n = 6$), 1 week reperfusion; group 4 ($n = 6$), 1 h reperfusion with hypothermia; group 5 ($n = 6$), reperfusion and hypothermia for 1 h, examined at 1 week; group 6 ($n = 10$), 1 h reperfusion and trimetazidine; and group 7 ($n = 10$), 1 h reperfusion and trimetazidine, examined at 1 week. Mean seminiferous tubular diameter (MSTD), mean tubular wall thickness (MTWT) and the percentage of tubules with spermatozoa were measured. Statistical analysis was performed using Student's unpaired t test.

	1	2	3*	4†	5†	6†	7†
MSTD (μm)	14·6	14·8	12·0	15·0	15·0	15·5	13·4
MTWT (μm)	3·3	3·2	2·1	4·9	4·3	4·6	3·8
Tubules with sperm (%)	84	92	32	96	96	90	3

*$P < 0{\cdot}05$ *versus* groups 1 and 2; †$P < 0{\cdot}05$ *versus* groups 1, 2 and 3

The results show that reperfusion significantly increases testicular injury compared with 3-h torsion alone and is most evident at 1 week. The anti-ischaemic agent trimetazidine given during reperfusion limits testicular injury. Hence, manipulation of reperfusion injury following torsion may limit subsequent testicular atrophy.

Major impairment of bile acid absorption from ileoanal pouches shown by ^{75}Se-HCAT enema scintigraphy

I.M. Bain, A.B. Mostafa, L.K. Harding, J.P. Neoptolemos and M.R.B. Keighley, *Department of Surgery, Queen Elizabeth Hospital and Department of Physics and Nuclear Medicine, Dudley Road Hospital, Birmingham, UK*

The enterohepatic circulation of bile acids is crucial for digestion, prevention of gallstones and aspects of intestinal motility. It is unclear whether the mucosal changes that follow ileoanal pouch (IAP) construction affect bile acid absorption (or vice versa). To overcome previous methodological difficulties, bile acid absorption has been examined using a novel technique.

0007-1323/93/111459-27 © 1993 Butterworth-Heinemann Ltd

A 50-ml enema of the radiolabelled bile acid ^{75}Se-HCAT (7 kBq ml^{-1}) and computerized dynamic scintigraphy were used to study bile acid absorption in 15 patients with an IAP (seven with poor pouch function clinically) and in six with an end ileostomy. Log transformation of the absorption curves revealed two components (fast component $t_{1/2}$ 2·8 min; slow component $t_{1/2}$ 49·5 min) in all patients with an ileostomy (six of six), in seven of eight with good pouch function, but in only one of seven with poor pouch function ($2P = 0{\cdot}01$, Fisher's exact test). In the other six patients with poor pouch function there was only one absorption component ($t_{1/2}$ 53 min). ^{75}Se-HCAT absorption in patients with IAP was significantly impaired, and markedly so in those with poor function.

Study group	No. of patients	^{75}Se-HCAT absorption (%)*	
		30 min	60 min
Ileostomy	6	81 (79–87)	—
IAP	15	43 (24–47)	53 (36–70)
IAP (good function)	8	46 (43–53)	65 (57–72)
IAP (poor function)	7	24 (18–38)	36 (24–54)

*Values are median (interquartile range); $P < 0{\cdot}05$ (multiple range tests)

Enema ^{75}Se-HCAT scintigraphy provided remarkably good objective discrimination between IAPs with good and poor function. The role of the non-toxic and easily absorbed bile acid ursodeoxycholate may be worth exploring as oral therapy in patients with pouches with poor function.

Effect of proteinase inhibitors on breast cancer cell invasion

P.S. Stonelake, P.D. Brown, J.P. Neoptolemos and P.R. Baker, *Department of Surgery, University of Birmingham and British Biotechnology Ltd, Oxford, UK*

Proteinases are implicated in the invasion of basement membrane (BM) by breast cancer cells. The roles of various proteinases were studied in an *in vitro* model.

Breast cancer cells were seeded on to [^{35}S]methionine-labelled BM from endothelial cells grown in 96-well plates. After 72 h incubation with and without proteinase inhibitors the percentage of radioactivity released into the culture medium was determined. Oestrogen receptor-negative MDA-MB-231 cells were found to be the most invasive and were used to study the effects of proteinase inhibition.

Pepstatin (cathepsin D inhibitor), E64 (cysteine proteinase inhibitor), aprotinin (a general serine proteinase inhibitor) and BB94, a novel metalloproteinase inhibitor, were used in medium containing 5 per cent fetal calf serum (FCS) or under serum-free conditions. With FCS, pepstatin and E64 produced no significant difference in the degradation of BM, but both aprotinin and BB94 significantly reduced degradation as assessed by one-way analysis of variance (mean(s.d.) proportion of control value: aprotinin 64(22·4) per cent ($n = 13$); BB94 76·1(14·6) per cent ($n = 12$); combined 30(10·3) per cent ($n = 8$)). Under serum-free conditions the aprotinin effect was not found (104·1(12·2) per cent ($n = 6$); $t = 4{\cdot}74$, $P < 0{\cdot}001$ *versus* FCS) whereas BB94 was more effective (41(9·5) per cent ($n = 8$); $t = 6{\cdot}2$, $P < 0{\cdot}001$ *versus* FCS). With FCS, inhibition of plasminogen binding with tranexamic acid (61(12) per cent ($n = 3$)), urokinase-type plasminogen activator (uPA) with specific anticatalytic antibody (47(7·4) per cent ($n = 3$)) and amiloride (57(15) per cent ($n = 4$)) and of plasmin with ε-amino-*n*-caproic acid (62(13) per cent ($n = 3$)) all had a similar effect to aprotinin.

These data suggest that uPA–plasmin and metalloproteinases are the major proteinases involved in breast cancer invasion and offer targets for therapeutic agents.

Tumour-specific monoclonal antibodies induce cytokine release by effector–target cell linkage

A.M. Pullyblank, P.J. Guillou and J.R.T. Monson, *Academic Surgical Unit, St Mary's Hospital, London, UK*

The mechanism of antitumour antibody-dependent cell-mediated cytotoxicity (ADCC) is not well elucidated. The authors have previously suggested that monokines may mediate ADCC by demonstrating that neutralization of tumour necrosis factor (TNF) α produces a partial, but significant, reduction in tumour cell lysis. In this study TNF-α and interleukin (IL) 1β generation was examined during ADCC mediated by the anticolorectal monoclonal antibodies murine 17-1A (m17-1A), chimeric 17-1A (c17-1A) and chimeric SF25 (cSF25). Peripheral blood mononuclear cells were isolated from healthy volunteers, added to the colorectal cell line LS180 and incubated for 18 h with antibody. The supernatant was aspirated and TNF-α and IL-1β levels measured by enzyme-linked immunosorbent assay.

	No antibody	m17-1A	c17-1A	cSF25
IL-1β (pg ml^{-1})				
ET	1080 (382–2000)	1512 (1149–2000)†	1484 (1139–2000)†	2000 (1426–2000)†
E	26 (0–587)*	0 (0–70)*	0 (0–0)*	0 (25–1141)*
TNF-α (pg ml^{-1})				
ET	0 (0–34)	337 (0–2000)‡	436 (157–804)‡	825 (354–1582)‡
E	0 (0–0)	0 (0–0)*	59 (0–73)	7 (0–47)*

Values are median (interquartile range). ET, effectors plus targets; E, effectors alone. $^*P < 0{\cdot}05$ (ET *versus* E); $^†P < 0{\cdot}002$, $^‡P < 0{\cdot}02$ *versus* no antibody (all paired *t* test)

The results show that more TNF-α and IL-1β was detected with m17-1A, c17-1A and cSF25 than without antibody. Combinations of antibody with either effector or target cells alone produced undetectable or low levels. Therefore, only following the union of effectors, targets and antibody is cytokine release induced which may be partially responsible for tumour cell lysis.

Development of less invasive operations for gastro-oesophageal reflux

S.S. Kadirkamanathan, C.P. Swain, F. Gong, E. Yazaki and D.F. Evans (introduced by N.S. Williams), *Gastrointestinal Science Research Unit, The Royal London Hospital, London, UK*

Three antireflux operations, fundoplication, gastroplasty and anterior gastropexy, were achieved at flexible endoscopy without laparotomy or laparoscopy. An endoscopic sewing machine mounted on a standard gastroscope, an endoscopic knotting device, over-tube and 0·2-mm diameter nylon threads were used to perform the operations. An anatomical arrangement similar to that of fundoplication was achieved by invaginating the oesophagus and fixing it to the stomach 2 cm distal to the cardio-oesophageal junction. Gastroplasty was accomplished by suturing the anterior and posterior wall of the stomach to create a gastric tube (neo-oesophagus) along the lesser curve. Anterior gastropexy was performed using a technique similar to that used in creating a percutaneous gastrostomy.

Each operation was performed on six beagle dogs. There were no complications. Manometry using a three-channel perfused catheter system before and after the procedure showed a significant increase in the mean lower oesophageal sphincter (LOS) and cardiac yield pressures (mean LOS pressure 4·4 mmHg before operation, 17·6 mmHg after operation; mean yield pressure 10·2 mmHg before operation, 18·0 mmHg after operation).

It is concluded that conventional antireflux operations may be performed at flexible endoscopy without laparoscopy or laparotomy. This study also suggests that a variety of new gastrointestinal surgical operations might be performed 'inside out', i.e. from the mucosal aspect rather than from the traditional surgical approach via the serosal surface.

Successful treatment of severe diabetes mellitus using hybrid artificial pancreas devices

J.P.A. Lodge, T. Maki, S.J. Sullivan, R. Lanza, T.E. Muller, B.A. Solomon, W.L. Chick and A.P. Monaco (introduced by S. Sadek), *New England Deaconess Hospital, Biohybrid Technologies, and W.R. Grace and Company, Connecticut and Massachusetts, USA*

The application of two types of hybrid artificial pancreas for the treatment of severe diabetes mellitus induced by total pancreatectomy in dogs is reported.

The intravascular device consists of a coiled ultrafiltration membrane (nominal molecular weight cut-off 80 kDa), surrounded by an annular islet chamber and anastomosed to the iliac vessels. The intraperitoneal device consists of multiple tubular (2–4 cm × 5 mm) membrane diffusion chambers ('straws') fabricated from the same membrane.

A single intravascular device was unable to control blood sugar levels consistently. In a series of double-device implants involving 65 dogs, control of the blood sugar level was achieved for between 1 and 9 months in 70 per cent of dogs and for 1 year in two animals. Device removal resulted in a rapid increase in the fasting blood sugar level and exogenous insulin requirement (>30 units per day) ($P<0\cdot001$).

Six dogs received straws. Three did not require any exogenous insulin for >50 days, with <10 units per day for >100 days. Failure was attributed to membrane fracture and islet isolation problems.

Metabolic studies, postexplant *in vitro* studies and histological analyses confirmed islet cell survival and insulin production. There was no rejection.

These hybrid artificial pancreas devices have a clear clinical potential for islet cell transplantation without immunosuppression.

Double-blind randomized controlled trial of dietary calcium supplementation in individuals with adenomas

P.S. Rooney, K.-A. Gifford, P.A. Clarke, J.D. Hardcastle and N.C. Armitage, *Department of Surgery, University Hospital, Nottingham, UK*

Dietary supplementation with calcium reduces rectal mucosal proliferation in individuals at high risk of colorectal cancer. However, there have been few long-term randomized controlled trials in individuals with sporadic adenomas.

A total of 138 individuals (age range 34–70 years) underwent colonoscopy, were found to have adenomas and offered dietary supplementation. Seventy-nine patients accepted and were entered into a double-blind randomized controlled trial of 1500 mg calcium per day or placebo.

Mucosal proliferation (crypt cell production rate (CCPR)) was measured by the *in vitro* metaphase arrest technique.

Four individuals withdrew from the study in the first 12 months.

	CCPR (cells per crypt per h)		
	0 months	3 months	12 months
Calcium ($n=40$)	12·2(5·5)	9·0(2·8)*	9·3(3·3)†
Placebo ($n=39$)	10·6(5·2)	9·4(2·9)	8·9(3·3)

Values are mean(s.d.). *$t=3\cdot15$, 76 d.f., $P=0\cdot002$ (3 *versus* 0 months); †$t=2\cdot7$, 74 d.f., $P=0\cdot009$ (12 *versus* 0 months)

There were no significant changes in proliferation in the control group. Supplementation with 1500 mg calcium produced a sustained reduction in rectal mucosal proliferation, even after 12 months.

It is too early to comment on the effect of calcium on new adenoma formation. However, there appears to be a role for dietary supplementation of calcium in larger and longer cancer prevention trials.

Effect of the surgeon's specialty interest on resection specimen lengths in surgery for colorectal cancer

D.H. Reinbach, J.R. McGregor and P.J. O'Dwyer, *University Department of Surgery, Western Infirmary, Glasgow, UK*

A number of studies have demonstrated a surgeon-related variability in patient outcome following surgery for colorectal cancer. The aim of this study was to determine whether there is a correlation between the length of the formalin-fixed resection specimen and the surgeon's specialty interest. Three surgical groups were identified: surgeons with an interest in colorectal cancer (CCI), those with an interest in gastroenterology (GII) and those with a specialty interest other than CCI or GII (OSI). Over a 1-year period 158 colectomies were performed; 125 were thought to be curative.

Resection lengths and margins for right-sided cancers were similar in each group. Median (range) resection lengths for curative left-sided colonic and rectal cancers for each group were:

Specialty interest	Resection length (mm)*
OSI ($n=21$)	130 (87·5–180)
GII ($n=19$)	200 (150–220)
CCI ($n=41$)	280 (220–320)

*Medians are highly significantly different (Kruskal–Wallis test)

Distal resection margins (30 mm) were similar for rectal cancer in all groups. However, for sigmoid cancer the median distal resection margin was 20 mm in groups GII and OSI compared with 55 mm in group CCI ($P=0\cdot001$). This study demonstrates a wide variability in the type of resection performed for left-sided colonic and rectal cancer by surgeons with different specialty interests. Prospective studies evaluating patient outcome in relation to surgical interest and type of resection are required.

Haemodynamic changes associated with colorectal liver metastases: evidence of a humoral mediator

H.W. Warren, W.J. Angerson, E. Leen, R. Carter, C.S. McArdle and T.G. Cooke, *University Department of Surgery, Royal Infirmary, Glasgow, UK*

Splanchnic haemodynamic derangement, including reduced portal venous inflow, appears to be one of the earliest manifestations of liver metastasis in colorectal cancer. To investigate the hypothesis that this is humorally mediated, splanchnic vasoconstrictor activity was assessed in plasma from rats with intrahepatic hooded sarcoma N tumour (group 1), in patients with overt colorectal liver metastases (group 2) and in patients with colorectal cancer without overt metastases but with abnormal haemodynamics as assessed by duplex ultrasonography (group 3) (Doppler perfusion index (DPI; ratio of hepatic artery:total liver blood flow) $>0\cdot30$), a high-risk group for early hepatic relapse. Respective control groups were sham-operated rats, patients with no cancer and patients with colorectal cancer but with no overt metastases and with normal haemodynamics (DPI $<0\cdot30$).

Paired experimental and control plasma samples (100 μl) were injected intra-arterially in rat small bowel preparations, vascularly perfused with oxygenated Krebs' solution (5·5 ml min^{-1}). Response was measured as the peak increase in perfusion pressure. Rat samples were retested after blockade of α-adrenergic, vasopressin, angiotensin II, 5-hydroxytryptamine$_2$ and P2$_x$-purinergic receptors and neural conduction.

Group	*n*	Response (%)*	*P*†
1 (tumour-bearing rats)	18	118(4)	<0·005
1 (in blocked preparation)	18	135(211)	<0·01
2 (overt metastases)	9	188(26)	<0·01
3 (abnormal haemodynamics)	16	120(7)	<0·05

*Values are mean(s.e.m.) percentage of control. †Wilcoxon test

This study provides the first direct evidence that prognostic haemodynamic changes in patients with colorectal cancer are associated with a humoral vasoconstrictor. This is unlikely to be one of the major circulating constrictor hormones, and could be a marker for occult liver metastasis.

Expression of cripto and amphiregulin in the prognosis of rectal cancer

G. Gagliardi*†, I.C. Talbot†, J.M.A. Northover†, G.W.H. Stamp*, W.J. Gullick‡ and M. Pignatelli*, **Department of Histopathology, Royal Postgraduate Medical School, †Imperial Cancer Research Fund Colorectal Unit, St Mark's Hospital and ‡Imperial Cancer Research Fund Molecular Oncology Laboratory, Hammersmith Hospital, London, UK*

Cripto and amphiregulin (AR) are two newly discovered members of the epidermal growth factor family. The aim of this study was to assess the expression of AR and cripto in rectal cancer and its relationship to prognosis.

Two 17-mer synthetic peptides corresponding to the *C*-termini in the human cripto and AR proteins were used to generate monospecific antisera in rabbits. Paraffin-embedded sections were stained by the avidin–biotin complex immunoperoxidase technique using polyclonal anticripto and anti-AR antibodies.

Of 58 rectal carcinomas, 53 (91 per cent) stained for AR and 41 (71 per cent) for cripto. Cripto was expressed more in tumours of the lower third of the rectum ($P<0\cdot005$) and in flat–excavated tumours ($P<0\cdot01$). Of 54 samples of normal mucosa adjacent to the tumour, 20 (37 per cent) were positive for cripto. Ten of these 20 expressed more cripto than the tumour and all had cancer recurrence and bowel wall penetration. High cripto immunoreactivity in the normal mucosa correlates with nodal involvement ($P<0\cdot01$).

In conclusion, high levels of AR and cripto expression are frequently found in rectal tumours. High cripto immunoreactivity in the normal mucosa adjacent to the tumour correlates with tumour recurrence. Further studies are in progress to validate the use of cripto as a prognostic marker in patients with rectal cancer.

Prevalence of anal intraepithelial neoplasia in renal allograft recipients

O.A. Ogunbiyi, J.H. Schofield, J.H.F. Smith, A. Raftery, F. Sharp and K. Rogers, *Departments of Surgery, Gynaecology and Pathology, and The Sheffield Kidney Institute, Northern General Hospital, Sheffield, UK*

An increase in the prevalence and incidence of human papilloma virus (HPV)-associated genital intraepithelial and invasive neoplasia occurs in immunosuppressed organ transplant recipients. Although a similar trend has been suggested for the aetiologically related anal squamous neoplasia, there have been no studies of the prevalence of anal squamous neoplasia in recipients of organ transplants. The present study tested the hypothesis that renal transplant recipients have a higher risk of intraepithelial neoplasia of the anus than control patients of a similar age.

Ninety-eight renal transplant recipients (59 men, mean age 45·6 years; 39 women, mean age 47·8 years) were recruited and underwent anal colposcopy. A histological diagnosis of anal intraepithelial neoplasia (AIN), including one case of anal cancer, was made in 24 per cent of the study group. The distribution of the lesions is shown.

	Men	Women	Total
AIN I	13	6	19
AIN II	0	2	2
AIN III	1	1	2
Anal cancer	0	1	1

HPV 16 DNA was identified in anal biopsies in 30 (42 per cent) of 72 patients in the study group. No evidence of AIN was found in the control group (50 women, 20 men). HPV 16 DNA was identified in seven anal biopsies (10 per cent) in the control group.

The results suggest that the prevalence of AIN is higher in renal transplant recipients than in controls. The need for anal examination in screening for AIN in these patients requires further investigation.

Swainsonine inhibits colorectal cancer tumour cell invasion *in vitro*

C. Galustian, S. Foulds and P.J. Guillou, *Academic Surgical Unit, Imperial College of Science, Technology and Medicine, St Mary's Hospital, London, UK*

Swainsonine, a plant alkaloid, inhibits murine tumour metastasis *in vivo*. Swainsonine has not been studied as an anti-invasive agent in human colorectal tumours. The human colorectal cancer cell line SW620 was cultured *in vitro* for 4 days with or without $10\,\mu g\,ml^{-1}$ swainsonine. Cells were plated on to basement membrane (Matrigel)-coated filters in double-chamber cassettes. Tumour cells invading from upper to lower chambers were counted. At 6 h after plating, swainsonine reduced cell migration on to lower chamber filters from 19·1 to a mean(s.d.) 8·4(2·5) cells per field ($n = 11$; $P < 0·01$, paired t test).

To determine whether swainsonine modified cell adhesion to Matrigel, SW620 cells were cultured for 4 days with varying concentrations of swainsonine and coated on to 96-well plates. After 1 h, non-adherent cells were removed and the remaining cells fixed, stained and counted.

	Swainsonine concentration ($\mu g\,ml^{-1}$)				
	0	1	2	5	10
No. of cells ($\times 10^3$ per well)	14·9(1·3)	10·9(2·3)*	11·4(1·7)*	9·4(1·7)*	10·8(2·0)*

Values are mean(s.d.) of 15 samples. $P < 0·001$ (one-way analysis of variance); *$P < 0·01$ versus control (Duncan's post-analysis of variance comparison)

It is concluded that swainsonine inhibits basement membrane invasion by tumour cells *in vitro*; this may be attributable to inhibition of tumour cell adherence to the membrane. This study indicates the need for further investigation of swainsonine as an antimetastatic agent.

Cytokines and signalling pathways controlling a cancer–stromal paracrine loop in breast cancer

D.J.A. Orr, M.C. Ryan, D. Lloyds, E.V. Davies and K. Horgan, *Department of Surgery, University of Wales College of Medicine, Cardiff, UK*

There is speculation that breast cancer cells and stromal fibroblasts participate in a positive feedback loop of paracrine growth stimulation. The putative growth factors controlling this loop have been investigated using human breast fibroblasts and the breast cancer cell line MCF-7.

Fractionation of serum-free fibroblast-conditioned medium (FCM) demonstrated a mitogen of approximately 8 kDa, inactivated by trypsin and dithiothreitol and non-heparin binding, which excludes the fibroblast growth factors. Activity was not inhibited by neutralizing antibodies to epidermal growth factor, transforming growth factor α or the insulin-like growth factor 1 receptor, eliminating the common non-heparin-binding mitogens. Treatment of MCF-7 cells with FCM resulted in tyrosine phosphorylation of specific cellular proteins demonstrated by Western blotting, suggesting a mechanism of signal transduction.

MCF-7-conditioned medium (CCM) was mitogenic for fibroblasts. Treatment of fibroblasts with either CCM or platelet-derived growth factor (PDGF) resulted in a transient rise in the intracellular calcium level, measured by dual-wavelength fluorimetry with the indicator Fura-2. CCM mitogenicity was inhibited by a neutralizing antibody to PDGF.

The results clearly show that PDGF released by breast cancer cells stimulates the growth of fibroblasts which, in response, release an 8-kDa peptide that is mitogenic for cancer cells.

Cyclosporin A-induced fibroadenomas: a model for tumour genesis

A.D. Baildam, C. Holcombe*, R.M. Higgins, E. Hurley, A. Furlong, J. Walls, M.C. Venning, P. Ackrill, D. Ashbury, N.J. Bundred and R.E. Mansel*, *Departments of Surgery, Radiology and Renal Medicine, University Hospital of South Manchester, Manchester and *University of Wales College of Medicine, Cardiff, UK*

Multiple bilateral fibroadenomas are uncommon. The finding of four cases in women who had received renal transplants prompted further enquiry. A prospective study was performed on 39 women under the age of 55 years who had received a renal transplant at least 1 year earlier. Clinical examination was performed by an experienced clinician and breast ultrasonography by an experienced radiologist. Factors considered included immunosuppressive treatment, steroids, renal function, diuretics, calcium channel and H_2-receptor blockers. Blood was taken for estimation of serum creatinine levels and hormone profiles. Fibroadenomas, generally multiple and bilateral, were found in 13 of the 39 patients. The mean(s.d.) serum oestradiol concentration in women with fibroadenomas was higher than in those without (569(162) *versus* 283(61) $pmol\,l^{-1}$).

In patients who had received cyclosporin A, 12 of 28 had fibroadenomas, compared with only one of 11 of those who had not ($\chi^2 = 4·05$, $P < 0·05$). The presence of gingival hypertrophy, a recognized side-effect of cyclosporin A therapy, did not correlate with the presence of fibroadenomas (six of 12 with fibroadenomas, seven of 16 without). There was no association between the presence of fibroadenomas and use of steroids, azathioprine or any other medication.

It is concluded that cyclosporin A induces the development of multiple breast fibroadenomas. Cyclosporin has an *in vitro* effect on fibroblast growth, which may be modulated *in vivo* by an increase in serum oestradiol, as is suggested by this study.

Investigation of a novel pure antioestrogen in women with primary breast cancer

D. De Friend, C. Saunders, P. Cannon, A. Howell, E. Anderson, R. Nicholson, M. Dowsett, R. W. Blamey, M. Baum and R.E. Mansel, *Departments of Surgery and Tumour Biochemistry, University Hospital of South Manchester, The City Hospital, Nottingham, The Royal Marsden Hospital, London and The Tenovus Institute, Cardiff, UK*

Tamoxifen is the antioestrogen of choice for the treatment of breast cancer but exhibits agonist activity, which may reduce its efficacy. The tolerance and short-term biological effects of ICI 182 780 (182), a novel pure oestrogen antagonist, have been investigated in postmenopausal women with primary breast cancer. Fifty-six patients were randomized to either a control group (19 patients) who received no preoperative treatment or a treatment group (37) who received daily intramuscular injections of 182 at doses of 6 mg (21 patients) or 18 mg (16) for 7 days before surgery. The expression of oestrogen receptor (ER), progesterone receptor (PR) and the proliferation-related antigen Ki67 was determined immunocytochemically in tumour samples taken before and after treatment. Serum gonadotrophin and sex hormone-binding globulin (SHBG) levels were measured by radioimmunoassay. Ethical committee approval for the study was obtained.

182 caused no serious drug-related adverse events and had no effect on serum gonadotrophin or SHBG levels. Expression of ER, PR and Ki67 was significantly reduced in ER-positive tumours after therapy with 182, but there were no significant changes in ER-negative or control tumours.

	Control		ICI 182 780	
	Before	After	Before	After
ER	35	60	45	3·5*
PR	38	60	30	0·5*
Ki67	3·7	3·4	3·2	1·1*

Values are median percentage of cells stained before and after treatment. *$P<0{\cdot}05$ *versus* before treatment (Wilcoxon matched-pairs signed rank test)

In conclusion, 182 is well tolerated during short-term administration and produces antioestrogenic effects in human breast tumours *in vivo*, with no evidence of agonist activity.

Chemotherapy–radiotherapy and L-arginine: clinical and pathological responses in patients with breast cancer

J. Brittenden, S.D. Heys, I. Millar*, F. Gilbert‡, G. Needham‡, M. McKean†, T.K. Sarkar§, A.K. Ah-See and O. Eremin, *Departments of Surgery, *Pathology, †Cytology, ‡Radiology and §Radiotherapy, University of Aberdeen, Aberdeen, UK*

L-arginine increases the synthesis of human breast tumour protein and the number of tumour cells in the growth phase of the cell cycle. Thus, it may potentiate the anticancer response to cell cycle-specific cytotoxic agents. This pilot study assessed clinical and pathological responses to neoadjuvant chemotherapy–radiotherapy in patients with breast cancer supplemented with L-arginine.

Forty-four patients with breast cancer (T_2, seven patients; T_3, 21; T_4, 18) received oral L-arginine (30 g day^{-1} for 3 days) before each cycle of combination chemotherapy, and then proceeded to radiotherapy. Following chemotherapy 92 per cent of patients achieved a clinical response: complete response in 22 per cent and partial response in 70 per cent (Union Internacional Contra la Cancrum criteria). The overall clinical response rate increased to 95 per cent following radiotherapy, and ultrasonography and mammography revealed response rates of 91 and 76 per cent respectively. Surgery was performed in 44 patients (mastectomy, 28; quadrantectomy, 16). Pathology specimens were graded I–IV: (I) changes in tumour cells but tumour nests not destroyed; (II–IV) mild, moderate and severe destruction of tumour structure; and (V) no tumour cells present. Results were: grade I, one patient; II, seven; III, 13; IV, 15; and V, eight (complete response rate 18 per cent).

These results suggest that L-arginine is able to potentiate clinical and pathological responses to chemotherapy–radiotherapy.

pLiv1: an oestrogen-regulated gene associated with lymph node involvement in breast cancer

P.M. Cannon, D.L. Manning*, J.F.R. Robertson, I.O. Ellis, R.W. Blamey and R.I. Nicolson*, *The City Hospital, Nottingham and *The Tenovus Institute, Cardiff, UK*

Oestrogen receptor (ER) status is an established prognostic marker in breast cancer. However, not all ER-positive tumours respond to endocrine therapy and this may be due to a non-functional receptor in some cancers. Several oestrogen-regulated genes have been cloned and investigated as better markers of a functional ER. The expression of two such genes, pLiv1 and pS2, has been examined in 74 patients with primary breast cancer.

The results show that pLiv1 and pS2 are expressed almost exclusively in ER-positive tumours, although they are not invariably coexpressed. Considering all 74 patients, pLiv1, but not pS2, expression correlated with lymph node involvement ($P<0{\cdot}01$). With ER-positive tumours alone, pLiv1 expression was even more strongly associated with nodal disease: 15 of 18 ER-positive pLiv1$^+$ tumours were node positive while 20 of 23 ER-positive pLiv1$^-$ tumours were node negative ($P<0{\cdot}001$). This association was further strengthened when small ER-positive tumours (<2 cm) alone were considered: 11 of 12 node-positive tumours were pLiv1$^+$ and 17 of 22 node-negative ones were pLiv1$^-$. pLiv1 expression did not correlate with tumour size or lymphovascular invasion.

In conclusion, pLiv1 is a candidate gene for metastatic spread in ER-positive breast cancer.

Quantitative polymerase chain reaction assay for pNR-2–pS2 messenger RNA in fine-needle aspirates from breast tumours

M. Carr, T.W.J. Lennard, F.E.B. May and B.R. Westley, *Departments of Surgery and Pathology, University of Newcastle upon Tyne, Newcastle upon Tyne, UK*

Because of the poor predictive value of oestrogen receptor (ER) status alone in assessing the endocrine responsiveness of breast tumours, the use of reverse transcription and the polymerase chain reaction (PCR) in the measurement of pNR-2–pS2 messenger RNA (mRNA) in fine-needle aspirates is described. This assay uses reverse transcription and PCR amplification of aliquots of cellular RNA, extracted using guanidinium thiocyanate and quantified by spectrophotometry.

Before reverse transcription, a known quantity of synthetic mutated pNR-2–pS2 RNA is added to each aliquot. The mutation generates a recognition site for BamH1 enzyme digestion which is found centrally in the PCR target sequence. Digestion of the PCR products with BamH1 cuts the product of mutant origin, leaving the product of cellular origin intact. The products can be distinguished by differential migration on gel electrophoresis and quantified by ethidium bromide staining and gel scanning.

pNR-2–pS2 mRNA levels, measured in 0·1 μg cell-line RNA, were:

	MCF-7	EFM-19	T47-D	MDA-MB-231
Oestrogen responsive	Yes	Yes	Yes	No
pNR-2–pS2 mRNA (pg per μg total RNA)	715	433	14	Not detectable

These levels are comparable to those obtained by hybridization. In a preliminary study, usable RNA was obtained from seven of ten fine-needle aspirates from mastectomy specimens. pNR-2–pS2 mRNA was assayed using 1 μg. The results were:

	1	2	3	4	5	6	7
pNR-2–pS2 mRNA (pg per μg total RNA)	15·0	4·8	3·0	2·6	n.d.	n.d.	n.d.
ER concentration (fmol per mg total protein)	313	n.d.	368	4·4	2·4	0·4	—

n.d., Not detectable

This assay may be useful in predicting the responsiveness of breast cancer to primary tamoxifen therapy.

Influence of pneumoperitoneum on lower-limb haemodynamics

Y.G. Wilson, P.E. Allen, R. Skidmore and A.R. Baker, *Department of Surgery, Frenchay Hospital, Bristol, UK*

The scope of laparoscopic surgery is increasing. Prolonged pneumoperitoneum may have adverse pathophysiological effects. Recent reports have suggested an associated increased incidence of thromboembolic disorder.

Lower-limb venous haemodynamics were studied in 40 patients (25 women, 15 men; median age 52 years) undergoing laparoscopic cholecystectomy. Half were randomized to wear graduated compression stockings during operation, and half wore no stockings. Standardized venous capacitance (VC) and venous outflow (VO) were measured non-invasively before, during and after induction of pneumoperitoneum.

In the group without stockings, VC and VO scores decreased during pneumoperitoneum in 65 per cent of patients, returning to previous levels on release of the pneumoperitoneum. In contrast, in 90 per cent of the patients with stockings, scores remained at preoperative levels or rose once pneumoperitoneum had been established. There was a significant difference in standardized median VC and VO values at mid-operation between the two groups for both legs:

Group	VC	VO
Stockings		
Left leg	1·29(1·02)	1·36(1·21)
Right leg	1·26(1·26)	1·26(1·29)
No stockings		
Left leg	0·82(0·52)*	0·82(0·52)†
Right leg	0·83(0·60)†	0·83(0·60)†

Values are median(interquartile range). $^*P = 0·001$; $^†P < 0·001$ *versus* stockings (Mann–Whitney *U* test)

Pneumoperitoneum creates a significant resistance to venous return from the lower limbs. Compression stockings counteract the observed changes.

Neutrophil degranulation produced by experimental venous hypertension

D.A. Shields, S. Andaz, J.H. Scurr and P.D. Coleridge Smith, *Department of Surgery, University College and Middlesex School of Medicine, The Middlesex Hospital, London, UK*

Neutrophil activation may cause skin damage in patients with chronic venous insufficiency. Two experimental models of venous hypertension were used: a thigh tourniquet inflated to 80 mmHg for 30 min and standing for 30 min.

Twelve normal volunteers (nine men, three women; mean age 31 years) were investigated. Cannulas (18 Fr) were placed in veins of both feet and of the right hand, and blood samples taken before and after the two periods of hypertension, separated by a 30-min rest period. Blood was taken for neutrophil count and estimation of the plasma lactoferrin level, a secondary granule enzyme that was used as a marker of neutrophil activation, measured using an enzyme-linked immunosorbent assay.

	Tourniquet		Standing	
	Before	After	Before	After
Lactoferrin (ng ml^{-1})*	221·5 (153–238)	248 (188·5–299·5)†	230 (179·5–349)	276·5 (201·5–420)‡

*Values are median (interquartile range). $^†P = 0·028$ *versus* before tourniquet (Wilcoxon test; difference between medians 39 (95 per cent confidence interval (c.i.) 10·5–91) ng ml^{-1}); $^‡P = 0·0009$ *versus* before standing (Wilcoxon test; difference between medians 45·5 (95 per cent c.i. 26·5–66) ng ml^{-1})

There was a significant rise in the plasma lactoferrin level compared with the baseline value in both models of venous hypertension. Short-term venous hypertension causes neutrophil activation in normal subjects.

Free radical-induced lipid peroxidation in carotid endarterectomy

C.V. Soong, I.S. Young, J.M. Hood, B.J. Rowlands, E.R. Trimble and A.A.B. Barros D'Sa, *Vascular Surgery Unit, Departments of Clinical Biochemistry and Surgery, Queen's University, Belfast, UK*

Reperfusion of ischaemic tissues can cause cellular damage by lipid peroxidation with the release of by-products such as malondialdehyde (MDA) and diene conjugates (DCs). This study investigated the occurrence of lipid peroxidation during carotid endarterectomy.

In 24 patients undergoing this operation, blood samples for plasma MDA and DCs were obtained from the jugular vein at the start of surgery, just before the application of carotid clamps during shunting, and at 30, 60, 120, 180 and 300 s after the clamps were released. Carotid clamp times were recorded.

Significant increases in mean(s.e.m.) concentrations of MDA and DCs were observed at 60 s after clamp release (MDA 559(64) pmol ml^{-1}, DCs 428(32) units ml^{-1}) compared with those at the beginning of surgery (MDA 408(34) pmol ml^{-1}, $P < 0·01$; DCs 374(28) units ml^{-1}, $P < 0·05$). A significant correlation was observed between the percentage rise in MDA concentration and clamp time ($r = 0·45$, $P = 0·03$).

These results suggest that clamping of the carotid artery leads to lipid peroxidation, which may adversely influence outcome in patients undergoing carotid endarterectomy and possibly in other situations of transient cerebral hypoperfusion.

Microvascular constriction follows skeletal muscle ischaemia–reperfusion and is associated with reduced endothelial capacity to mediate vessel dilatation

R.M. Pemberton, J.H. Barker and G.A. Anderson (introduced by M.W.R. Reed), *Departments of Surgery, Physiology and Biophysics, University of Louisville, Kentucky, USA*

Arteriolar vasoconstriction and spasm have been postulated to contribute to no-reflow following ischaemia–reperfusion and so add to tissue injury. This work investigated skeletal muscle microvascular response to ischaemia–reperfusion using direct *in vivo* microscopy in a paired (CD-1) mouse cremaster model. Arteriolar diameters (30–80 μm) were measured before and after a 6-h period of complete ischaemia. In other groups, the effect of topical acetylcholine (10^{-4} mol l^{-1}) and nitroprusside (10^{-5} mol l^{-1}) treatment were compared with topical saline alone. One muscle was rendered ischaemic, while the contralateral muscle served as a non-ischaemic control (six animals in each group).

Results showed diameter changes 15–30 min after starting reperfusion. Topical saline had no significant effect on arteriolar diameter.

	Arteriolar diameter		
	Postreperfusion	Acetylcholine	Nitroprusside
No ischaemia	89(7)	104(4)*	103(3)*
Ischaemia–reperfusion	55(9)	65(8)	84(5)*

Values are mean(s.e.m.) percentage of preischaemic diameter. $^*P < 0·05$ *versus* saline (paired *t* test)

In conclusion, significant vasoconstriction ($P < 0·05$) followed ischaemia–reperfusion in this model. The ability of nitroprusside to induce vessel dilatation indicates that extrinsic nitric oxide-mediated smooth muscle relaxation was preserved, while the failure of acetylcholine to cause dilatation indicates impaired endothelium-dependent (intrinsic nitric oxide-mediated) vasodilatation. Loss of critical local (nitric oxide-dependent) influences on dilatation may therefore contribute to reperfusion-induced microvascular constriction.

Thromboxane antagonism prevents hindlimb ischaemia–reperfusion-induced gut damage

R.J. Corson, M. Fisher*, I. Ward†, N.Y. Haboubi, R.A. Little* and C.N. McCollum, *University Hospital of South Manchester, *North Western Injury Research Centre and †Booth Hall Hospital, Manchester, UK*

Thromboxane released on reperfusion of ischaemic tissue may promote intestinal permeability causing endotoxin absorption and multiorgan failure. The effect of the thromboxane receptor antagonist ICI 192 605 on the penetration of horseradish peroxidase (HRP) beyond the tight junctions of ileal enterocytes, and on the absorption of mannitol from the bowel into the portal circulation, was studied in anaesthetized rats in two experiments of four groups.

	HRP permeability		
Group	Negative	Positive	Mannitol (mg l^{-1})*
1 (ischaemia)	6	0	15·1(4·1)
2 (reperfusion)	0	6	36·2(8·1)
3 (DMSO)	2	4	34·2(4·6)
4 (antagonist)	6	0†	16·4(3·5)‡

*Values are mean(s.d.). $^†P < 0·05$ *versus* group 2 (Fisher's exact test); $^‡P < 0·05$ *versus* group 2 (analysis of variance)

Group 1 underwent a 5-h period of hindlimb ischaemia, and groups 2–4 underwent 3 h hindlimb ischaemia and 2 h reperfusion. During the period of reperfusion, an infusion of dimethyl sulphoxide (DMSO) was given to animals in group 3 and an infusion of ICI 192 605 in the solvent DMSO to those in group 4. Groups receiving HRP contained six rats and the groups given mannitol contained ten.

Thromboxane receptor antagonism prevents the abnormal permeability that follows hindlimb ischaemia and reperfusion.

Nitric oxide attenuates revascularization-induced lung injury

C.J. Kelly, H. Abdih, D. Bouchier-Hayes, H.P. Redmond, R.W.G. Watson, P. Burke and D.J. Bouchier-Hayes, *Department of Surgery, Royal College of Surgeons in Ireland, Beaumont Hospital, Dublin, Ireland*

Limb revascularization following aortic occlusion leads to lung injury dependent on activated neutrophil adherence. Nitric oxide inhibits neutrophil aggregation and adherence to endothelial cells. To determine *in vivo* whether nitric oxide has a role in attenuating ischaemia–reperfusion-induced lung injury, the effect of increasing or decreasing nitric oxide levels with sodium nitroprusside (SNP) or *N*-nitro-L-arginine methyl ester (L-NAME) respectively was evaluated in an aortic occlusion–lung injury model of 30-min ischaemia and 2-h reperfusion.

Sprague–Dawley rats (ten per group) were randomized to controls, ischaemia–reperfusion, ischaemia–reperfusion treated with L-NAME (10 mg kg^{-1}) and ischaemia–reperfusion treated with SNP (0·4 mg kg^{-1}) during reperfusion. Myeloperoxidase (MPO) activity measured pulmonary neutrophil influx. Pulmonary endothelial permeability was measured by wet:dry weight and bronchoalveolar lavage protein (BAL protein) and neutrophil counts (BAL PMN).

	Control	Ischaemia–reperfusion	L-NAME	SNP
Wet:dry weight	3·15(0·05)	4·08(0·9)*	5·9(0·4)‡	2·8(0·2)§
MPO (units g^{-1})	3·05(0·4)	6·1(0·1)†	8·9(0·7)‡	3·5(0·4)‡
BAL protein (mg)	347(32)	454(16)*	581(40)§	330(61)
BAL PMN	0·7(0·05)	1·8(0·07)†	2·7(0·16)‡	0·9(0·1)§

Values are mean(s.e.m.). $^*P < 0·05$, $†P < 0·001$ *versus* control; $‡P < 0·05$, $§P < 0·001$ *versus* ischaemia–reperfusion (all unpaired Student's *t* test)

A significant increase in MPO activity and microvascular leakage was produced by ischaemia–reperfusion, which was exacerbated further by administration of L-NAME. SNP therapy attenuated the ischaemia–reperfusion-induced lung injury. These data suggest that nitric oxide *in vivo* inhibits ischaemia–reperfusion-induced lung injury, perhaps by inhibiting pulmonary neutrophil influx.

Deletion mapping in colorectal cancer: sublocalization of a putative tumour suppressor gene on chromosome 8p

C. Cunningham, A.H. Wyllie and M.G. Dunlop*, *Cancer Research Campaign Laboratories, Department of Pathology, University of Edinburgh and *Medical Research Council Human Genetics Unit, Edinburgh, UK*

Several genetic events are implicated in colorectal carcinogenesis. Abnormalities of tumour suppressor genes p53 (chromosome 17p), *APC* (5q) and *DCC* (18q), in addition to activating mutations in the K-*ras* oncogene, are frequent occurrences. Results that indicate a novel tumour suppressor gene locus on the short arm of chromosome 8 are reported.

Allele loss studies were performed using polymorphic chromosome 8 markers comparing 120 tumour and matched normal DNA samples.

Some 52 per cent of tumours showed allele loss with chromosome 8p markers which were independent of deletions at chromosomes 5q and 17p. No correlation was noted between allele loss of 8p markers and site or stage of the tumour, or the sex or age of the patient at diagnosis.

The use of high-density markers allowed sublocalization of the region of interest. Six tumours were identified with crucial breakpoints indicating that the tumour suppressor gene locus on chromosome 8p lies between the ankyrin 1 and lipoprotein lipase genes, a region of approximately 30 cM.

These findings indicate a small target region for molecular cloning and eventual isolation of the putative tumour suppressor gene.

Luminal adrenergic agents modulate ileal transport by activation of α_1 and α_2 receptors

M.K. Barry, J.D. Aloisi, S.P. Pickering and C.J. Yeo (introduced by H.F. Given), *Department of Surgery, Johns Hopkins Medical Institutions, Baltimore, Maryland, USA*

Luminal α-adrenergic agonists alter ileal transport. This study tested the hypothesis that luminal α-adrenergic agents modulate ileal transport selectively, via specific α_1 and α_2 receptors.

Absorption studies ($n = 63$) were performed on dogs with 25-cm ileal Thiry–Vella fistulas. Perfusion with [^{14}C]polyethylene glycol was used to calculate absorption of water, ions and glucose from the fistula. Experiments included four 1-h periods: basal, α-antagonist infusion, α-antagonist with and without α-agonist infusion, and recovery. Agonists used were phenylephrine (PHE; α_1), clonidine (CLON; α_2) and noradrenaline (NA; $\alpha_1 > \alpha_2$). Antagonists were terazosin (TZ; α_1) and yohimbine (YOH; α_2). All adrenergic agents were delivered luminally at 10^{-4} mol l^{-1}.

The agonists PHE and NA caused significant increases in water and ion absorption, while CLON caused significant decreases in water, ion and glucose absorption. The antagonists TZ and YOH had no effect alone. TZ prevented the proabsorptive effect of PHE and NA. YOH increased the NA-induced proabsorptive effect. Data are expressed as the integrated water absorption (ΔA) for hours 3 and 4, compared with hour 2:

Infusion*	ΔA water
PHE	+10·7(6·0)†
PHE plus TZ	−2·1(4·5)
CLON	−11·8(8·2)†
CLON plus YOH	−7·4(8·0)†
NA	+11·3(6·6)†
NA plus TZ	+1·9(2·2)
NA plus YOH	+21·3(5·5)†

Values are mean(s.e.m.). *Nine animals were used for each infusion. +, Increased absorption; −, decreased absorption. $†P < 0·05$ *versus* hour 2 (analysis of variance)

Ion absorption paralleled water absorption. In conclusion, α_1-receptor activation causes a proabsorptive response for water and ions, while α_2 activation causes a prosecretory response for water, ions and glucose. The combination of a luminal α agonist (NA) with α_2 blockade may prove useful in pathological secretory states such as intestinal transplants or diarrhoea-associated endocrinopathies.

Breast cancer mortality in carriers of the *BRCA1* gene mutation is significantly lower than that in the general population

D.E. Porter, C.M. Steel, E. Smyth, J.M. Dixon and D.C. Carter, *Medical Research Council Human Genetics Unit, Edinburgh Breast Unit and University Department of Surgery, The Royal Infirmary, Edinburgh, UK*

Female carriers of the *BRCA1* gene mutation have a lifetime risk of breast cancer >80 per cent. To investigate whether breast cancer survival in *BRCA1* carriers is different from that in the general population, DNA from 35 women with breast cancer was typed using polymorphic markers D17S588 and D17S579 on chromosome 17q12-21 in eight breast cancer pedigrees with a high probability of linkage to *BRCA1* (range 79·2–99·9 per cent). Genetic typing suggested that all women had linkage to the *BRCA1* mutation.

The 5-year survival rate in *BRCA1* carriers was 83 per cent (24 of 29 individuals). In an age-matched control population, the 5-year survival rate was significantly lower at 61·1 per cent (556 of 910 individuals) ($\chi^2 = 4·70$, $P < 0·05$). In contrast, the 5-year survival rate in women from seven breast cancer pedigrees not obviously linked to *BRCA1* (probability of linkage range 41·1–63·5 per cent) was 59 per cent, similar to that in an age-matched population (59·2 per cent).

It is unlikely that *BRCA1*-linked pedigrees are preselected to favour prolonged survival. Furthermore, epidemiological data do not suggest an earlier stage of disease at presentation in women with strong family history of breast malignancy.

In conclusion, predisposition to breast cancer with prolonged survival may be a phenotypic effect of the *BRCA1* mutation.

Glutamine-supplemented total parenteral nutrition improves T cell response in surgical patients

M.G. O'Riordain, K.C.H. Fearon, J.A. Ross, J.S. Falconer, D.C. Carter and O.J. Garden, *University Department of Surgery, The Royal Infirmary, Edinburgh, UK*

Many *in vitro* studies have demonstrated potential benefits of glutamine on T cell function, but T cell response after glutamine administration to patients is unknown. Glutamine is unstable and is not contained in conventional total parenteral nutrition (TPN). As the dipeptide, it is stable and is rapidly hydrolysed *in vivo* to the amino acid form. This prospective study evaluated the effect of glutamine dipeptide supplementation of TPN on the T cell response and on production of the proinflammatory cytokines interleukin (IL) 6 and tumour necrosis factor (TNF) from peripheral blood mononuclear cells (PBMCs) of patients with cancer undergoing colorectal resection.

Twenty patients were randomized to either conventional TPN (0·2 g nitrogen $\text{kg}^{-1}\,\text{day}^{-1}$) or an isocaloric, isonitrogenous regimen containing 0·18 g glutamine $\text{kg}^{-1}\,\text{day}^{-1}$ from days 1–6 after operation. *Ex vivo* peripheral blood T cell response (DNA synthesis on blastogenic stimulation) and IL-6 and TNF production from endotoxin-stimulated PBMCs were determined before surgery and on days 1 and 6 after operation.

	T cell response	PBMC TNF	PBMC IL-6
Glutamine			
Pre-TPN (day 1)	90 (64–105)	129 (51–201)	167 (103–221)
Post-TPN (day 6)	137 (105–166)*‡	182 (131–263)*	108 (85–131)
Control			
Pre-TPN (day 1)	88 (69–124)	146 (69–293)	176 (85–264)
Post-TPN (day 6)	108 (77–129)	179 (89–228)†	107 (72–149)

Values are median (interquartile range) percentages of the preoperative value. *$P=0{\cdot}02$, †$P=0{\cdot}03$ *versus* preoperative value (paired Wilcoxon test); ‡$P=0{\cdot}03$ *versus* control (Tukey–Duckworth test)

Glutamine supplementation significantly improved T cell response without altering production of IL-6 or TNF. It may be a method of enhancing T cell function in the immunocompromised patient receiving TPN.

Cytokines, the acute-phase response and resting energy expenditure in patients with pancreatic cancer

J.S. Falconer, K.C.H. Fearon, C.E. Plester, J.A. Ross, M.G. O'Riordain and D.C. Carter, *University Department of Surgery, The Royal Infirmary, Edinburgh, UK*

Patients with pancreatic cancer frequently lose weight. Anorexia is a recognized phenomenon in these patients, but the role of a raised energy expenditure and the acute-phase response remains more controversial.

Twenty-four patients with pancreatic cancer who were losing weight and 17 controls underwent measurement of resting energy expenditure (REE) by indirect calorimetry and of body cell mass (BCM) by bioelectrical impedance analysis. The REE of patients with cancer was significantly raised compared with that in controls (72·5(4·4) *versus* 54·1(1·6) kcal per kg BCM per 24 h; $P<0{\cdot}002$). The association of REE to the systemic inflammatory response in patients with cancer was assessed by measurement of serum C-reactive protein (CRP), tumour necrosis factor (TNF) and interleukin (IL) 6 levels and the production of IL-6 and TNF by isolated peripheral blood mononuclear cells (PBMCs).

	CRP $\leqslant 10\,\text{mg}\,\text{l}^{-1}$ ($n=13$)	CRP $>10\,\text{mg}\,\text{l}^{-1}$ ($n=11$)	P*
REE (kcal per kg BCM per 24 h)	64·2(2·7)	82·1(8·1)	0·0406
Serum TNF (pg ml^{-1})	n.d.	n.d.	—
Serum IL-6 (pg ml^{-1})	102(10)	169(56)	0·22
PBMC TNF (pg per ml per 10^5 cells)	210(55)	1193(240)	0·0003
PBMC IL-6 (ng per ml per 10^5 cells)	3·4(1·3)	11·7(1·4)	0·0003

Values are mean(s.e.m.). n.d., Not detectable. *Student's unpaired t test

Of patients with pancreatic cancer 46 per cent had a systemic inflammatory response (CRP $>10\,\text{mg}\,\text{l}^{-1}$). These patients had a significantly raised REE compared with those without an inflammatory response and they also had significantly increased rates of cytokine production by PBMCs. Such patients might benefit from treatment with agents that attenuate the inflammatory response.

Calcipotriol inhibits rectal epithelial cell proliferation in ulcerative colitis

M.G. Thomas, K.P. Nugent*, A. Forbes* and R.C.N. Williamson, *Royal Postgraduate Medical School, Hammersmith Hospital and *St Mark's Hospital, London, UK*

Vitamin D reduces human rectal crypt cell production rate (CCPR) and may protect against colorectal cancer by reducing cell proliferation. Cell turnover is also increased in ulcerative proctocolitis, which might therefore respond to vitamin D metabolites. The effect of calcipotriol, a synthetic vitamin D analogue that avoids hypercalcaemia, on human rectal CCPR in ulcerative proctocolitis was investigated.

Paired rectal biopsies from seven patients with severe disease were established in organ culture with or without calcipotriol ($1\times10^{-6}\,\text{mol}\,\text{l}^{-1}$). After 15 h, vincristine ($0{\cdot}6\,\mu\text{g}\,\text{ml}^{-1}$) was added to induce metaphase arrest, and the CCPR was determined by linear regression analysis of accumulated metaphases.

Compared with values in 17 controls with incidental anal conditions, the median (range) rectal CCPR was 28 per cent higher in patients with ulcerative proctocolitis (5·90 (2·85–7·07) *versus* 4·80 (5·00–9·50) cells per crypt per h, $P<0{\cdot}01$). Calcipotriol reduced the mean(s.e.m.) CCPR by 69 per cent in patients with ulcerative proctocolitis, from 6·58(0·78) to 2·06(0·36) cells per crypt per h ($P<0{\cdot}001$).

Thus, calcipotriol can dampen the hyperproliferative state in ulcerative proctocolitis and could have a therapeutic role in the control of this inflammatory condition.

Glutathione S transferase μ gene deletion is a significant risk factor for transitional cell carcinoma of the bladder

D.J. Thomas, A. Daley*, J. Cooper*, D.E. Neal and J.R. Idle*, *Departments of Surgery and *Pharmacological Sciences, University of Newcastle upon Tyne, UK*

The major risk factors for development of transitional cell carcinoma (TCC) of the bladder are smoking and occupational exposure to chemicals. These risks may be modified according to genetic host factors. The enzyme glutathione S transferase μ (GSTM1) acts by detoxifying reactive intermediate compounds, for example benzo(*a*)pyrene-4,5 oxide. GSTM1 is polymorphic and 50 per cent of the population lacks the gene coding for this enzyme. The hypothesis was that GSTM1 gene deletion is a significant risk factor in TCC.

Using a polymerase chain reaction-based restriction fragment length polymorphism technique, genomic DNA was analysed in 53 patients with proven TCC of the bladder. DNA from 52 age-matched controls undergoing transurethral resection of the prostate and that from 58 healthy volunteers was also analysed. Some 46 per cent of healthy volunteers and 40 per cent of patient controls were positive for GSTM1. Of 53 patients with bladder cancer, eight (15 per cent) were GSTM1 positive, fewer than in the two control groups ($\chi^2=8{\cdot}41$, $P<0{\cdot}005$ for patient controls; $\chi^2=12{\cdot}67$, $P<0{\cdot}001$ for healthy controls). A relative risk of 1·42 (95 per cent confidence interval (c.i.) 1·12–1·79) with an odds ratio of 3·81 (95 per cent c.i. 1·53–9·34) was found for gene deletion.

The enzyme GSTM1 may have a protective role in the development of TCC.

Oesophageal squamous cell carcinoma: prediction of response to chemoradiotherapy

K. Hickey, D. Grehan, D.S. O'Brien, T.N. Walsh and T.P.J. Hennessy, *University Departments of Surgery and Pathology, Trinity College and St James's Hospital, Dublin, Ireland*

Up to 30 per cent of patients with a squamous tumour of the oesophagus will undergo complete regression following combined chemoradiotherapy. The ability to predict responders from pretreatment biopsy specimens would have obvious advantages. Epidermal growth factor receptor (EGFR) overexpression in oesophageal squamous cell carcinoma has been shown to be associated with a poor outcome; its role in predicting response to treatment has not been explored. Proliferating cell nuclear antigen (PCNA) is a cell-proliferating associated nuclear protein.

Biopsy material was taken endoscopically before treatment from 14 patients undergoing chemoradiotherapy (cisplatin, 5-fluorouracil and 40-Gy radiotherapy) before surgery. At subsequent oesophagectomy, six patients had no residual tumour (group 1) while eight had persistent tumour (group 2). Formalin-fixed paraffin-processed biopsy material taken from each patient before treatment was analysed histologically for tumour grade and immunocytochemically stained using monoclonal antibody to EGFR and PCNA. The proliferation index and EGFR expression for each tumour were assessed.

Tumour grade was a poor predictor of response to therapy. The mean PCNA index was lower in responders than in non-responders (25 *versus* 42 per cent), but there was considerable overlap (P not significant). In contrast, all the non-responders showed intense staining for EGFR, while five of six responders were negative ($P = 0{\cdot}003$, Fisher's exact test).

The results indicate that EGFR expression may be a useful indicator of patient response to combined chemoradiotherapy for oesophageal squamous carcinoma.

Smoking in patients with periductal mastitis and duct ectasia

J.M. Dixon, O.R. Sekar, A. Waverely and U. Chetty, *Edinburgh Breast Unit, Western General Hospital, Edinburgh, UK*

It is not clear whether the clinical syndrome of periductal mastitis (PDM), which is characterized by periareolar inflammation with or without nipple discharge and/or retraction, and its complications, non-lactating breast abscess and mammary duct fistula, and the clinical syndrome of duct ectasia (DE), characterized by nipple discharge, crusting of the nipple, nipple retraction and non-inflammatory periareolar mass, are related or separate conditions. The present study looked at the incidence of smoking and previous benign breast disease in the two conditions.

A prospective study of 14 322 patients presenting over a 4-year period is summarized. Patients with PDM and DE were compared with an age-matched group.

Clinical diagnosis	No. of patients	Smokers (%)	Previous benign disease (%)	Median age (years)
PDM	68	88*	47*	33
Non-lactating abscess	39	87*	71*	35
Mammary duct fistula	32	94*	100*	31
DE	186	24†	28†	58

*$P < 0{\cdot}0001$, †P not significant (*versus* age-matched controls without PDM)

The same findings for smoking are true when the analysis is restricted to patients who have histologically proven PDM or DE. Previous benign disease in patients with PDM was almost exclusively inflammatory episodes, compared with a single inflammatory episode in the DE group. PDM and DE are separate conditions with different aetiologies.

Interaction of vitamin D and parathyroid hormone-related protein in patients with breast cancer

J. Walls, E.B. Mawer*, M. Davies*, P. Gargan*, W.A. Ratcliffe†, A. Howell and N.J. Bundred, *Departments of Surgery and Oncology, Withington Hospital, *Bone Disease Research Centre, University of Manchester and †Wolfson Research Laboratories, Birmingham, UK*

Serum vitamin D ($1{,}25(OH)_2D$) has previously been shown to be suppressed in hypercalcaemia of malignancy (HM). However, animal studies have suggested that parathyroid hormone-related protein (PTHrP), the putative cause of HM, stimulates $1{,}25(OH)_2D$ synthesis.

The aim of this study was to measure serum $1{,}25(OH)_2D$ and plasma PTHrP concentrations in three groups of patients with breast cancer: those with early breast cancer (EBC; 27 patients), breast cancer bone metastases (BM; 11) and hypercalcaemia of malignancy (HM; 11). Plasma PTHrP levels were measured using a two-site immunoradiometric assay (normocalcaemic controls, PTHrP $< 0{\cdot}23$ pmol l^{-1}). Serum $1{,}25(OH)_2D$ was measured using an inhouse radioimmunoassay (normal range 20–50 pg ml^{-1}).

In normocalcaemic patients with EBC and in those with BM plasma PTHrP was undetectable. In patients with HM, however, eight of nine had raised PTHrP levels (mean 3·51 (range $< 0{\cdot}23$–20·74) pmol l^{-1}). Serum $1{,}25(OH)_2D$ levels were higher in patients with EBC (mean 47 (range 22–71) pg ml^{-1}) than in those with BM (mean 34 (range 12–76) pg ml^{-1}). Sequential levels at monthly intervals were shown to fall in five patients with BM ($P = 0{\cdot}059$). In patients with HM, all $1{,}25(OH)_2D$ serum levels were low (mean 16 (range 5–29) pg ml^{-1}).

In summary, the serum $1{,}25(OH)_2D$ level falls as breast cancer progresses and this is associated with an increase in plasma PTHrP concentration. These results indicate that PTHrP does not stimulate $1{,}25(OH)_2D$. The progressive action of PTHrP on bone resorption and renal tubular reabsorption of calcium may lead to inhibition of renal 1-α hydroxylase, with the onset of hypercalcaemia.

Screen-detected prevalent breast cancer: axillary dissection is necessary

E.F. Mooney, P. Kent, S. Donohue, P. Dervan, J. Ennis, J.M. Fitzpatrick and T.F. Gorey, *Professorial Surgical Unit, Mater Hospital and University College Dublin, Ireland*

The results of first-round screening over 3 years in a mammography screening programme were assessed. The objective of the study was to measure parameters in patients found to be node positive or negative to analyse whether axillary dissection is necessary in all cases.

Eighty-four cancers were detected. Twenty-one patients had positive nodes on level II axillary clearance and 63 had no nodal involvement. Nodal blocks deemed negative on initial haematoxylin and eosin staining were stained with monoclonal antibody to epidermal membrane antigen to detect micrometastases. Some 8 per cent of node-negative patients were found to have micrometastatic disease. Differences in tumour size, grade and type between node-negative and node-positive groups were assessed.

	Node-positive patients (%)	Node-negative patients (%)
Tumour grade		
I	5	3
II	20	54
III	75	43
Tumour size (cm)		
< 1	5	16
1–2	25	43
2–3	35	35
3–4	10	3
> 4	25	3

There were no characteristics of the primary tumours, taken either separately or in combination, that could accurately predict the presence of nodal metastases or micrometastases. It is therefore recommended that axillary clearance is necessary in all patients with prevalent cancer detected by mammographic screening.

Preliminary evaluation of a combined optical–Doppler ultrasonographic instrument for the detection of breast cancer

J. Brittenden, D. Watmough*, S.D. Heys, A. Ah-See and O. Eremin, *Departments of Surgery and *Medical Physics, Aberdeen University, UK*

The use of a combined optical–Doppler ultrasonographic technique was evaluated in the detection of breast carcinoma. Light absorption (TDDU), determined by the number of blood cells per unit volume of breast, results in the detection of an opaque lesion, and subsequent Doppler ultrasonography detects neovascularization at the periphery of the tumour.

In total, 189 patients (147 symptomatic, 42 attending breast screening) were investigated (mean age 54 years). In only two cases was TDDU considered undiagnostic (compared with 11 mammograms, seven in very dense breasts); cysts showed as translucent areas but fibroadenomas and other benign lesions not associated with neovascularization were not detected.

There were 97 neoplastic lesions. The sensitivity and specificity were: light scanning, 74 and 90 per cent; and mammography 99 and 90 per cent respectively. TDDU was less sensitive for small and impalpable tumours and did not detect ductal carcinoma *in situ* (26 false negatives; mean(s.d.) diameter 1·1(0·3) cm). Subsequent Doppler ultrasonography did not further increase the sensitivity of the examination. Patients with locally advanced breast cancer showed significant changes on repeated optical–Doppler examination, in concordance with the clinical response documented following neoadjuvant chemotherapy.

The combined optical–Doppler instrument, with its low sensitivity, is not suitable for screening, even in the young dense breast, but may have a role in assessing the response of large tumours to chemotherapy.

Screening mammography: prospective evaluation of a combined mammographic and cytological scoring system

M.J. Kerin, E. Mulligan, P. Kent, J. Ennis, M. Dowling, P. Dervan, J.M. Fitzpatrick and T.F. Gorey, *Departments of Surgery, Pathology and Radiology, Mater Misericordiae Hospital, Dublin, Ireland*

Stereotactic localization and fine-needle aspiration cytology (FNAC) has a role in the management of non-palpable breast abnormalities. As part of a regional breast screening programme the mammograms of more than 18 000 patients with no palpable breast lesion were scored 1–5 by two radiologists; 208 patients whose mammogram scored in the range 3–5 had localization biopsies and prior stereotactic cytological assessment.

The cytological smears were scored as benign (grade 1), acellular (2), atypical (3), suspicious (4) and malignant (5) by an independent cytologist. A combined score was thus generated. This study evaluated its potential in the management of screen-detected abnormalities.

Of 96 malignant lesions, 70 were correctly diagnosed by cytology. The sensitivity (85 per cent), specificity (98 per cent) and positive predictive value (99 per cent) of grade 4 or 5 cytology results compared favourably with those of other series. Significantly, all 60 patients with combined mammographic and cytology scores $\leqslant 4$ had true benign disease following excision biopsy and all 40 with a combined score $\geqslant 8$ had malignancy.

Repeat mammography rather than excision biopsy can now be recommended for patients with a mammography–cytology score $\leqslant 4$ and primary wide local excision for those with a score $\geqslant 8$.

Comparison of the effects of relaxation and befriending on anxiety reduction in patients with breast cancer

W.P. Fox, J. Gray, A. Wilkinson, K. Harrison*, R. Elliott*, R. Spence*, S. Lewis† and W. Odling-Smee, *Departments of Surgery and †Mental Health, Queen's University of Belfast and *Belfast City Hospital, UK*

Initial findings are presented from an ongoing longitudinal study to measure the effects of two psychological interventions on reducing anxiety in patients with breast cancer.

Sixteen patients were randomized to receive either relaxation (taught by volunteers), befriending (by nurses trained in psychotherapy) or the current level of care (control).

A battery of questionnaires was administered to all patients before operation and at fixed intervals afterwards. These questionnaires included the Hospital Anxiety and Depression (HAD) and the Mental Adjustment to Cancer (MAC) scales.

For all patients the therapeutic interventions showed no group effects on anxiety (HAD) at the postoperative level. However, for 19 patients who reported severe anxiety (>10) before operation, relaxation produced a significant reduction ($P=0{\cdot}02$) in anxiety at 3 and 6 months after surgery compared with control values.

In addition, for all patients the type of surgery had more effect in reducing anxiety between the preoperative and postoperative stages. Patients undergoing mastectomy showed a greater reduction in anxiety than those having partial mastectomy ($P<0{\cdot}009$). Those receiving relaxation also had a significant reduction in their fatalism (MAC) score ($P=0{\cdot}01$).

It is concluded that: (1) relaxation produces beneficial effects after operation in patients reporting severe preoperative anxiety; and (2) the type of surgery has a more immediate effect than psychological intervention in reducing initial levels of anxiety.

Axillary node status provides additional prognostic information

J. Walls, A. Donne, F. Knox*, J. Redford, R. Swindell†, A. Howell‡ and N.J. Bundred, *Departments of Surgery, *Pathology, †Statistics and ‡Oncology, University Hospital of South Manchester, Manchester, UK*

Axillary node status is accepted as the best prognostic factor in breast cancer. Many surgeons only sample nodes and thus miss important prognostic information. The prognostic value of full axillary node clearance performed on 540 women undergoing mastectomy for early breast cancer, with a minimum of 10 years' follow-up, was compared with that of 16 different standard prognostic factors.

Tumour grade and size, menopausal status, number of positive nodes (NPN), level of axillary nodal involvement (ANL), node-positive ratio (NPR) and the Nottingham Prognostic Index (NPI) ($P<0{\cdot}001$) were all univariately predictive of survival. Multivariate analysis revealed that only NPR, ANL, NPN, grade and menopausal status remained significant. For node-positive patients, only NPN, ANL, NPR and tumour size provided independent prognostic information.

Factor	Univariate P (χ^2 test)	Cox multivariate analysis z	Cox multivariate analysis P
ANL	$<0{\cdot}001$	3·33	$<0{\cdot}005$
Tumour size	$<0{\cdot}009$	2·92	$<0{\cdot}005$
Tumour grade	$<0{\cdot}02$	2·91	$<0{\cdot}013$
Menopausal status	$<0{\cdot}02$	2·48	$<0{\cdot}01$
NPN	$<0{\cdot}001$	2·44	0·17
NPR	$<0{\cdot}001$	2·42	0·16

A new index based on ANL, NPN and NPR detected four groups of patients; the 10-year survival rate was 93 per cent (group 1, $n=62$), 69 per cent (group 2, $n=176$), 46 per cent (group 3, $n=114$) and 6 per cent (group 4, $n=60$). Prognostic indices that utilize node sampling data (e.g. the NPI) provide poor discrimination compared with those utilizing full axillary node clearance.

Tissue polypeptide-specific antigen: a new serum marker of proliferative activity in breast cancer

P.M. Cannon, R.W. Blamey and J.F.R. Robertson, *The City Hospital, Nottingham, UK*

Serum tumour markers have been widely investigated in breast cancer. Current tumour markers reflect tumour bulk, and this unit has reported on the use of some of these in managing metastatic disease. Tissue polypeptide-specific antigen (TPS) is a novel serum marker in that it has been shown to reflect cell proliferative activity, rather than bulk, for a range of solid tumours. Few studies have evaluated TPS as a marker in breast cancer.

TPS was assayed in serum from 19 normal subjects and from patients with stage I and II (19), stage III (20) and stage IV (20) breast cancer before therapy. Mean (95 per cent confidence interval) serum TPS levels were: normals 76·69 (56–97), stage I and II 92·26 (61–122), stage III 217·58 (73–361) and stage IV 1183·75 (615–1752) units l^{-1}. Patients with stage IV disease had a significantly higher level of TPS than those with stage I–III disease, with no overlap of confidence intervals ($P<0{\cdot}001$, analysis of variance with range testing).

In stage IV disease, the serum TPS level showed no correlation with the site of metastases, response to endocrine therapy, duration of response or survival from metastases.

In conclusion, serum TPS assay is a useful indicator of metastatic spread in breast cancer.

Essential fatty acids inhibit breast cancer growth *in vivo*

G.T. Neades, D.L. Jones and L.E. Hughes, *Department of Surgery, University of Wales College of Medicine, Cardiff, UK*

Manipulation of fats in experimental breast cancer has produced conflicting results. Individual fats may be more important than overall quantity. Essential fatty acids (EFAs) of the n-6 series are metabolized abnormally in malignant cells and profoundly alter human breast cell proliferation *in vitro*. Their effect *in vivo* is unknown.

The effect of the n-6 EFA γ-linolenic acid (GLA) on xenografted human breast cancer growth in nude mice was examined.

Three groups of 22 female athymic mice (MF1 *nu/nu*01A) were inoculated with 2×10^6 fibroblasts and 2×10^6 MCF-7 human breast cancer cells in the right hind mammary fat pad. GLA suspended in 1 per cent Tween-80 at doses of 200 and 400 mg kg^{-1} was administered daily by intraperitoneal injection. Control animals received 1 per cent Tween-80. After 5 weeks the animals were killed, tumours weighed and examined histologically.

Three deaths occurred from infective complications. Fewer tumours were retrieved from the treated animals than from controls (six of 21 in the 200 mg kg^{-1} group, seven of 20 in the 400 mg kg^{-1} group *versus* 19 of 22 in the control group) ($P<0\cdot001$, χ^2 test). The median (interquartile range) tumour weight in controls (195·5 (35·5–252·0) mg) was significantly greater than that in treated animals (0 (0–52·0) and 0 (0–53·8) mg for the 200 and 400 mg kg^{-1} groups respectively) ($2P<0\cdot01$ and $<0\cdot001$ respectively, Mann–Whitney U test).

Systemic administration of GLA significantly reduces the growth of xenografted human breast cancer in athymic mice.

Water and electrolyte absorption is not altered by small bowel autotransplantation

A.M. Walters and M.G. Sarr (introduced by S.A. Sadek), *Gastroenterology Research Unit, Mayo Clinic, Rochester, Minnesota, USA*

The absorptive abilities of transplanted small intestine are not well documented. A model that eliminates the confounding factors of rejection, ischaemia and reperfusion, and that retains portal venous drainage, was used to study water and electrolyte absorption in both the jejunum and ileum.

An 80-cm isolated loop was created in four groups of six dogs that had: neurally intact jejunum (group 1), 'autotransplanted' jejunum (group 2), neurally intact ileum (group 3) and 'autotransplanted' ileum (group 4). Dogs were studied 1, 2, 8 and 9 weeks after operation. The loops were perfused with a solution of 150 mmol l^{-1} sodium chloride at 3 ml min^{-1} for 3 h. Each dog was studied on three separate occasions at each of the four time points.

Net absorptive fluxes for water, and for sodium and chloride (data not shown) were similar ($P>0\cdot05$) in neurally intact and autotransplanted animals in both the jejunum and ileum, and at all time points, despite the autotransplanted dogs having severe diarrhoea for the duration of the study. The normal physiological pattern of the ileum absorbing more than the jejunum ($P<0\cdot02$) was retained in the autotransplants.

	Net absorptive flux of water ($\mu\text{l cm}^{-1}\text{ min}^{-1}$)			
Week	Group 1	Group 2	Group 3	Group 4
1	6·3(0·5)	4·1(2·0)	13·0(1·5)	13·8(2·0)
2	6·2(0·8)	7·0(0·8)	11·2(1·2)	12·4(1·1)
8	4·4(1·2)	5·4(1·4)	11·3(1·4)	11·0(1·4)
9	4·5(0·8)	5·4(1·1)	9·8(1·2)	11·8(1·9)

Values are mean(s.e.m.)

The denervation resulting from small intestinal transplantation does not alter basic water and electrolyte absorption. Patients with an uncomplicated small bowel transplant should have the ability to absorb clear fluids 1 week after operation.

Preferences for decision making in women newly diagnosed with breast cancer

K. Beaver, S.J. Leinster*, K. Luker and R.G. Owens†, *Departments of Nursing and *Surgery, University of Liverpool and †Department of Health Sciences, University of Bangor, UK*

This study examined women's wishes with regard to involvement in decision making when breast cancer had been diagnosed.

Some 150 women with early breast cancer were compared with 200 with benign breast disease. Five cards, representing all levels of involvement in decision making from the completely active through collaboration to the completely passive, were shown to the subjects in randomly ordered pairs. Using Coomb's unfolding theory, 57 per cent of women with breast cancer were shown to have preference orders that fell on to a single psychological dimension of keep, share or give away control. Of patients with breast cancer, 52 per cent wanted a passive role, with 13 per cent wanting the most passive order. In the benign group, a second dimension was found in 39 per cent of women in the order share, keep or give away control. Overall, newly diagnosed subjects wanted to play a passive role while those with benign disease were more likely to want to play a collaborative role (46 per cent).

Patients with breast cancer were offered an active role in the decision-making process but 61 per cent of the subjects believed they had played a passive role. Comparing the actual role with the desired one, 38 per cent of patients had what they wanted, 39 per cent wanted a more active role and 23 per cent to be more passive.

Quality of life after renal transplantation: surgical perspective

K.M. Rigg, P.E. Buckley*, R. Reaich*, K. Russell*, G. Proud* and R.M.R. Taylor*, *Transplant Units, City Hospital, Nottingham and *Royal Victoria Infirmary, Newcastle upon Tyne, UK*

Transplantation is the ideal renal replacement therapy, but is quality of life really improved? Surgeons have been slow to address this issue. A prospective study of quality of life before and after transplantation was undertaken.

The Nottingham Health Profile (NHP) is a self-completion questionnaire measuring perceived health. Part I covers distress in six areas of daily living: energy, emotional reactions, social isolation, sleep, physical mobility and pain. Part II covers seven aspects of living that are most affected by ill health: occupation, looking after the home, social, home and sex life, hobbies and holidays.

The NHP was completed by 145 potential recipients awaiting a cytotoxic crossmatch (91 underwent transplantation, 54 continued dialysis) and again at 3 and 12 months. Demographic details and initial NHP scores were similar in both groups.

Scores for energy, emotional reactions and social isolation were improved at 3 and 12 months compared with pretransplant values ($P<0\cdot01$, Wilcoxon test), as were all aspects in part II ($P<0\cdot01$, McNemar test). In the dialysis group, higher scores were found at 12 months for all areas in part I compared with initial scores ($P<0\cdot01$), but with no difference in part II responses.

Quality of life is improved by successful renal transplantation, while deteriorating with time on dialysis. Efforts to increase transplantation rates need to be pursued.

Cyclosporin, nifedipine and gingival hyperplasia: a randomized controlled study

J.D.T. Morgan, M.J. Swarbrick, C.M. Edwards and P.K. Donnelly, *Department of Surgery, Leicester General Hospital, Leicester, UK*

Gingival hyperplasia is a common and distressing side-effect of cyclosporin A (CsA) therapy, with reported incidences of 7–80 per cent. It has been linked in this context with nifedipine, a calcium-channel blocker, frequently used in transplantation for control of hypertension. The incidence of gingival hyperplasia was studied within the framework of a randomized trial comparing three immunosuppressive regimens, with nifedipine treatment in one arm.

At transplantation, patients were randomized to receive either high-dose CsA and prednisolone (group 1), high-dose CsA, prednisolone and nifedipine (group 2) or low-dose CsA, prednisolone and azathioprine (group 3). Assessment of gingival hyperplasia was made 3 months after transplantation and graded as none, mild, moderate or severe. Edentulous patients do not develop gingival hyperplasia and were excluded from the analysis.

Group	No. of patients	None or mild	Moderate or severe
1	15	15	0
2	17	8	9*
3	17	14	3

$^*P<0\cdot001$ *versus* groups 1 and 3

Results showed that patients in group 2 were at significantly higher risk of developing gingival hyperplasia than those in groups 1 or 3.

This study confirms that the combination of high-dose CsA and nifedipine predisposes to gingival hyperplasia. Importantly, there have been reports of malignancy arising within areas of gingival hyperplasia, in a group of patients already at high risk of *de novo* cancer.

Effect of low-dose dopamine on bowel mucosa oxygenation in aortic surgery

C.V. Soong, J.M. Hood, B.J. Rowlands and A.A.B. Barros D'Sa, *Vascular Surgery Unit and Department of Surgery, Queen's University, Belfast, UK*

It has been proposed that dopamine, given in low doses, improves mesenteric blood flow. The effect of administering dopamine at a rate of $3\,\mu g\,kg^{-1}\,min^{-1}$ on the intramucosal pH (pH$_i$) of the sigmoid colon was examined in patients undergoing elective abdominal aortic aneurysm repair. pH$_i$ was measured tonometrically. The development of intramucosal acidosis is a reliable indicator of bowel ischaemia.

Nineteen patients were randomized into two groups, one of which received dopamine. Nine of the 19 patients were given dopamine, commencing at induction of anaesthesia and continued for 24 h. The mean(s.e.m.) urinary output was significantly higher in those who received dopamine than in those who did not (3·1(0·4) *versus* 2·1(0·2) litres, $P<0\cdot05$). The mean(s.e.m.) pH$_i$ was significantly lower in the dopamine group than in the other group (6·85(0·10) *versus* 7·09(0·07), $P<0\cdot05$). Five of the nine patients in the dopamine group developed intramucosal acidosis compared with only one of the ten in the other group ($P=0\cdot06$).

These results indicate that dopamine did not have a beneficial effect on oxygenation of the bowel mucosa in this group of patients. Its use to improve mesenteric blood flow in this situation should be further evaluated as it may have significant deleterious effects.

Cyclosporin-induced renal vasoconstriction is due in part to nitric oxide substrate depletion

I.T.M. Bloom, F.R. Bentley and R.N. Garrison (introduced by H.C. Polk), *Department of Surgery, University of Louisville, Louisville, Kentucky, USA*

Cyclosporin A (CsA) causes intrarenal vasoconstriction, which may account for its nephrotoxic effects. Nitric oxide (NO) is produced by vascular endothelial cells and protects the microcirculation during other vasoconstrictive states. In this study *in vivo* microscopy was used to investigate the role of NO in maintaining renal vascular tone and in protecting against CsA-induced vasoconstriction.

Hydronephrotic kidneys, in decerebrate rats, were suspended in an environmentally controlled tissue bath with neurovascular supply intact. Arteriolar diameters and flow in the interlobular artery (ILA), afferent arteriole (AFF) and efferent arteriole (EFF) were measured by videomicroscopy and Doppler velocimetry. Measurements were made at baseline and 15-min intervals following addition of CsA to the bath. In study groups ($n=6$), L-arginine (L-Arg), a NO substrate, or *Nω*-nitro-L-arginine methyl ester (L-NAME), a NO antagonist, were added to the bath.

	Saline	CsA	L-Arg	L-NAME	CsA plus L-Arg	CsA plus L-NAME
ILA diameter	−1(1)	−20(2)*	7(5)	−14(3)*	−8(4)†	−18(2)*
ILA flow	−1(3)	−66(4)*	4(9)	−39(7)*	−23(8)†	−61(6)*
AFF diameter	5(1)	−20(2)*	11(5)*	−19(6)*	−9(4)†	−23(5)*
EFF diameter	1(2)	−15(2)*	12(3)*	−5(6)	−8(4)†	−18(6)*

Values are mean(s.e.m.) percentage increase or decrease (−) from the baseline at 60 min. *$P<0\cdot05$ *versus* saline; †$P<0\cdot05$ *versus* CsA alone (analysis of variance)

CsA-induced vasoconstriction was significantly reduced by the addition of L-Arg. Inhibition of NO by L-NAME constricted preglomerular vessels but had no further effect on CsA-induced vasoconstriction. NO plays a significant role in maintaining renal vascular tone. Inadequate substrate may limit the NO counter-regulatory dilator response to CsA-induced vasoconstriction.

Induction of heat-shock proteins in transplanted human liver

K.S. Wynne, S.A. Sadek, J.P.A. Lodge and S.M. Farmery, *Academic Unit of Surgery, St James's University Hospital, Leeds, UK*

The heat-shock or stress proteins (HSPs) are cytoprotective agents that are known to be induced by noxious stimuli. Transplanted organs are subjected to such insults during preservation and reperfusion. Changes in the expression of inducible HSP 70 during routine liver transplant procedures were assessed.

Tru-cut liver biopsies were taken before and after hepatic reperfusion from 30 adult livers transplanted into 28 recipients. Total RNA was extracted and reverse transcribed. Complementary DNA (cDNA) was amplified by a novel semiquantitative polymerase chain reaction technique using primers specific for HSP 70 and β-actin (internal standard) and incorporating [^{32}P]2′-deoxyadenosine 5′-triphosphate. Results were expressed as the ratio of HSP 70:β-actin products.

RNA was reverse transcribed successfully from 26 sample pairs. Comparison of HSP 70:β-actin product ratios revealed a significant induction of HSP 70 with a median increase of 63 per cent ($P<0\cdot05$, Wilcoxon matched-pairs signed rank test).

	Before reperfusion ($n=26$)	After reperfusion ($n=26$)
HSP 70:β-actin ratio	0·74 (0·23–2·33)	1·24 (0·40–3·08)

Values are median (interquartile range)

This novel technique allows the determination of changes in gene expression using small surgical biopsies. Using this method induction of the potentially cytoprotective protein HSP 70 following hepatic reperfusion has been described.

Depletion of Langerhans' cells in renal allograft recipients: a possible factor in cutaneous neoplasia

N.J. London, S.P. MacDonald Hull, W.J. Cunliffe and J.P.A. Lodge, *Academic Unit of Surgery and Department of Dermatology, St James's University Hospital, Leeds, UK*

Cutaneous squamous cell carcinoma (SCC) is the commonest neoplastic lesion following renal transplantation. It is well documented that patients are also at increased risk of viral and other skin infections. Although a failure of immunosurveillance has been postulated as the cause of the increased level of cutaneous infection, little evidence exists to support this concept. The aim of this study was to investigate the distribution of Langerhans' cells (LCs) (cutaneous antigen-presenting cells) in renal allograft recipients with SCC and in matched controls.

Punch biopsies from non-lesional skin of renal allograft recipients with SCC, control allograft patients, healthy controls and control subjects with SCC were studied using an immunoperoxidase method employing antibodies against LCs. The skin sections were assessed semiquantitatively (graded 0–4) by two independent observers.

	LCs	
	Epidermis	Dermis
Allograft plus SCC ($n=15$)	2 (1–3)	0 (0–1)
Control allograft ($n=24$)	2 (1–3)	0 (0–1)
Controls plus SCC ($n=15$)	3 (3–3)	1 (1–1)
Healthy controls ($n=8$)	3 (3–4)	1 (1–1)

Values are median (interquartile range)

There were significantly fewer LCs in the skin of renal allograft recipients in all layers studied ($P<0\cdot005$, Mann–Whitney *U* test) and many recipients demonstrated virtually total depletion. There was no difference between subjects with or without SCC in either transplant or non-transplant groups.

The severe depletion of LCs in allograft recipients may be a major factor in the development of neoplastic skin disease.

Provision of back-up arteriovenous fistulas in patients receiving continuous ambulatory peritoneal dialysis

I.J. Beckingham, J.S. O'Rourke, M. Hinwood, M.C. Bishop and R.W. Blamey, *Professorial Surgery Unit, Nottingham City Hospital, Nottingham, UK*

Arteriovenous fistulas (AVFs) are provided for patients undergoing continuous ambulatory peritoneal dialysis (CAPD) as a 'back-up' to allow emergency haemodialysis during episodes of severe peritonitis or CAPD failure from other causes. Of AVFs performed in the authors' unit last year 53 per cent were back-ups, representing a significant financial and time cost in terms of surgical workload.

A preliminary survey confirmed that 42 per cent of renal units in the UK currently have a policy for providing patients receiving CAPD with back-up AVFs.

An audit was made of 176 patients who started CAPD between 1986 and 1989. Over a median follow-up period of 4 years the majority of patients (73 per cent) did not require haemodialysis.

Of the 153 back-up fistulas formed in 114 patients, only ten were ever used for emergency haemodialysis. Twenty-three other patients required emergency haemodialysis but, when required, their fistulas were no longer functioning. Mean fistula patency times in this study compare favourably with those of other published series, with 1- and 3-year rates of 73 and 60 per cent respectively.

This study has shown that the need for emergency haemodialysis has been overstated. When it is required, most fistulas are not available; 94 per cent of fistulas were never used for haemodialysis. We consider that it is no longer justifiable to provide back-up fistulas in patients undergoing CAPD.

Anti-Epstein–Barr virus monoclonal antibody prophylaxis of post-transplantation lymphoma

T.J. Boyle*†, J.M. DiMaio*, K.R. Berend*, S.J. Pruitt*, R.E. Coles* and H.K. Lyerly* (introduced by N.A. Habib), *Departments of Surgery, *Duke University Medical Center, North Carolina, USA and †Royal Postgraduate Medical School, Hammersmith Hospital, London, UK*

Opportunistic Epstein–Barr virus (EBV) infection is implicated in the pathogenesis of B cell lymphoma (BCL) complicating immunosuppression in transplant recipients. Inhibition of EBV infection may prevent BCL. Severe combined immunodeficient (SCID) mice develop BCL when engrafted with human peripheral blood leucocytes (PBLs) and infected with EBV. This model was employed to assess the ability of an anti-EBV-specific monoclonal antibody (MAb) THP-5, which inhibits EBV entry into susceptible B cells, to delay or prevent development of BCL.

SCID mice were engrafted by intraperitoneal inoculation of 50×10^6 PBLs preincubated with THP-5 (5 or 50 μg per ml protein) or control murine immunoglobulin (Ig) G (50 $\mu\text{g ml}^{-1}$) and infected by intraperitoneal inoculation of 5×10^3 transforming units of EBV. Mice were observed for tumour development and killed when weight loss ≥ 40 per cent occurred with palpable abdominal masses. The day of death was taken as the endpoint for each assay.

Engraftment–infection	Category	*n*	Mortality rate (%)	Death after engraftment–infection (days)*
PBLs (no EBV)	Negative control	10	0	—
PBLs plus EBV	Positive control	10	100	31 (27–40)
PBLs plus EBV plus IgG	MAb control (group 1)	10	100	55 (48–79)†
PBLs plus EBV plus THP-5	MAb (5 $\mu\text{g ml}^{-1}$) (group 2)	10	100	77 (55–101)‡
PBLs plus EBV plus THP-5	MAb (50 $\mu\text{g ml}^{-1}$) (group 3)	10	80	83 (63–114)§

*Values are median (range). †$P<0{\cdot}05$ *versus* group 2; ‡$P<0{\cdot}05$ *versus* group 3; §$P<0{\cdot}01$ *versus* group 1 (all log rank test)

In addition to the implications for the pathogenesis of post-transplantation lymphoma, these data suggest that MAbs protective against EBV infection may prove beneficial for the prophylaxis and treatment of this and other EBV-associated disorders in the expanding population of immunosuppressed solid-organ transplant recipients.

Cultured small intestinal stem cells retain the capacity for morphogenesis

I.S. Tait, G.S. Evans*, N. Flint* and F.C. Campbell, *Department of Surgery, Ninewells Hospital, Dundee and *Department of Epithelial Biology, Paterson Institute, Manchester, UK*

The culture of small intestinal stem cells (SISCs) with expansion of cell numbers could facilitate extensive mucosal replacement from minimal donor tissue. However, enterocytes in culture dedifferentiate and SISCs may lose their capacity for morphogenesis. This study characterized epithelial cells in culture and assessed whether culture before transplantation affects the regenerative capacity of SISCs.

Rat small intestine was disaggregated using collagenase and Dispase digestion. This releases cell aggregates containing SISCs, which were then cultured for 4 days. Cell proliferation was assessed by crystal violet assay and cell morphology by histochemistry, immunohistochemistry and electron microscopy. Cultured cells were then grafted with fetal intestinal mesenchyme to athymic mice and retrieved after 7 or 14 days for histological evaluation.

Cell numbers increased tenfold *in vitro*. Over 90 per cent of cells showed an enterocytic phenotype with expression of alkaline phosphatase, cytokeratins 8, 18 and 19, and microvillus brush borders. Cells transplanted after 4 days in culture showed progressive morphogenesis with development of a simple polarized epithelium at day 7 and rudimentary crypt and villus structures by day 14, which expressed distinct stem-cell lineages including goblet cells and enterocytes.

In conclusion, epithelial SISCs retain a multipotent capacity for epithelial regeneration after short-term primary culture and transplantation. The ability to culture SISCs should allow molecular manipulation before syngeneic stem-cell transplantation.

Modulation of impaired cellular function in intraperitoneal sepsis by pentoxifylline

S.E. Refsum, B.J. Rowlands* and V.E. Boston, *Royal Belfast Hospital for Sick Children and *Department of Surgery, Queen's University of Belfast, Belfast, UK*

In sepsis, cell membrane dysfunction can lead to hyponatraemia with resultant morbidity and mortality. Resting membrane potential (RMP) is a measure of cellular function and reflects ion distribution across the cell membrane. Therapy that improves the RMP in sepsis may potentially be useful in electrolyte management. Pentoxifylline (oxpentifylline) may act by stabilizing the cell membrane and inhibiting tumour necrosis factor. A caecal ligation and puncture (CLP) model was used to mimic clinical sepsis.

Wistar rats (170–250 g) were randomly allocated into six groups of 24 animals. Pentoxifylline was administered intraperitoneally, 20 mg per kg body-weight, at the various time intervals. RMP was measured at 6, 12 and 18 h after operation using a microelectrode inserted into the thigh musculature.

Time after surgery (h)	Sham	CLP	Pentoxifylline given 1 h before CLP	Pentoxifylline given 1 h after CLP	Pentoxifylline given 10 h after CLP	Pentoxifylline given 16 h after CLP
6	−83·1(0·6)	−82·1(0·6)	−82·8(2·8)	−81·6(1·2)	—	—
12	−80·4(1·1)	−77·9(1·1)	−81·6(1·8)	−81·0(1·9)	−83·9(0·8)*	—
18	−82·1(0·7)	−76·2(0·7)	−77·8(1·8)	−86·8(2·2)†	−85·4(1·2)†	−83·1(0·6)*

Values are mean(s.e.m.) RMP expressed as mV. *$P<0{\cdot}01$, †$P<0{\cdot}001$ (intergroup analysis using the Newman–Keul test). Two-way analysis of variance gave $P<0{\cdot}02$ at 12 h and $P<0{\cdot}001$ at 18 h

In conclusion, administration of pentoxifylline after the establishment of sepsis reliably prevents decreases in RMP. Pentoxifylline should be investigated for its clinical value in sepsis.

Effects of octreotide, insulin, epidermal growth factor and gastrin on the proliferation of tumorigenic cells *in vitro*

N. Davies, H. Kynaston, B.A. Taylor and S.A. Jenkins, *University Department of Surgery, Royal Liverpool University Hospital, Liverpool, UK*

There is evidence that the growth of a number of human tumours is stimulated by peptides and growth factors such as insulin, epidermal growth factor (EGF) and gastrin. Since octreotide (somatostatin; SMS) inhibits the growth of some experimental tumours *in vivo*, its effects alone or in combination with insulin, EGF and gastrin on the proliferation (uptake of [^{3}H]thymidine) of three tumorigenic cell lines were investigated *in vitro*. The proliferation of HSN cells (fibrosarcoma) and K12-Tr and WB2054M cells (colonic adenocarcinomas) was assessed in the presence of SMS (125 μg ml^{-1}), insulin (12·5 μg ml^{-1}), EGF (1·25 ng ml^{-1}), gastrin (5 nmol l^{-1}) and saline (control) alone or with SMS in combination, in the presence of [^{3}H]thymidine for 48 h.

	Cell type		
	HSN	K12-Tr	WB2054M
SMS	−28·0	−25·6	−19·6
Insulin	29·1	16·6	28·6
SMS plus insulin	1·5	−14·7	6·0
EGF	45·7	14·0	16·4
SMS plus EGF	−14·1	2·4	−8·2
Gastrin	15·5	−5·6*	29·8
SMS plus gastrin	−12·2	−15·6	11·2

Values are percentage change in [^{3}H]thymidine uptake compared with controls. **P* not significant (analysis of variance)

These results indicate that SMS not only significantly inhibits cell proliferation *in vitro* but also reduces the stimulatory effects of insulin, EGF and gastrin. These observations suggest that the inhibitory effect of octreotide on the growth of tumour *in vivo* may be mediated, at least in part, by its antiproliferative action.

Polymorphonuclear cytokine production after thermal injury

A.F. Horgan, J.A. Mannick and M.L. Rodrick, *Department of Surgery, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, USA*

The polymorphonuclear leucocyte (PMN) is a fundamental participant in the inflammatory process. It has recently been shown to be capable of both synthesis and release of numerous cytokines in response to mitogenic or antigenic stimulation. PMN cytokine production in patients following thermal injury, however, has yet to be demonstrated.

Highly purified populations of PMNs were isolated from the peripheral blood of patients following thermal injury. Cells were cultured in the presence or absence of bacterial endotoxin (lipopolysaccharide; LPS) stimulation for varying periods of time and compared with PMNs from normal controls. Total RNA was isolated and messenger RNA (mRNA) expression determined by Northern blot analysis using radiolabelled complementary DNA (cDNA) probes for interleukin (IL) 1, IL-6 and tumour necrosis factor (TNF) α.

mRNAs for IL-1 and TNF were expressed only after *in vitro* stimulation with LPS and both decreased following thermal injury. mRNA for IL-6, however, was constitutively expressed by PMNs from both normals and patients. *In vitro* LPS stimulation increased the expression of mRNA for IL-6 in normal PMNs but had no demonstrable effect on the PMNs from thermally injured patients. No decrease in the expression of mRNA for IL-6 was observed following thermal injury.

It is concluded that the PMN is an important source of inflammatory cytokine production following thermal injury. The quantitative predominance of the PMN following such injury establishes its role as an important modulator of both cellular and humoral immune responses in the thermally injured patient.

Role for nitric oxide in pancreatitis-induced lung injury

D. O'Donovan, C.J. Kelly, D. Bouchier-Hayes, R.W.G. Watson, H.P. Redmond, S. Monkhouse*, P. Burke and D.J. Bouchier-Hayes, *Departments of Surgery and *Anatomy, Royal College of Surgeons in Ireland, Beaumont Hospital, Dublin, Ireland*

Nitric oxide (NO) is an endogenous vasodilator that also inhibits neutrophil activation and adherence to endothelial cells. Inactivation of NO by superoxide anion released from activated neutrophils, inducing neutrophil-mediated microvascular injury, may be central to adult respiratory distress syndrome. The effect of increasing NO concentration, with sodium nitroprusside (SNP), on lung injury associated with pancreatitis was evaluated.

Sprague–Dawley rats were randomized to control (saline infusion) or caerulein-induced pancreatitis groups, which were treated with saline or sodium nitroprusside (0·4 mg kg^{-1}). The myeloperoxidase (MPO) concentration was used to measure neutrophil infiltration in the lung. Wet:dry lung weights and broncheolar lavage protein (BAL protein) level were used to measure pulmonary microvascular permeability.

Caerulein (5 μg kg^{-1} h^{-1}) induced pancreatitis in all animals, with a mean(s.e.m.) increase in serum amylase concentration from 1851(208) units l^{-1} (control) to 5198(924) units l^{-1} (pancreatitis) ($P < 0{\cdot}05$).

	Control ($n = 10$)	Pancreatitis ($n = 10$)	SNP ($n = 10$)
MPO (units per g)	2·1(0·5)	7·3(0·7)†	2·5(0·4)§
Wet:dry weight	3·0(0·0)	8·6(1·9)†	3·0(0·1)§
BAL protein (mg)	347(32)	6024(209)*	1441(166)‡

Values are mean(s.e.m.). *$P < 0{\cdot}05$, $P < 0{\cdot}001$ *versus* control; ‡$P < 0{\cdot}05$, §$P < 0{\cdot}005$ *versus* pancreatitis (all Student's unpaired *t* test)

These data show that pancreatitis induced significant pulmonary neutrophil influx and microvascular leakage, which were attenuated by SNP. They support the hypothesis that inactivation of endogenous NO may in part be responsible for neutrophil-mediated lung injury in pancreatitis and suggest a possible therapeutic role for NO.

Exercise induces neutrophil activation in claudicants but not in age-matched controls

P. Hickman, A. Hill*, M. McLaren*, J.J.F. Belch* and P.T. McCollum, *Vascular Laboratory and *University Department of Medicine, Ninewells Hospital, Dundee, UK*

Claudicants have a mortality rate from cardiovascular disease that is three times that in men of the same age. Recent evidence not only implicates neutrophils in the pathogenesis of atherosclerosis but also suggests that exercise in claudicants results in neutrophil activation. When activated, neutrophils may adhere to the endothelium and release elastase and oxygen-derived free radicals.

With ethical committee approval, 27 claudicants and 15 healthy controls were studied. All claudicants had ankle:brachial pressure indices (ABPIs) $\leq 0{\cdot}95$ and arterial disease proven by angiography. Controls had no history of cardiovascular disease and ABPIs $> 0{\cdot}95$. After informed consent, all subjects were rested supine for 1 h. Blood samples were then taken for measurement of free radical activity and plasma elastase concentration, before and after a period of standardized treadmill exercise. Free radicals cause the plasma thiol:albumin (PSH:Alb) ratio to fall and lipid peroxide concentration (e.g. malondialdehyde (MDA)) to rise.

	Before exercise	After exercise	*P**
Claudicants			
MDA (nmol ml^{-1})	7·8 (6·7–9·9)	8·7 (7·6–11·1)	<0·001
PSH:Alb	114 (103–120)	107 (95–118)	<0·01
Elastase (ng ml^{-1})	23 (12·9–33·6)	29 (19·1–36·2)	<0·01
Controls			
MDA (nmol ml^{-1})	6·9 (5·8–7·8)	7·3 (6·6–8·4)	n.s.
PSH:Alb	118 (100–123)	120 (107–127)	n.s.
Elastase (ng ml^{-1})	20 (16·6–25·7)	24 (21·3–29·0)	n.s.

Values are median (interquartile range). *Wilcoxon paired test; n.s., not significant

These results show that exercise causes neutrophil activation in claudicants only. Both elastase and free radicals cause endothelial damage. Exercise-induced neutrophil activation may therefore contribute to the higher cardiovascular mortality rate seen in claudicants.

Immunological alterations in patients undergoing open and laparoscopic surgery

H.P. Redmond, R.W.G. Watson, T. Houghton, C.J. Kelly, P.E. Burke, A. Leahy, R.G.K. Watson and D. Bouchier-Hayes, *Department of Surgery, Royal College of Surgeons in Ireland, Beaumont Hospital, Dublin, Ireland*

Abnormal release of inflammatory mediators following surgical injury is associated with immunological alteration that may predispose to sepsis. Laparoscopic surgery is associated with fewer postoperative complications, but mechanisms are unclear. It was hypothesized that the early recovery seen following laparoscopic surgery may relate to minimal impairment of immune function. This study analysed temporal immune responses in two similar groups of patients randomized to open ($n=15$) or laparoscopic ($n=15$) cholecystectomy.

Patients were matched for age, height, weight, American Society of Anesthesiologists score, anaesthetic used and operation time. The length of hospital stay and complications were recorded. Immune parameters measured included monocyte superoxide anion (O_2^-) and tumour necrosis factor (TNF) release, as well as polymorphonuclear neutrophil (PMN) chemotaxis and O_2^- release. White cell count (WCC) and arterial partial pressure of oxygen (P_{aO_2}) were assessed before operation and on day 1 after surgery.

	Open cholecystectomy	Laparoscopic cholecystectomy
Monocyte O_2^- release ($\times 10^{-2}$ nmol)	1·1(0·8)	0·1(0·2)*
TNF (pg)	217(122)	14·4(0·6)*
PMN chemotaxis	149(86)	−28(11)*
PMN O_2^- release ($\times 10^{-2}$ nmol)	18·4(5·5)	2·4(3·1)*
WCC ($\times 10^4$ ml^{-1})	10·3(5·0)	2·1(1·6)*
P_{aO_2} (kPa)	2·6(0·5)	0·7(0·3)*

Values are mean(s.d.) difference before and on day 1 after surgery. $^{*}P<0\cdot001$ *versus* open procedure (Student's *t* test)

There were significant increases in monocyte O_2^- and TNF release, as well as in PMN chemotaxis, O_2^- release and WCC in the open *versus* laparoscopic cholecystectomy groups, with a concomitant decrease in P_{aO_2}. These differences correlated with a significant increase in the length of hospital stay ($P<0\cdot05$) and respiratory complications ($P<0\cdot05$) in the open surgery group.

This study demonstrates that the beneficial effects of laparoscopic surgery are due, in part, to preservation of immune function in the postoperative period.

Cell membrane vesicle production for the derivation of antiendothelial cell antibodies

C.T. Baillie, A.I. Skene, E.M. Anderson, A.J. Wakefield, M.C. Winslet and N.J. Bradley (introduced by K.E.F. Hobbs), *University Departments of Surgery and Medicine, Royal Free Hospital and Department of Surgery, Westminster and Chelsea Hospital, London, UK*

The effectiveness of antiepithelial monoclonal antibodies (MAbs) in the imaging and treatment of tumours is limited by antigen expression and deficiencies of tumour microcirculation. The aim of this study was to isolate tumour endothelial cell membrane antigens (ECMAs) for derivation of antiendothelial cell MAbs.

Six tumour-bearing organs (placenta, two; kidney, two; lower-limb sarcoma or melanoma, two) were perfused at 120 mmHg in an *ex vivo* system (modified Krebs' solution, 95 per cent oxygen saturation, 37°C) with the chemical vesicant *n*-ethyl maleimide (150 mg dl^{-1}) for 1 h. Perfusate was differentially centrifuged (25–150 000*g*). Vesicles were dialysed against 0·1 mol l^{-1} phosphate-buffered saline and characterized with respect to phosphate content, electron microscopy and immunocytochemistry (*Ulex europeaeus* lectin type I, antithrombomodulin, β_2-microglobulin).

Renal adenocarcinoma vesicles (500 μg protein per ml) were injected intraperitoneally into BALB/c mice ($n=6$) at a dose of 50 μg per mouse. Eight MAbs were isolated by limiting dilution hybridoma techniques. RB-1 MAb demonstrated organ specificity, binding only to kidney endothelium. RB-2 demonstrated pan-human organ specificity. Six MAbs failed to demonstrate endothelial specificity.

Ex vivo endothelial cell vesicle production is an effective method of isolating ECMAs for potentially deriving antiendothelial cell MAbs.

Paradoxical rise in neutrophil L-selectin in septic shock

S.M. Plusa, J.N. Primrose and N. Webster, *St James's University Hospital, Leeds, UK*

Neutrophil adhesion to endothelium requires the attachment and subsequent shedding of the neutrophil adhesion molecule L-selectin. Further adhesion is mediated by the β_2-integrins, including cluster designation (CD) 11b. As intravascular neutrophil activation may be the cause of organ failure (multiple organ dysfunction syndrome (MODS)) seen in sepsis, expression of these molecules in patients with MODS and systemic inflammatory response syndrome (SIRS) (no organ failure) was compared with that in control subjects.

Nine patients (median age 74 (range 49–88) years) with MODS were compared with six (median age 72 (range 54–80) years) with SIRS and 14 controls (median age 44 (range 21–81) years).

Neutrophils were labelled with fluorescein-conjugated monoclonal antibodies and median fluorescence measured by flow cytometry.

	Control	SIRS	MODS
L-selectin	6·5 (5·1–13·1)	9·8 (3·1–15·4)	21·1 (7·2–41·6)*
CD11b	22·2 (11·3–75·6)	22·1 (14·4–52·7)	65·6 (26·9–80·4)*

Values are median (range). $^{*}P<0\cdot05$ *versus* control

Thus, in MODS, failure of L-selectin to shed is paradoxically associated with the upregulation of CD11b. These changes may be crucial in the development of MODS as they may allow the activated neutrophil to 'roll' on the endothelium, resulting in diffuse damage.

Chemokine Rantes and traffic of lymphocytes in acute inflammation

K.S. Soo, C.A. Michie*, J.H. Wyllie and P.C.L. Beverley*, *Academic Unit of Surgery, Whittington Hospital and Imperial Cancer Research Fund Human Tumour Immunology Group, University College London, UK*

The inflamed human appendix has been demonstrated to recruit 'memory' T lymphocytes (CD3$^+$, CD45R0$^+$) selectively from the peripheral circulation. It was used as a model of acute inflammation in this study. The chemotactic cytokine Rantes is known to cause selective chemotaxis of 'memory' T lymphocytes *in vitro*. The appendices of 25 patients (15 acutely inflamed, ten histologically normal) were studied in an attempt to establish the role of Rantes in the recruitment of 'memory' T lymphocytes *in vivo*.

Immunocytochemical investigation of inflamed appendices using a monoclonal antibody demonstrated increased expression of Rantes compared with minimal staining in histologically normal appendices. Flow cytometric analysis of appendiceal lymphocytes showed significantly increased levels of Rantes expression when the organ was inflamed.

	Positive appendiceal cells (%)		
Histology	Rantes$^+$	Rantes$^+$/CD3$^+$	Rantes$^+$/CD45R0$^+$
Normal	0·6	0·3	0·5
Acute	7·5*	5·0*	7·5*

Values are means. $^{*}P<0\cdot01$

Rantes positivity was predominantly in the 'memory' T lymphocyte population. *In situ* hybridization using a digoxigenin-labelled messenger RNA (mRNA) probe confirmed the upregulation of mRNA for Rantes in inflamed appendices compared with its near absence in the normal group.

It is concluded that Rantes secretion is a significant component in the active recruitment of 'memory' T lymphocytes to the inflamed human appendix. This mechanism may be a general feature of T lymphocyte recruitment *in vivo*.

Defect in phagocytosis induced by blood transfusion

P. Super, J. Dye, A. Darzi, C. Wakefield and P.J. Guillou, *Academic Surgical Unit, Imperial College of Science, Technology and Medicine, St Mary's Hospital, London, UK*

Blood transfusion is an independent risk factor for infection following elective and emergency surgery. The mechanism for this is unknown but no studies exist of the effects of transfusion on the opsonic capacity of serum or on the phagocytic ability of neutrophils. Measurement was made of the phagocytosis of fluorescein-labelled *Staphylococcus aureus*, whose injestion by neutrophils is quantified by flow cytometry.

Staphylococcal phagocytosis was measured in ten patients before and 24 h after homologous blood transfusion (2–4 units), the bacteria being opsonized with a control serum. In addition, the opsonizing capacity of serum taken from patients before and after transfusion was quantified by the same technique using neutrophils from healthy donors.

	Before transfusion	After transfusion	*P*
Patient neutrophils			
Control serum	246·2(18·1)	694·5(249·2)	<0·01
Patient serum	299·8(29·2)	310·1(27·5)	n.s.
Control neutrophils			
Control serum	524·7(55·0)	—	—
Patient serum	477·0(64·9)	394·4(29·3)	<0·05

Values are mean(s.e.m.) mean channel fluorescence. n.s., Not significant

Thus, after transfusion, neutrophils have an increased capacity to ingest optimally opsonized bacteria. However, post-transfusion serum is less capable of opsonizing bacteria for ingestion than pretransfusion and healthy serum. Transfusion causes an increase in neutrophil phagocytosis but at the same time an opsonic defect. These findings may help to elucidate the increased susceptibility of patients to infection after blood transfusion.

Flow cytometric analysis of *in vivo* 5-bromo-2′-deoxyuridine labelling of gastric cancer: a valid interinstitutional technique for measuring proliferative indices

D. Fenton-Lee, D.A. Rew*, P.D. Stanton and T. Cooke, *University Department of Surgery, Royal Infirmary, Glasgow and *Southampton General Hospital, Southampton, UK*

Multiparameter flow cytometric analysis of gastric carcinoma labelled *in vivo* with 5-bromo-2′-deoxyuridine (BrdU) allows measurement of proliferative indices, including total (TLI) and aneuploid (AnLI) labelling indices, S phase duration (T_s), potential tumour doubling time (T_{pot}) and tumour heterogeneity. It has been suggested that such data may have prognostic and therapeutic application. However, considerable interinstitutional variation may exist with complex analyses, being in part observer-dependent.

The aim of this study was to measure the proliferative indices of 53 gastric tumours and compare the data from independent analyses in each institution. Tumours were labelled with 200–250 mg BrdU 2·5–15·75 h before surgery over a 4-year period from 1988 to 1992. Statistical analysis was performed using the Mann–Whitney *U* test and the Bland–Altman test.

	Institution 1			Institution 2		
Proliferative index	Aneuploid ($n=17$)	Diploid ($n=36$)	*P*	Aneuploid ($n=22$)	Diploid ($n=31$)	*P*
TLI	2 (0·4–12·9)	7 (1·9–21)	<0·0001	3·7 (1–10·8)	6·5 (1·4–18)	0·002
AnLI	8·6 (4·3–21)	—	—	10 (1·4–20)	—	—
T_s	9·4 (1·3–39)	12 (1·8–49)	0·36	9 (5–32)	11·4 (6·2–25)	0·17
T_{pot}	23 (3·3–80·5)	4·5 (0·5–27)	<0·0001	11·5 (2·6–32)	4 (1·4–31)	<0·0001

Values are median (range)

There were statistically significant differences in TLI and T_{pot} between aneuploid and diploid tumours. BrdU is a robust marker from which proliferative data are routinely obtained by flow cytometric analysis. There was no significant difference between population measurements for each of the proliferation indices in either institution, except for T_{pot}. However, there were significant differences for individual tumours identified by the Bland–Altman test. Further standardization of analytical techniques will improve the application of proliferative assays in solid tumours.

Proliferating cell nuclear antigen and p53: failed markers of outcome in gastric cancer

T. Ismail, D. Rowlands, J. Fielding and M. Hallissey, *Department of Surgery, Queen Elizabeth Hospital, Birmingham, UK*

It has been suggested that new markers of tumour biology will help to determine prognosis in patients with solid tumours. In particular, proliferating cell nuclear antigen (PCNA) and mutations of the oncosuppressor gene p53 have been reported as markers of poor prognosis in gastric cancer.

Immunohistochemical investigation was carried out on 76 formalin-fixed gastric cancers using the monoclonal antibody PC10 against PCNA and the polyclonal antibody CM1 to the p53 protein product. The results of PCNA and p53 staining were compared with tumour node metastasis (TNM) status, tumour stage and patient survival. Most tumours showed heterogeneity of staining. PCNA expression did not correlate with TNM status, stage ($P>0·1$) or survival ($P=0·57$). The incidence of p53-negative tumours was higher in the group with metastatic disease. Patients in the p53-positive group had a 30 per cent 5-year survival rate compared with 15 per cent in the p53-negative group.

Neither PCNA nor p53 protein product expression was shown to have any adverse prognostic influence in this series. The variability of expression suggests that these markers are unlikely to be robust predictors of outcome in patients with gastric cancer.

Exfoliative brush cytology as an adjunct to endoscopic biopsy in the detection of upper gastrointestinal malignancy

J.M. O'Donoghue, M.K. O'Donohoe, D. O'Hanlon and H.F. Given, *Department of Surgery, University College Hospital, Galway, Ireland*

The role of exfoliative cytology as an adjunct to endoscopic biopsy in the detection of upper gastrointestinal malignancy is controversial in so far as some claim that its use is of little clinical benefit. The role of cytology in the differentiation of benign from malignant mucosal lesions in 2183 consecutive patients who underwent oesophagogastroduodenoscopy was examined.

Malignancy was confirmed in 394 patients. Both endoscopic biopsy and cytology were positive in 275 (69·8 per cent). Endoscopic biopsy suggested the diagnosis in the presence of negative cytology in 73 (18·5 per cent) of 394 patients, while cytology was positive after a negative biopsy in 36 (9·1 per cent) of 394. Ten (2·5 per cent) of 394 patients were not diagnosed before operation using either method.

Endoscopic biopsy yielded a sensitivity of 88·3 per cent, a specificity of 99·9 per cent, a positive predictive value of 99·7 per cent and a negative predictive value of 97·6 per cent. Cytology alone, on the other hand, yielded a sensitivity of 79·0 per cent, a specificity of 98·5 per cent, a positive predictive value of 92·0 per cent and a negative predictive value of 95·7 per cent. With the additional use of cytology, the diagnostic yield was increased from 88·3 to 97·5 per cent.

It is concluded that upper gastrointestinal exfoliative cytology is a useful adjunct in the investigation of patients with suspicious mucosal lesions.

Effect of chemoradiotherapy on oesophageal motility

P.J. Byrne, T.N. Walsh, P. Lawlor and T.P.J. Hennessy, *University Department of Surgery, Trinity College and St James's Hospital, Dublin, Ireland*

Dysphagia in oesophageal carcinoma may reflect luminal obstruction or motility disturbance. The effect of chemoradiotherapy (CR) on motility is unknown. Stationary manometry and 24 h pHmetry was performed in eight patients with oesophageal carcinoma before and 2 weeks after the completion of a CR regimen of 5-fluorouracil, cisplatin and 40-Gy radiotherapy. Oesophageal body pressure waves were categorized as propagated, simultaneous, non-transmitted or isolated.

	Before operation	After operation	*P*†
Propagated waves (%)*	28·8(11·5)	52·2(11·9)	0·03
Simultaneous waves (%)*	28·6(12·6)	18·8(11·3)	0·26
Non-transmitted waves (%)*	23·3(13·7)	3·3(2·3)	0·13
Isolated waves (%)*	7·8(5·7)	14·4(7·8)	0·25
No. with acid reflux	4	3	n.s.

*Values are mean(s.e.m.). †Wilcoxon signed rank test; n.s., not significant

All patients with oesophageal carcinoma had abnormal motility. The propagation of waves increased significantly following CR, corresponding with a reduction (but not elimination) of the tumour mass in all patients. There was a trend towards normality in isolated, simultaneous and non-propagated waves. It is concluded that oesophageal dysmotility due to tumour is partially reversed by CR.

Haemorrhagic shock and lower oesophageal sphincter pressure: an experimental model

M.T.P. Caldwell, P. Marks, P.J. Byrne, T.N. Walsh and T.P.J. Hennessy, *University Department of Surgery, Trinity College and St James's Hospital, Dublin, Ireland*

Aspiration is a frequent problem in shocked patients but the role of the physiological barrier, the lower oesophageal sphincter (LOS), has received little attention. The effect of hypotension, induced by haemorrhage, on LOS pressure (LOSP) was examined in seven adult mongrel dogs acting as their own controls. Animals were studied under general anaesthesia induced by thiopentone and maintained with 0·5–1·0 per cent enflurane. Blood pressure (BP) was reduced in two phases: mean BP reduced to 80 per cent (BP1) and then to 60 per cent (BP2) of control value and maintained at each of these values for 15 min. BP was monitored by intra-arterial catheter and heart rate by electrocardiographic tracing. BP was then restored to prehaemorrhage levels via autologous retransfusion. LOSP was recorded continuously using a solid-state sleeve catheter.

	Heart rate (beats per min)	Mean BP (mmHg)	Mean(s.e.m.) LOSP (mmHg)
Control	88	88	13·4(1·7)
BP1 (20% reduction)	107*	70	12·0(0·8)
BP2 (42% reduction)	101	51	7·7(0·8)†
Retransfused	100	92	13·6(1·3)

$^*P < 0·05$, $^†P < 0·01$ *versus* control (Wilcoxon signed rank test)

Haemorrhage producing a 42 per cent drop in the mean BP led to a significant fall in LOSP. This was restored to normal following autologous retransfusion. This may explain the high incidence of aspiration pneumonia in hypotensive patients and provides a useful model for prophylactic manipulation of LOSP.

Hypochlorhydria as a factor in the aetiology of gastroparesis in functional dyspepsia

B. Waldron, D. Smith, P.K. Small, M.A. Louden and F.C. Campbell, *Department of Surgery, Ninewells Hospital and Medical School, Dundee, UK*

Disordered gastric motor function is common in functional dyspepsia (FD) but the causative mechanism is poorly understood. In this study 83 patients were diagnosed as having functional FD after exclusion of peptic ulcer, gallstones, gastro-oesophageal reflux and irritable bowel syndrome. Patients were investigated by scintigraphic solid-meal gastric emptying (GE), peak acid output (PAO) following pentagastrin stimulation, and gastric biopsies. GE was validated in 15 controls.

Overall GE was delayed in FD compared with controls (mean t_{50} 100 (95 per cent confidence interval (c.i.) 90–111) *versus* 67 (57–78) min; $P < 0·001$, Mann–Whitney U test). This delay was due to a decrease in the mean emptying rate (ER) (0·019 (95 per cent c.i. 0·016–0·021) in FD *versus* 0·026 (0·020–0·032) min^{-1} in controls; $P < 0·01$, Mann–Whitney U test). Lag phase duration in FD did not differ from that in controls (mean t_{lag} 30 (95 per cent c.i. 23–36) *versus* 21 (14–27) min; $P = 0·09$, Mann–Whitney U test). Overall PAO was within the normal range (mean 25 (95 per cent c.i. 20–30) mmol h^{-1} in men and 21 (16–25) mmol h^{-1} in women), but 13 patients had hypochlorhydria. Gastritis was present in 34 patients and *Helicobacter pylori* in 31.

Helicobacter colonization was related to severity of gastritis ($r = 0·73$, $P < 0·01$, Pearson's product moment test of correlation). Severe gastritis was associated with decreased acid secretion. In all patients, delay in GE was associated with decreased PAO ($r = -0·33$, $P < 0·01$, Pearson's product moment test of correlation). A marked delay in GE was evident in the 13 patients with hypochlorhydria (mean t_{50} 143 (95 per cent c.i. 101–186) min).

Hypochlorhydria may be an end-stage phenomenon of *Helicobacter* gastritis and the loss of acid–peptic activity impairs GE causing gastroparesis, a dominant abnormality in functional dyspepsia.

Ambulatory 24-h bile reflux monitoring in Barrett's oesophagus

M.T.P. Caldwell, D. Evoy, P.J. Byrne, P. Lawlor, S.E.A. Attwood, T.N. Walsh and T.P.J. Hennessy, *University Department of Surgery, St James's Hospital, Dublin, Ireland*

Reflux of bile has been implicated in Barrett's oesophagus, but assessment of this problem has been impractical, requiring aspiration studies that are both cumbersome and non-physiological. Bilitec 2000 allows 24-h ambulatory monitoring of gastric or oesophageal bile using an optical fibre sensor and the spectrophotometric properties of bilirubin (peak 453 nm).

Simultaneous 24-h ambulatory monitoring of oesophageal bile and dual-channel (gastric and oesophageal) pH studies were carried out in two groups of patients. Group 1 ($n = 5$) were normal controls; group 2 ($n = 7$) were patients with Barrett's oesophagus.

	Controls ($n = 5$)	Barrett's oesophagus ($n = 7$)
Bile absorbance (percentage of time >0·15 supine)	1·6(0·9)	20·8(4·3)*
DeMeester acid score	6·6(2·2)	68·2(18·8)*
Percentage of time oesophageal pH > 7·5	4·5(4·4)	0·4(0·3)
Percentage of time gastric pH > 4 (supine)	3·1(1·9)	5·3(4·2)

Values are mean(s.d.). $^*P < 0·01$ (Wilcoxon rank sum test)

The ambulatory bile reflux monitor detected significant concentrations of bile in the oesophagus of patients with Barrett's oesophagus compared with controls. There was no increase in oesophageal pH and no significant gastric alkaline shift, indicating that bile reflux may occur in the presence of a low pH.

It is concluded that the bile probe provides a useful and practical assessment of oesophageal bile reflux problems.

Quantification and localization of epidermal growth factor receptor in gastric cancer

D. Fenton-Lee, B. Ozanne*, J. Primrose†, G. Miller†, J. Reeves and T. Cooke, *University Departments of Surgery, Glasgow Royal Infirmary and †St James's Hospital, Leeds and *Beatson Oncology Centre, Glasgow, UK*

Overexpression of epidermal growth factor receptor (EGFR) may be related to poor prognosis and advanced stage in gastric cancer. Quantification of receptors using established radioligand binding assays on membrane preparations may be inaccurate due to variable stromal contamination and provides no information on cellular localization. Immunohistochemical techniques produce only semiquantitative results. The aim of this study was to quantify and localize EGFR expression in tumours to increase the understanding of receptor biology.

Forty frozen gastric tumours and mucosal controls were examined. A quantitative autoradiographic technique using a ^{121}I-labelled monoclonal antibody EGFR-1 was compared with a standard three-layer immunohistochemical technique for assessing EGFR expression in 5-μm sections. An automated Joyce–Lobel image analysis system was used for counting labelled receptors in ten (×40) high-powered fields per section and reproducibility confirmed on duplicate samples.

	Autoradiography (receptors per cell)	Immunohistochemistry (grade)
Gastric tumours		
$n = 8$	$4–10 \times 10^3$	–
$n = 22$	$2·3–9·9 \times 10^4$	+
$n = 6$	$1·2–5·9 \times 10^5$	+ +
$n = 4$	$1·2–1·7 \times 10^6$	+ + +
Controls		
Mucosa ($n = 40$)	$1–4 \times 10^4$	+
Normal skin (dermis)*	2×10^5	+ +
A431 cells*	2×10^6	+ + +

*Internal calibration control

With this novel technique, EGFR-negative tumours were found on immunohistochemical staining to have fewer receptors per cell than normal mucosa. Receptor internalization or a decrease in EGFR messenger RNA could account for this finding. This technique could also be used for other antigenic markers and for identifying heterogeneity in tumours.

Organotypical mucosal morphogenesis occurs during regeneration, in the absence of luminal contents

I.S. Tait, G.S. Evans*, N. Flint* and F.C. Campbell, *Department of Surgery, Ninewells Hospital, Dundee and *Department of Epithelial Biology, Paterson Institute, Manchester, UK*

After mucosal injury, stem cells restore normal epithelium by organotypical morphogenesis, while abnormal regeneration may result in metaplasia. The relative roles of regulatory factors on this process remain obscure and include (1) stem-cell 'niche' factors and (2) luminal content. To investigate these factors, disaggregated epithelium was grafted to an ectopic subcutaneous site and the capacity for organotypical mucosal regeneration assessed in the absence of luminal content.

Cell aggregates containing small intestinal stem cells were isolated from postnatal inbred rats by enzymatic digestion and then grafted to adult recipients. Fifty subcutaneous transplantations were performed. The transplants were retrieved after 14 days; morphology was assessed by histology and cell proliferation by autoradiography. Stem-cell lineage studies used alkaline phosphatase to identify enterocytes and alcian blue for goblet cells; polyclonal antibodies against lysozyme and serotonin were used to identify Paneth and enteroendocrine cells.

Some 80 per cent of subcutaneous transplants regenerated neointestinal structures, with well formed crypts and villi. Proliferation was confined to basal crypt regions, as occurs in normal intestine. All stem-cell progeny were identified within this neomucosa.

In conclusion, stem cells regenerate organotypical small intestinal neomucosa after transplantation to ectopic sites. Thus, stem-cell niche factors (epithelial–mesenchymal interactions) are more important than luminal content in directing mucosal regeneration.

Relationship between tumour size and quality of life in patients with colorectal liver metastases

S.A. Earlam, C.A. Fordy and T.G. Allen-Mersh, *Department of Surgery, Chelsea and Westminster Hospital, London, UK*

The justification for palliative chemotherapy is that control of tumour size improves physical and mental well-being. However, chemotherapy has side-effects and tumour size may not be the crucial influence on mental and physical well-being in patients with cancer. The relationship between mental and physical symptoms and tumour size was assessed in patients with colorectal liver metastases.

Ninety-five patients with colorectal metastases confined to the liver underwent regular computed tomography and completed quality-of-life questionnaires to assess physical (Rotterdam Symptom Checklist, Sickness Impact Profile (SIP)) and mental (Hospital Anxiety and Depression scale, SIP) status.

There was a significant ($P < 0{\cdot}01$) correlation between the extent of liver disease and physical symptoms ($r = 0{\cdot}6$), anxiety ($r = 0{\cdot}3$) and depression ($r = 0{\cdot}5$). Patients treated by intrahepatic artery chemotherapy subsequently had tumour shrinkage, which did not occur in the no-treatment controls. This was associated with a significant improvement ($P < 0{\cdot}05$, Mann–Whitney U test) in physical symptoms, anxiety and depression.

It is concluded that control of tumour size with palliative chemotherapy improves physical and mental well-being.

New prognostic variable for rectal cancer

G. Gagliardi, K.A. Stepniewska*, M.J. Hershman, P.R. Hawley and I.C. Talbot, *St Mark's Hospital and *Medical Statistics Laboratory, Imperial Cancer Research Fund, London, UK*

A sizeable minority of rectal carcinomas show a cribriform growth pattern (microacinar) rather than large irregular tubules. This study aimed to evaluate the prognostic value of this histological variable.

A total of 138 consecutive patients undergoing radical rectal excision who had a complete 5-year follow-up or known recurrence were staged by the schemes of Dukes and Jass. The median follow-up for survivors was 95 (range 11–204) months and 35·5 (range 3–120) months for those who died. Tumour acini were classified according to their size into microacinar (28) and macroacinar (108). Patients with microacinar structures had a significantly worse 5-year survival rate than those with macroacinar (43 *versus* 68 per cent; $P = 0{\cdot}01$, log rank analysis) and a higher 5-year recurrence rate (64 *versus* 42 per cent; $P = 0{\cdot}04$, log rank analysis). The size of the acinar structure had independent prognostic value for survival (relative risk 2·60, $P = 0{\cdot}003$, Cox regression analysis). This was true even when Dukes' or Jass' classification was included in the model (relative risk 2·18, $P = 0{\cdot}02$ and 2·46, $P = 0{\cdot}004$ respectively).

These data show that classifying rectal cancer as microacinar or macroacinar adds prognostic value to Dukes' and Jass' classifications. This may be a more objective criterion than conventional histological grade.

Prolonged administration of levamisole in the adjuvant setting

I.J. Adam, H. Sue-Ling, P.J. Finan and D. Johnston, *Academic Unit of Surgery and Centre for Digestive Diseases, The General Infirmary, Leeds, UK*

It has been suggested that the apparent synergistic effect of 5-fluorouracil (5-FU) and levamisole is due to the immunomodulatory effects of levamisole. To investigate this, natural killer (NK) cell cytotoxicity was assessed before operation, in the immediate postoperative period and 3 months after operation in 20 patients with Dukes' B_2 or C tumours randomized to receive: (1) surgery alone ($n = 7$); (2) surgery with 5-FU 450 mg m^{-2} plus levamisole 150 mg ($n = 7$); (3) surgery with 5-FU plus folinic acid 20 mg m^{-2} ($n = 6$).

Induction of chemotherapy was for 3 days, starting the day after operation; chemotherapy was continued weekly for 6 months. NK cell cytotoxicity was measured by a standard chromium release assay against a K562 cell target and results expressed as the percentage lysis achieved at an effector:target ratio of 20:1.

	Before operation	Day 5 (after induction of chemotherapy)	At 3 months (during weekly maintenance)
Surgery alone	34·0 (17·0–40·6)	17·0 (9·8–33·6)	28·0 (20·6–32·6)
5-FU plus levamisole	30·0 (25·5–31·0)	37·5 (23·9–46·0)*	33·1 (22·5–39·1)
5-FU plus folinic acid	39·0 (29·5–49·5)	19·4 (10·5–21·2)*	30·8 (23·0–39·0)

Values are median (interquartile range). *$P < 0{\cdot}05$ (Mann–Whitney U test)

Levamisole, when given with 5-FU, led to a quicker recovery of immune function in the immediate postoperative period, but did not influence immune function during maintenance chemotherapy. These findings question the need for prolonged administration of levamisole in the adjuvant setting.

Intraoperative lavage with short-chain fatty acids and glucose promotes anastomotic healing in the colon

J.E. Aguilar-Nascimento, M.G. Thomas, W.K. Man, R.T. Mathie, J.P. Chacon and R.C.N. Williamson, *Department of Surgery, Royal Postgraduate Medical School, London, UK*

The type of fluid used during intraoperative lavage may influence the healing of a left-sided colonic anastomosis performed for obstruction. This possibility was investigated in 120 Wistar rats.

Primary colonic anastomosis was performed in five groups of rats 24 h after ligature obstruction of the rectosigmoid. Rats were lavaged with saline, 10 per cent glucose, 10 per cent povidone–iodine, a short-chain fatty acid (SCFA) solution or had no lavage (controls). Maximum bowel wall tension during resistance to hydrostatic pressure and hydroxyproline content were measured 3 and 6 days after surgery.

Mean(s.d.) bowel wall tension was raised over control values at 3 days in rats lavaged with glucose (29(10) *versus* 12(12) $\times 10^3$ dynes cm^{-1}; $P < 0{\cdot}01$) and SCFAs (30(8) $\times 10^3$ dynes cm^{-1}; $P < 0{\cdot}05$) and over controls at 6 days in those lavaged with povidone (77(8) *versus* 58(19) $\times 10^3$ dynes cm^{-1}; $P < 0{\cdot}05$) and glucose (85(13) $\times 10^3$ dynes cm^{-1}; $P < 0{\cdot}01$). In all groups at 3 days hydroxyproline content fell at the anastomosis compared with the value in the proximal and distal colon ($P < 0{\cdot}05$–$0{\cdot}001$). Thereafter, the content rose in all lavaged groups, reaching peak values at 6 days in those receiving SCFAs (12·5(1·8) *versus* 9·1(1·6) μg mg^{-1}) in controls and 9·6(1·8) μg mg^{-1} in those receiving saline; $P < 0{\cdot}05$).

Intraoperative lavage with nutrient solutions, both SCFAs and glucose, improves colonic healing in rats.

Prospective clinical trial to determine the influence of sulindac on the formation of recurrent colonic adenomatous polyps

A.C. Rowntree, J.T. Allardice, W.W. Woods, S.F. Purkiss, A.M. Abulafi, H.W. Taylor and N.S. Williams, *Surgical Unit, The Royal London Hospital, London, UK*

Patients who develop adenomatous polyps are advised to undergo regular colonoscopy because of the risk of developing metachronous polyps, imposing strains on endoscopic resources and patients themselves.

Previous reports have suggested that sulindac is associated with regression of polyps in patients with familial adenomatous polyposis (FAP).

A double-blind randomized controlled trial was undertaken to determine whether sulindac had any influence on the rate of recurrence of polyps in non-FAP patients. A total of 100 patients who had undergone removal of colorectal carcinoma or polyps were randomized to receive sulindac 200 mg twice daily or placebo. Following colonoscopy to exclude the presence of cancer or polyps, endoscopy was performed at 6-monthly intervals. Metachronous development of a carcinoma or colonic polyp was taken as a positive endpoint.

Forty-nine patients were randomized to receive placebo and 51 to sulindac. Seven patients taking placebo and six taking sulindac developed polyps. The mean length of follow-up was 12·8 months.

No significant difference in the number of patients developing a metachronous polyp or carcinoma was detected between those receiving sulindac and those given placebo (χ^2 test). These data suggest that sulindac does not influence the rate of recurrence of adenomatous polyps.

Bilateral unstimulated gracilis neosphincter reconstruction: initial experience

D. Kumar, *University Department of Surgery, Queen Elizabeth Hospital, Birmingham, UK*

Single-muscle graciloplasty has been used for the treatment of idiopathic faecal incontinence with disappointing results. Bilateral gracilis reconstruction of the anal sphincters was used to evaluate the efficacy of using both muscles to create a more balanced sphincter complex.

Five patients, aged 18–72 years, had bilateral gracilis reconstruction (three for idiopathic faecal incontinence, one reconstruction after panproctocolectomy, one after traumatic sphincter loss) of sphincters. The mean resting and squeeze pressures before operation were 20 and 40 cmH_2O respectively. After operation the mean pressures were 50 cmH_2O (resting) and 100 cmH_2O (squeeze). All five subjects were able to hold simulated stool during defaecography. On saline continence testing, four patients were able to hold 900 ml saline without leakage but one could hold only 100 ml. Clinically, all patients were continent to liquid and solid stool. None of the patients complained of urgency or soiling after a mean follow-up of 9 months.

These initial results of bilateral gracilis neosphincter reconstruction indicate an acceptable alternative to the more expensive and difficult single-muscle stimulated graciloplasty for faecal incontinence.

$\alpha_2\beta_1$-integrin regulates the morphological differentiation of colorectal tumour cells *in vivo* and *in vitro*

A.K. Nigam, M. Pignatelli*, D. Liu* and P.B. Boulos, *Department of Surgery, University College London and *Department of Histopathology, Royal Postgraduate Medical School, Hammersmith Hospital, London, UK*

Intercellular and cell–matrix interactions are mediated through cell adhesion molecules (CAMs), of which integrins and cadherins comprise the main subgroups expressed by epithelial cells. Integrins are heterodimers composed of α and β subunits.

The expression and function of the β_1-integrin subfamily was studied in SW1222 colonic carcinoma cells. The methods used were enzyme-linked immunosorbent assay, immunohistochemistry and immunoprecipitation. Several β_1 receptors were expressed but only monoclonal antibodies to α_2 and β_1 subunits inhibited function in terms of adhesion to type I collagen (90 and 80 per cent respectively) and glandular differentiation in collagen gel (61 and 68 per cent).

This work was expanded to consider changes in the expression of integrin and other CAMs *in vivo*. Twenty-eight colorectal carcinomas and normal colonic mucosa were immunostained utilizing antibodies against β_1, α_2, α_6, α_v, $\alpha_v\beta_3$, epithelial-specific cadherin and carcinoembryonic antigen. Significant downregulation of α_2 ($P < 0{\cdot}01$) and β_1 ($P < 0{\cdot}05$) was observed in moderate and poorly differentiated tumours. Other integrins demonstrated no such loss. No correlation with Dukes' stage was found.

Loss of $\alpha_2\beta_1$ from carcinomas *in vivo*, and the observation that this is the key integrin modulating differentiation *in vitro*, are strong evidence for the role of this receptor in the biological behaviour of colorectal tumours.

Cholinergic agents modulate transport in the isolated perfused rabbit ileum

M.K. Barry, J.D. Aloisi and C.J. Yeo (introduced by H.F. Given), *Department of Surgery, Johns Hopkins Medical Institutions, Baltimore, Maryland, USA*

Catecholamines, acting via the α_2-adrenergic receptor, directly influence transport in the isolated perfused ileum. This study tested the hypothesis that cholinergic agents modulate ileal transport independently of intestinal vascular resistance.

Thirty-two 10-cm segments of rabbit ileum were vascularly perfused *ex vivo* with a buffer solution containing red cells. The lumen was perfused with a buffer containing [^{14}C]polyethylene glycol. Net fluxes of water and ions (Na^+, Cl^-) were calculated during three 20-min periods: basal, drug infusion and recovery. Perfusion pressure documented changes in vascular resistance. Agents infused arterially at 10^{-5} mol l^{-1} included acetylcholine (ACh), atropine (Atr) and hexamethonium chloride (Hex). Water flux (F) and perfusion pressure (PP) are expressed as the change from basal value during drug infusion.

ACh caused significant secretion of water and ions. The infusion of Atr or Hex alone had no effect. Atr, but not Hex, prevented the prosecretory effect of ACh. There were no significant changes in perfusion pressure for any agent.

Infusion	*n*	ΔF H_2O (μl min^{-1})	ΔPP (cmH_2O)
Control	6	−2·8(8·1)	+8·2(1·1)
ACh	6	−20·2(6·2)*†	+7·5(2·7)
ACh plus Atr	4	+4·0(14·9)	+5·4(0·8)
ACh plus Hex	4	−16·7(20·2)*	+2·5(1·0)
Atr	6	−11·2(15·2)	+6·2(1·1)
Hex	6	+1·9(3·3)	+5·6(1·7)

Values are mean(s.e.m.). +, Increased absorption; −, increased secretion. *$P < 0{\cdot}05$ *versus* basal value (analysis of variance); †$P = 0{\cdot}03$ (ACh *versus* ACh plus Atr)

In conclusion, ACh causes secretion independently of changes in vascular resistance, supporting a direct effect on intestinal transport. ACh-induced secretion is mediated via Atr-sensitive muscarinic cholinergic receptors and is independent of extraintestinal neural pathways.

Reverse transcription polymerase chain reaction: a new technique for the investigation of wound repair

D.P. Berry, K.G. Harding and I. Hopkinson (introduced by H.L. Young), *Wound Healing Research Unit, University Department of Surgery, University of Wales College of Medicine, Heath Park, Cardiff, UK*

A technique to detect transcripts encoding structural proteins and regulatory peptides in small wound biopsies has been developed. Regulation of the increase in the expression of types I and III procollagen is of central importance in human wound healing. The two interleukin (IL) 1 isoforms (IL-1α, IL-1β) have been identified as candidate regulatory peptides involved in this process.

With ethical committee approval, 6-mm punch biopsies were obtained weekly from ten patients with acute pilonidal sinus excision wounds. Total RNA was isolated from these biopsies. Complementary DNAs (cDNAs) were generated from the messenger RNA by reverse transcription. Polymerase chain reaction amplification of α1(I) and α1(III) procollagen and IL-1α and IL-1β cDNAs was performed using specific oligonucleotide primers.

The results show that the α1(I) and α1(III) procollagen genes are transcribed from day 3 after surgery until closure of the wound. Transcription of IL-1β was demonstrated throughout the healing process, while IL-1α transcripts were detectable only after 40 days, consistent with the results of previous *in vitro* studies.

Reverse transcription polymerase chain reaction provides a sensitive and rapid analysis of gene expression in small wound biopsies, facilitating the elucidation of biological processes in human wound healing. Its use may be further developed for diagnostic studies on small biopsies, e.g. fine-needle aspirates.

Metabolic adaptation of terminal ileal mucosa after ileoanal pouch construction

M.A.S. Chapman, M.F. Grahn, M. Hutton and N.S. Williams, *Academic Department of Surgery, The Royal London Hospital, London, UK*

Glutamine is the major fuel substrate for the small bowel enterocyte and butyrate that for the large bowel colonocyte. It is not known whether the terminal ileal mucosa adapts metabolically after ileoanal pouch construction.

Mucosal oxidation of three fuel substrates was assayed in triplicate biopsies from the terminal ileum or mature pouch (> 6 months since ileostomy closure) of patients with ulcerative colitis. The biopsies were incubated with either [^{14}C]glucose, glutamine or butyrate and the evolved [^{14}C]carbon dioxide captured and quantified by liquid scintillation counting. Lowry protein estimations of the biopsies were performed.

	Ileum	Pouch	*U*
Glucose ($n=8, 15$)	12·5 (3·6–22)	15 (6·0–21)	58*
Glutamine ($n=9, 14$)	77 (34–207)	24 (11–58)	28†
Butyrate ($n=9, 16$)	194 (81–321)	169 (74–726)	65*

Values are median (95 per cent confidence interval), expressed as pmol per μg mucosal protein per h. *$P>0{\cdot}05$, †$P<0{\cdot}05$ (Mann–Whitney *U* test)

In keeping with published data, butyrate was the preferred fuel substrate, followed by glutamine then glucose ($P<0{\cdot}05$). Following ileoanal pouch construction, mucosal glutamine oxidation was significantly decreased, reflecting metabolic adaptation, possibly as a consequence of faecal stasis and bacterial colonization. There was no compensatory increase in butyrate oxidation despite its production by colonizing bacteria.

Peritonitis impairs intestinal absorption of amino acids

K.R. Gardiner, R.E. Gardiner and A. Barbul, *Department of Surgery, Sinai Hospital and Johns Hopkins Medical Institutions, Baltimore, Maryland, USA*

Sepsis adversely affects mesenteric blood flow, intestinal fine structure and mucosal barrier function. This study investigated the effect of sepsis on *in vivo* absorptive function using an experimental model of peritonitis.

Rats underwent caecal ligation and double puncture (CLP) or sham laparotomy. Animals were resuscitated with 10 ml 1 mol l^{-1} saline per 100 g body-weight subcutaneously. At relaparotomy 24 h later, the small intestine was ligated at the ligament of Treitz and the ileocaecal junction. Using a jejunal catheter, 3 ml complete defined diet and 2 ml test amino acid (2·5 μCi in 100 mmol l^{-1} cold leucine or proline) were then administered into the small intestine. Portal venous (PV) and femoral arterial (FA) sampling was performed 60 min later and the ligated gut excised for measurement of the percentage of gut residual (GR) leucine or proline in a scintillation counter.

All CLP rats had positive blood and peritoneal cultures.

			Amino acid concentration (c.p.m. per 100 μl)	
	n	GR (%)	PV	FA
Leucine				
CLP	6	67·2(3·6)*	246·6(52·6)*	223·1(55·3)*
Sham	6	18·0(3·5)	807·0(58·4)	726·4(55·4)
Proline				
CLP	6	64·7(6·0)*	369·3(81·2)*	331·5(73·5)*
Sham	6	15·1(3·7)	676·3(34·7)	615·8(15·3)

Values are mean(s.e.m.). *$P<0{\cdot}005$ *versus* sham (Student's *t* test)

GR values showed significant negative correlations with both portal and systemic concentrations of leucine and of proline ($P<0{\cdot}001$). Sepsis was therefore seen to reduce intestinal disappearance and portal and systemic appearance of luminal amino acid. This reduction in the absorptive capacity of the gut may limit the ability of enteral feeding alone to maintain nutrition during sepsis and contribute to the associated morbidity.

Selenium deficiency during total parenteral nutrition

A.C. Gordon, H. Hamilton, R. Morgan and M.G.W. Kettlewell, *John Radcliffe Hospital, Oxford, UK*

Selenium deficiency is increasingly recognized as a cause of disease (especially cardiac disease). Correct levels of supplementation during intravenous nutrition are unknown and high-dose replacement is potentially dangerous.

Thirty-seven patients undergoing total parenteral nutrition (TPN) were noted to be selenium deficient, 36 (5·2 per cent) of them over a 4-year period during which 690 patients were treated. Eighteen patients (49 per cent) had Crohn's disease, six (16 per cent) were neonates and 13 (35 per cent) had other diseases.

All patients receiving TPN for more than 1 month were given selenium supplementation; the initial assay of micronutrients was carried out within the first month. The time interval from starting treatment to the detection of selenium deficiency is shown.

Group	Mean time (weeks)
Crohn's disease	4·7*
Non-Crohn's	6·8*
Paediatric	6·0*

*$P>0{\cdot}05$

Three of the patients in the group with Crohn's disease developed significant complications directly attributable to selenium deficiency (one death from cardiomyopathy, one severe dysrhythmia secondary to cardiomyopathy, one difficulty in weaning from ventilatory support). Additionally, one child developed clinically increased muscular strength after selenium levels returned to normal.

Selenium deficiency may pre-exist or develop within a very short time of commencing TPN, particularly if the patient was previously malnourished. Identification of 'at risk' groups is difficult.

Hypermanganesaemia following standard total parenteral nutrition

F. Scanlan, H.T. Delves and S.J. Karran, *University Surgical Unit, Southampton General Hospital, Southampton, UK*

Hypomanganesaemia is a recorded hazard of prolonged total parenteral nutrition (TPN). Addition of this trace element to parenteral nutrition is therefore currently recommended. The normal whole blood reference range is 73–210 nmol l^{-1}. Chronic manganese poisoning has been reported at 360 nmol l^{-1}, with psychosis and parkinsonism at levels of 1000 nmol l^{-1}.

At present, the recommended daily intravenous dose of manganese for adults weighing 70 kg is 3–15 μmol.

Whole blood manganese level was monitored in 34 patients receiving standard TPN (14 g nitrogen, 11×10^3 kJ). Supraoptimal levels were found in 12 patients, four of whom had received Addamel (40 μmol manganese) daily and eight Additrace (5 μmol manganese). The mean value was 323 (range 213–928) μmol l^{-1}.

Raised levels were found to be prolonged in inpatients for several weeks after either a reduction in dosage or complete withdrawal of manganese. Initial estimates indicated a half-life of approximately 3 months.

Subsequently, all patients receiving parenteral nutrition were treated with Additrace three times per week instead of daily. However, even with this reduced level of administration, excessive levels of manganese are still being recorded.

The lack of published information about hypermanganesaemia suggests that the toxic effects are not widely understood. Monitoring of serum levels, with appropriate reduction of dosage as necessary, is therefore recommended.

Effects of lipid emulsions containing medium-chain triglycerides on phosphatidyl–inositol–glycan-linked leucocyte receptors

J.F. Dye, A. Darzi, P. Super and P.J. Guillou, *Academic Surgical Unit, Imperial College of Science, Technology and Medicine, St Mary's Hospital, London, UK*

It has been suggested that emulsions containing medium- and long-chain triglycerides (MCT–LCT) are a more appropriate energy source in the injured or septic patient than emulsions of LCTs alone. No comparisons exist of the effect of these two lipids on leucocyte function.

Three different classes for receptor of immunoglobulin F_c (CD16, CD32 and CD64) are differentially expressed on neutrophils and monocytes. The receptor for lipopolysaccharide (LPS)-binding protein (CD14) is expressed on monocytes only. Using fluorescent conjugated monoclonal antibodies, the expression of these receptors was examined by flow cytometry after 4 h incubation *in vitro* with either LCTs or MCT–LCT (0·5 $\mathrm{mg\,ml^{-1}}$) in a non-opsonizing medium. The data are expressed as mean(s.e.m.) of the mean channel fluorescence for each measurement ($n = 12$). Measurement was also made of the phagocytic uptake of opsonized *Staphylococcus aureus*, expressed as the phagocytic index (PI), and of LPS-stimulated production of cellular oxidants, expressed as the peak change in fluorescence.

	PI	Oxidative burst	CD16	CD32	CD64	CD14
Neutrophils						
Nil	7791(806)	34(17)	84(21)	108(6)	18·1(2·4)	—
LCTs	6743(525)	126(52)	88(22)	109(6)	20·4(2·5)	—
MCTs	6337(597)*	160(131)	24(3)*	104(8)	26·8(5·7)	—
Monocytes						
Nil	5449(648)	14(12)	10·5(1·9)	101(11)	42·8(5·5)	390(76)
LCTs	4625(633)	104(53)	11·2(1·6)	95(8)	42·0(2·9)	366(80)
MCTs	4094(443)*	64(37)	6·6(0·6)*	93(7)	45·5(5·5)	34(27)*

*$P < 0{\cdot}05$ *versus* control (Student's paired t test)

Thus, MCT-containing lipid emulsions influence the functional status of leucocytes, but affect the expression only of phosphatidyl–inositol–glycan-linked receptors. The cellular effects of these lipid emulsions demand more detailed analysis to determine the metabolic basis of their clinical value.

In vitro modulation of natural cytotoxicity by nitric oxide synthetase inhibitors

J. Brittenden, J. Ross, S.D. Heys, B. Benjamin*, K.G.M. Park and O. Eremin, *Departments of Surgery and *Medicine, University of Aberdeen Medical School, Aberdeen, UK*

The amino acid L-arginine has well known immunostimulatory properties. It was previously shown that L-arginine supplementation (30 g daily for 3 days) increased natural killer (NK) and lymphokine-activated killer (LAK) cell cytotoxicity significantly in 16 patients with locally advanced breast cancer (mean increase 81 and 107 per cent respectively; $P < 0{\cdot}001$). Although L-arginine is a known precursor of the nitric oxide (NO) pathway, its exact mode of action is unclear. In this study the *in vitro* effect of NO synthetase inhibitors *N*-nitro-arginine (NNA) and *N*-methyl-arginine (NMA) on the NK and LAK cell cytotoxicity of peripheral blood lymphocytes (PBLs) from patients with breast cancer was assessed.

In medium containing 1·14 $\mathrm{mmol\,l^{-1}}$ L-arginine (RPMI 1640), LAK cell activity was significantly reduced by 1 $\mathrm{mmol\,l^{-1}}$ NNA or 10 $\mathrm{mmol\,l^{-1}}$ NMA. NK cell activity was significantly reduced only by prior incubation in medium containing 0·1 $\mathrm{mmol\,l^{-1}}$ L-arginine and 1 $\mathrm{mmol\,l^{-1}}$ NNA or NMA.

	Percentage reduction in activity	
	NK (72 h)	LAK (92 h)
NNA	32*	29*
NMA	26*	32†

*$P < 0{\cdot}05$, †$P = 0{\cdot}002$ *versus* controls (log-transformed data, paired t test)

Results are expressed as the mean percentage decrease in cytotoxicity at a ratio of 40:1 (effector:target cells). Similar results were also seen using PBLs from healthy volunteers.

This study shows that NO production from L-arginine is essential for optimal natural cytotoxicity.

Neutrophil response to endotoxin is downregulated in obstructive jaundice

S.M. Plusa, N. Webster and J.N. Primrose, *St James's University Hospital, Leeds, UK*

Neutrophil function in the control of infection depends on the expression of adhesion molecules on the cell surface; these are induced by stimulants, including endotoxin. As patients with obstructive jaundice are prone to septic complications, adhesion molecule expression was examined in nine jaundiced patients (median age 77 (range 29–91) years) and eight controls (median age 50 (range 23–81) years).

Blood was incubated with fluorescein-conjugated monoclonal antibodies to adhesion molecules and the effect of stimulation with endotoxin analysed by flow cytometry.

	Control	Jaundice	Control plus endotoxin	Jaundice plus endotoxin
CD11a	46·8 (42–71)	33·9 (20–47)*	55·5 (42–62)	38·5 (19–50)†
CD11b	22·2 (11–75)	34·6 (11–76)	88·6 (63–122)	66·3 (33–97)†
CD11c	7·6 (5–12)	10·1 (5–17)	22·6 (15–30)	17·2 (7–23)
CD15	229 (124–636)	100 (56–242)*	327 (173–745)	131 (74–268)†

Values are median (range) channel fluorescence. CD, cluster designation. *$P < 0{\cdot}05$ *versus* control; †$P < 0{\cdot}05$ *versus* control plus endotoxin

Basal expression of CD11c and CD15 was lower in jaundiced patients and the response to endotoxin of all the adhesion molecules was attenuated compared with values in the control group. The downregulated response may be due to chronic endotoxaemia, which is known to occur in jaundiced patients, and may in part explain the level of septic complications in patients with obstructive jaundice.

Role of platelet-activating factor in a model of acute pancreatitis

L.J. Formela, M. Whittaker* and A.N. Kingsnorth, *Department of Surgery, University of Liverpool and *British Biotechnology Group, Oxford, UK*

Platelet-activating factor (PAF), a bioactive phospholipid that has effects on capillary permeability, was investigated for its role in the pathogenesis of acute pancreatitis by administration of BB-882, a selective PAF antagonist.

Pancreatitis was induced by microvascular ischaemia in 24 Wistar rats, creating increases in serum pancreatic enzymes, pancreatic weight and histological evidence of acute pancreatitis. Histological changes were assessed using an established point scoring system for each of the features of oedema, inflammatory infiltrate, fat necrosis, parenchymal necrosis and haemorrhage. Treatment with BB-882, 5 $\mathrm{mg\,kg^{-1}}$ intraperitoneally 30 min after induction of pancreatitis, significantly inhibited elevation of serum amylase concentration and histological changes of pancreatitis.

	Pancreatitis plus saline	Pancreatitis plus BB-882	P*
Serum amylase (units $\mathrm{l^{-1}}$)	3928 (2800–5900)	2477 (2100–3280)	<0·001
Pancreatic weight (g)	2·35 (1·75–3·08)	2·39 (1·92–2·96)	n.s.
Histology score (0–27)	12·3 (8–18)	5 (3–10)	<0·001

Values are mean (range). *Wilcoxon rank sum test; n.s., not significant

PAF may be released endogenously during the evolution of acute pancreatitis. Administration of BB-882, an ethyl ester with specific anti-PAF activity, alters the progression of acute pancreatitis induced in this model.

Circulating intact parathyroid hormone levels in acute pancreatitis

C. McKay, G. Beastall*, C.W. Imrie and J.N. Baxter, *Departments of Surgery and *Biochemistry, Glasgow Royal Infirmary, Glasgow, UK*

Proteolytic degradation of parathyroid hormone (PTH) has been demonstrated in the serum from patients with severe acute pancreatitis. It has been suggested that this may contribute to the hypocalcaemia seen in this conditions. Previous studies investigating the parathyroid response in acute pancreatitis have been criticized for using traditional immunoassays that may detect inactive PTH fragments in addition to the intact molecules.

Forty patients with prognostically severe acute pancreatitis had serial measurement of serum calcium, phosphate and PTH levels. PTH was assayed using a two-site immunometric assay specific for the intact molecule.

Sixteen patients developed complications, of whom eight died. PTH levels during the first 3 days of admission were significantly higher in patients with a complicated or fatal outcome than in those with an uncomplicated course (day 1, $P=0{\cdot}003$; day 2, $P=0{\cdot}003$; day 3, $P=0{\cdot}014$, Mann–Whitney U test). Thirteen patients developed hypocalcaemia (adjusted calcium level $<2{\cdot}00\,\text{mmol}\,\text{l}^{-1}$), eight with a complicated and five with an uncomplicated outcome ($P=0{\cdot}114$, Fisher's exact test). Inappropriately low levels of intact PTH ($<5\,\text{pmol}\,\text{l}^{-1}$) were detected in five of these patients, of whom four were in the uncomplicated group.

It is concluded that high levels of intact PTH are found early in the course of acute pancreatitis and are associated with a poor prognosis. It remains to be determined why some patients develop hypocalcaemia without an appropriate rise in the level of PTH.

Pathophysiological studies of postoperative bilious vomiting

P.K. Small, M.A. Loudon and F.C. Campbell, *Department of Surgery, Ninewells Hospital and Medical School, Dundee, UK*

Despite perioperative fasting, bile vomiting is a common postoperative complication that may lead to pulmonary aspiration; its pathophysiology is obscure.

This study sought to determine: (1) enterogastric bile reflux by prolonged intragastric pH monitoring; and (2) causal motor activity by prolonged gastric, duodenal and jejunal manometry in 13 patients both before operation and for 24 h after cholecystectomy. Motility alone was evaluated in three further patients.

Preoperative studies demonstrated stable pH and normal motility in all subjects. Gastric pH was higher after operation than before operation (mean(s.e.m.) pH 4·7(0·5) *versus* 2·9(0·4) respectively; $P<0{\cdot}01$, paired t test) and abnormal motor patterns comprising frequent incoordinate contraction bursts were observed in all patients. Phasic bursts that migrated retrogradely (RPBs) were associated with bile vomiting (35 RPBs occurred in nine vomiters *versus* seven in seven non-vomiters; $P<0{\cdot}05$, paired t test). Intragastric pH fell after bile vomiting episodes (mean(s.e.m.) pH 5·2(0·5) before *versus* 4·8(0·4) after vomiting; $P<0{\cdot}05$, paired t test).

In conclusion, RPBs are the principal motility abnormality associated with postoperative bilious vomiting, probably by inducing enterogastric bile reflux. Postoperative motility disturbances are accompanied by a rise in intragastric pH which falls after episodes of bile vomiting.

Nitric oxide inhibition maintains vasopressin-induced hepatic vasoconstriction

M.J. Dworkin, P. Carnochan* and T.G. Allen-Mersh, *Department of Surgery, Chelsea and Westminster Hospital, London and *Department of Physics, Institute of Cancer Research, Sutton, UK*

Hepatic parenchymal vasoconstriction is thought to increase cytotoxic drug uptake into hepatic metastases. However, prolonged infusion of the vasoconstrictor vasopressin does not lead to prolonged vasoconstriction. This study assessed whether loss of vasopressin-induced vasoconstriction is mediated by the endogenous vasodilator nitric oxide (NO).

Hepatic perfusion was monitored by laser Doppler flowmetry in 23 Chester Beatty Hooded rats. Vasopressin ($0{\cdot}5\,\mu\text{g}\,\text{min}^{-1}$) was infused into the hepatic circulation via the gastroduodenal artery in eight animals. In a further seven rats the vasopressin was infused with the NO inhibitor L-nitro-arginine methyl ester (L-NAME). Hepatic perfusion was also measured in eight control animals receiving either L-NAME alone or saline.

Prolonged vasopressin infusion alone produced a reduction >50 per cent in hepatic perfusion, which returned to the preinfusion level within 20 min in all animals. When L-NAME was administered concurrently with vasopressin, a reduction >50 per cent in perfusion was again noted but, unlike the case with vasopressin alone, this lasted >30 min in all animals ($P<0{\cdot}05$). A fall >50 per cent in hepatic perfusion was not noted in any control animal. Furthermore, tachyphylaxis to vasopressin was reversed by the administration of L-NAME.

It is concluded that vasopressin-induced tachyphylaxis is mediated by NO.

Propranolol reduces portosystemic shunting

B. Jaffray, W.J. Angerson, J.R. Anderson and J.N. Baxter, *University Department of Surgery, Glasgow Royal Infirmary, Glasgow, UK*

Propranolol reduces the risk of variceal haemorrhage. The mechanism of action is unclear, since portal pressure does not always fall, although a reduction in azygos flow is typical, suggesting an action on collateral flow. Azygos flow is an invasive technique and measures only one aspect of shunting. Using the systemic availability of low-dose oral galactose to quantify shunting, the effects of chronic β-blockade were assessed.

Ten patients with portal hypertension were entered into a prospective double-blind placebo-controlled crossover trial. Portosystemic shunting, galactose clearance (an index of hepatic flow), galactose excretion capacity (GEC) and modified Child's grade were assessed. Patients underwent repeated measurements at monthly intervals while receiving propranolol 80 mg or placebo. Results were analysed using the Mann–Whitney U test.

Shunting was significantly reduced ($P=0{\cdot}021$) following administration of propranolol. Clearance was not significantly altered ($P=0{\cdot}59$).

	Shunting (%)	Clearance ($\text{l}\,\text{min}^{-1}$)
Propranolol	39·1	0·88
Placebo	70·8	1·03

The reduction in shunting did not correlate with either the GEC or Child's grade.

In conclusion, a reduction in shunting with unaltered hepatic flow suggests a direct action on collateral tone. This may explain the lack of portal hypotensive effect of propranolol in some patients. The alteration in shunting is not dependent on the degree of hepatic decompensation.

Liver function and splanchnic blood flow in critically ill patients

N.D. Maynard, R.C. Mason, D.J. Bihari and I. McColl, *Departments of Surgery and Intensive Care, Guy's Hospital, London, UK*

Hepatic dysfunction is common in critically ill surgical patients and is causally related to multiple organ failure. Splanchnic ischaemia may be important. The aim of this study was to assess hepatic function and blood flow in these patients using two dynamic tests (indocyanine green (ICG) clearance and lignocaine metabolism to monoethylglycinexylidide (MEGX)), to compare them with standard liver function test results and to relate them to measurements of gastric intramucosal pH (pH_{im}), which vary with splanchnic blood flow. Ethical committee approval was obtained.

In all, 27 patients (median 24-h Acute Physiology and Chronic Health Evaluation II score 22) were studied for 3 days following admission to the intensive care unit. Measurements were made of ICG clearance, MEGX formation, serum levels of bilirubin; transaminase and alkaline phosphatase, and pH_{im}.

There were no significant differences between non-survivors and survivors in any parameter except for MEGX levels on day 3 (2·4 *versus* $16\,\text{ng}\,\text{ml}^{-1}$ respectively, $P<0{\cdot}001$) and pH_{im} on days 2 and 3 (7·26 *versus* 7·37, $P<0{\cdot}05$, and 7·14 *versus* 7·40, $P<0{\cdot}001$, respectively). Both MEGX concentration and pH_{im} fell significantly in non-survivors over the 3 days (from 20·6 to $2{\cdot}4\,\text{ng}\,\text{ml}^{-1}$, $P<0{\cdot}002$, and from 7·34 to 7·14, $P<0{\cdot}01$, respectively). MEGX levels and pH_{im} were significantly correlated ($r_s=0{\cdot}69$, $P<0{\cdot}001$).

The metabolism of lignocaine to MEGX depends on both liver blood flow and hepatocellular function, and this test provides a dynamic assessment of hepatic function in critically ill patients. This study suggests that hepatic dysfunction is related to reduced splanchnic blood flow and oxygenation, and therefore improvement of splanchnic blood flow may improve both hepatic function and outcome.

Defective mucin response to *Helicobacter pylori* infection in patients with duodenal ulcer

P. Kent, T. Hennebry, J. Burke, E. Mooney, P. McMathuna, J.M. Fitzpatrick and T. Gorey, *Department of Surgery, Mater Misericordiae Hospital and University College Dublin, Dublin, Ireland*

Helicobacter pylori is implicated in the pathogenesis of both peptic ulcer and non-ulcer dyspepsia. Decreased mucin synthesis alters the balance between mucosal protection and acid–pepsin damage. The aim of this study was to measure the effect of *H. pylori* infection on 24-h gastric mucosal mucin secretion using a human explant model.

A total of 90 gastric antral mucosal biopsies were taken at upper gastrointestinal endoscopy from 27 patients. Subjects were classified according to endoscopic findings and *Helicobacter* status. Biopsies were incubated in CMRL 1066 medium supplemented with [^{3}H]glucosamine for 24 h. Mucin secreted into the culture medium was measured using a technique based on acid precipitation of the glycoprotein and scintillation counting of incorporated tritiated glucosamine. The quantity of protein in the gastric biopsies was measured using the Lowry method.

Endoscopy *H. pylori*	Normal Negative	Normal Positive	Gastritis Negative	Gastritis Positive	Duodenal ulcer Positive
No. of patients	8	4	3	6	6
No. of biopsies	23	16	13	21	17
Mucin secretion*	1096(135)	1563(137)	954(108)	2158(381)	952(99)

*Values are mean(s.e.m.) disintegrations per min per μg protein

Significantly increased mucin production occurred in response to *H. pylori* infection in patients with and without gastritis ($P<0{\cdot}002$, analysis of variance). This did not occur in patients with duodenal ulceration ($P>0{\cdot}01$), indicating a defective mucosal protective response that may result in ulceration.

Treatment of patients with perforated peptic ulcer for *Helicobacter pylori* infection

M. Sebastian, V.P. Prem Chandran, Y.I.M. El Ashaal and A.J.W. Sim, *Department of Surgery, Al Ain Hospital and United Arab Emirates University, Al Ain, United Arab Emirates*

Perforated peptic ulcers are well treated by simple surgical closure. However, ulcers persist in at least 30 per cent of patients. This study looked at a possible aetiological agent, *Helicobacter pylori*, in peptic ulcer disease and its relationship to ulcer perforation and persisting ulcer.

Twenty-nine patients with perforated ulcers were studied. [^{13}C]urea breath tests (^{13}C-UBTs) were performed on day 8 after surgery. Of the 29 patients, 17 underwent upper gastrointestinal endoscopy 6 weeks after discharge.

All patients underwent simple ulcer closure and none received antibiotics in the postoperative period. Twenty-four patients had positive ^{13}C-UBT results. Of the 17 patients who underwent postoperative endoscopy, 14 had positive ^{13}C-UBT results, seven a duodenal ulcer, ten duodenitis or gastritis or both, and one a deformed duodenum. Twelve of the 14 patients with a positive breath test result also had a positive biopsy urease (CLO) finding at the time of endoscopy, indicating the presence of *H. pylori*. None of the patients with a negative ^{13}C-UBT result had evidence of active ulceration, but one had a positive CLO test result.

H. pylori infection is commonly found in patients with perforated peptic ulcer and consideration should be given to prescribing treatment designed to eradicate this infection in all patients after simple perforation closure.

Spontaneous basement membrane formation development in a tissue-culture graft

T.F. Browne, S.L. Haynes, P. Harnden, S.K. Smith, V.J. Sergeant, G.A. Davies and R.C. Kester, *Cardiac Research Unit, Killingbeck Hospital, Leeds, UK*

An essential prerequisite of a small-diameter vascular graft is that the luminal surface should be non-thrombogenic. Seeding of synthetic grafts with long-term adherence of endothelium has not been achieved, primarily because of the failure of the attachment factors used.

Smooth muscle cells obtained from the vein of a 65-year-old man were serially cultured. At second passage they were added to a $1{\cdot}0\,\mathrm{mg\,ml^{-1}}$ type I collagen gel and cast on to Dacron. Endothelium derived from the same vein was seeded at a concentration of $5\times10^4\,\mathrm{cells\,cm^{-2}}$ on day 17 on to the collagen and left for 7 days.

Histological sections revealed a monolayer of factor VIII-positive endothelium tightly adherent to the underlying collagenous matrix populated by smooth muscle cells. Immunocytochemical staining showed the presence of the basement membrane proteins laminin and type IV collagen throughout the cytoplasm and on the periphery of the endothelium. Mechanical abrasion inflicted on the endothelialized surface was confirmed by scanning electron microscopy to be completely healed at 7 days.

In conclusion, cells that produce their own basement membrane proteins behave more like endothelium *in vivo* and may be more adherent to grafts than those seeded on to synthetic surfaces by artificially applied attachment factors.

Indocyanine green potentiation of laser–tissue interaction

T.J. Greenwell, A. Wyman and K. Rogers, *University Department of Surgery, Northern General Hospital, Sheffield, UK*

Palliation of gastrointestinal malignancy by neodymium yttrium–aluminium–garnet (NdYAG) laser therapy is a well established technique. Enhanced tissue destruction may be possible using an 805-nm diode laser with potentiation of laser–tissue interaction by intravenous indocyanine green (ICG), a water-soluble tricarbocyanine dye with a peak spectral absorption at 800–810 nm in blood and plasma. Studies on the possible potentiation of 805-nm diode laser–tissue interaction were carried out *in vivo* on rat liver.

Using a 600-μm bare fibre in non-contact mode with a distance of 1 cm between fibre and tissue, thermal injury was produced at a power of 20 W applied for 2 s with laser energy at 805 and 1064 nm. The extent of thermal tissue destruction was then assessed.

ICG dose ($\mathrm{mg\,kg^{-1}}$)	Diameter of thermal injury 5 min after ICG (mm) 805 nm	 1064 nm
0	4·19 (3·25–5·12)	3·85 (3·33–4·37)
0·1	3·13 (2·25–4·01)	3·08 (2·53–3·62)
1·0	5·90 (5·38–6·42)*	3·06 (2·71–3·42)
10·0	7·38 (6·74–8·01)†	2·99 (2·56–3·41)

Values are median (95 per cent confidence interval). *$P<0{\cdot}005$, †$P<0{\cdot}0001$ *versus* control

Potentiation also occurred at all powers in the range 5–25 W at a dose of $1\,\mathrm{mg\,kg^{-1}}$ ICG. There was no potentiation of NdYAG activity.

Intravenous ICG potentiated 805-nm diode laser–tissue interactions in this model. The 805-nm diode laser with ICG potentiation may enhance gastrointestinal tumour destruction.

Modulation of cytotoxic drug accumulation into human tumour cell lines and explanted cultures by essential fatty acids

S. Mudan, M. Loizidou*, A.J. Cooper, D.A. Rew and I. Taylor*, *University Surgical Unit, Southampton General Hospital and *Department of Surgery, University College London, UK*

Endeavour to achieve improved efficacy while minimizing the dose-related side-effects of cancer chemotherapy fuels the search for response-modifying agents. Using flow cytometry to measure cellular levels of intrinsically fluorescent anthracyclines, the modifying effects of the essential fatty acids (EFAs) γ-linolenic acid (GLA) and eicosapentaenoic acid (EPA) on drug accumulation in human cancer cells were studied.

Human colorectal (HT29) and breast (MCF7) cancer cell lines and primary cultures from human bladder transitional cell carcinoma (TCC) biopsies ($n = 11$) were grown *in vitro*. Following 24-h pretreatment with EFAs at pharmacologically achievable doses (25–50 μg ml^{-1}), cells were exposed to mitozantrone (for MCF7), Adriamycin (for HT29) and epirubicin (for TCC) at clinically relevant doses for 1 h. Cells were enzymatically disaggregated and read live by flow cytometry.

A highly significant increase in drug accumulation was seen in cells modified by lipids, specifically HT29 modified with EPA and MCF7 with GLA. EPA at high dosage ($>100\,\mu$g ml^{-1}) also enhanced drug accumulation for MCF7. Bladders responded to both EFAs and exhibited intratumour and intertumour variability.

	HT29	MCF7	TCC
Control	9·3(1·5)	15(5)	43·8(8)
Drug	149·7(4)	109(10)	240(150)
Drug plus EPA	185(7)	107(15)	1240*
Drug plus GLA	145(15)	151(20)	

Values are mean(s.d.). *Increase 2–800-fold

The addition of EFAs alone did not change control values.

Clostridium perfringens α-toxin in acute gastrointestinal inflammation

R.J. Holdsworth and D. Parratt, *Departments of Surgery and Microbiology, Ninewells Hospital and Medical School, Dundee, UK*

Some examples of intra-abdominal tissue necrosis may be the result of locally produced toxin at the site of bacterial multiplication rather than the result of vascular infarction. *Clostridium perfringens* is present in the gastrointestinal tract of a large proportion of the population. The type A strain produces α-toxin (phospholipase C), which has the ability to degrade cell membranes directly, leading to cell necrosis. *C. perfringens* α-toxin has been measured by sandwich enzyme-linked immunosorbent assay in the serum of patients presenting as acute abdominal emergencies.

	No. of patients	Mean(s.e.m.) toxin level (assay units)	*P*
Control patients	22	5(6)	
Acute biliary disease	18	137(18)	<0·00001
Acute appendicitis	12	123(24)	<0·00001
Acute pancreatitis	21	81(38)	0·051
Colonic perforation	12	144(20)	<0·00001

In acute biliary disorders, appendicitis and colonic perforation, very high levels of toxin were detected ($P<0{\cdot}00001$). The highest individual level (772 units) was in a patient with acute pancreatitis but, as a group, levels of toxin in patients with pancreatitis were not statistically significantly raised ($P=0{\cdot}051$).

Raised levels of toxin in acute biliary disorders and appendicitis support the hypothesis that *C. perfringens* infection may be a factor in the pathogenesis of these conditions. High levels of toxin in some patients with acute pancreatitis may be of importance in view of the progression of this condition to necrotizing pancreatitis.

Somatostatin analogue inhibits tumour growth in regenerating liver

N. Davies, H. Kynaston, J. Yates, B.A. Taylor and S.A. Jenkins, *University Department of Surgery, Royal Liverpool University Hospital, Liverpool, UK*

Since tumour growth is enhanced by partial hepatectomy and because octreotide inhibits the growth of experimentally induced hepatic tumours, the effects of octreotide on tumour growth in the regenerating liver were investigated.

Hepatic tumour was induced by the intraportal injection of HSN cells (fibrosarcoma) or K12-Tr cells (adenocarcinoma) into Hooded Lister (HL) and BDIX rats respectively, immediately after a 70 per cent hepatectomy. The hepatectomized rats received either octreotide 2 μg subcutaneously twice daily or the same volume of saline for 3 weeks, after which time the percentage hepatic replacement (PHR) of liver by tumour was calculated.

PHR was significantly reduced in octreotide-treated animals compared with saline-treated rats ($P<0{\cdot}001$, Mann–Whitney *U* test). In the HL–HSN model, the median PHR of 71·3 (range 32·3–85·7) was reduced to 8·4 (0–22·1) by octreotide, and in the BDIX–K12-Tr model from 38·3 (29·1–42·6) to 4·5 (0·04–7·7).

The results of this study suggest that octreotide inhibits tumour growth in the regenerating liver and that it may have a role as an adjuvant following liver resection for hepatic metastasis or hepatoma.

Loss of bombesin receptor G-protein linkage in human colonic cancer cells

S.R. Preston, L.F. Woodhouse and J.N. Primrose, *Academic Unit of Surgery, St James's University Hospital, Leeds, UK*

Human gastric and colonic cancer cell lines are known to express receptors for the mitogenic bombesin family peptide gastrin-releasing peptide (GRP). Cloning of the GRP receptor from Swiss 3T3 fibroblasts has demonstrated it to be a member of the seven-transmembrane domain superfamily, which activate second messenger systems via guanine nucleotide-binding regulatory proteins (G proteins). It has been proposed that the *ras* oncogene product, p21, is the G protein by which the GRP receptor activates phospholipase C.

The aim of the study was to determine G-protein linkage of GRP receptors on membrane preparations from human gastric (St42) and colonic (COLO320HSR) cancer cell lines by assessing the ability of a non-hydrolysable GTP analogue, guanosine-5′-*O*-3-thiotriphosphate (GTP-γ-S) (10^{-8}–10^{-4} mol l^{-1}), to inhibit specific binding of ^{125}I-labelled Tyr^{4}-bombesin.

Results showed that GRP receptors on St42, but not those on COLO320HSR, are G-protein linked.

	IC$_{50}$ for GTP-γ-S(mol l^{-1})
St42	2×10^{-7}
COLO320HSR	$>1 \times 10^{-4}$

IC$_{50}$, mean inhibitory concentration

In conclusion, loss of G-protein linkage of the GRP receptor has occurred in COLO320HSR but not in St42 cell lines. A *ras* mutation, which is common in patients with colorectal carcinoma but uncommon in those with gastric cancer, is the most likely explanation for the finding. This loss of linkage may result in permanent activation of the 'downstream' signal transduction pathway, thus contributing to the uncontrolled proliferation found in colorectal cancer cells.

Streptokinase inhibits experimental pulmonary seeding without significant systemic fibrinolysis

A. Choy and P.G. McCulloch, *University Department of Surgery, Royal Liverpool University Hospital, Liverpool, UK*

The haemostatic system plays an important role in the metastatic process. Fibrin and platelets are often found around tumour emboli and may aid tumour adhesion to the endothelium of target organs. The aim of this study was to investigate the dose-related effects of streptokinase (SK) on the coagulation system and to assess its efficacy as an antimetastatic agent in a rat model of metastasis.

Four groups of five female F344 rats were given different doses of SK or saline (control) intravenously. Blood was taken for estimation of thrombin time (TT) and fibrin plate lysis assay (FPLA) after 30 min.

	Dosage of SK (units kg^{-1})			
	0	15 000	30 000	45 000
TT (s)	47·8(6·5)	42·4(1·1)	409·8(38·2)	528(123·3)
FPLA (mm)	4·76(0·10)	4·44(0·19)	7·70(0·43)	8·92(0·54)

Values are mean(s.e.m.)

Four groups of seven female F344 rats were given 10^{5} Mtln3 cells intravenously, together with different doses of SK or saline (control). Animals were killed at 17 days and pulmonary nodules assessed.

	Dosage of SK (units kg^{-1})			
	0	5000	15 000	30 000
No. of lung nodules	49·1(2·5)	33·6(2·3)*	29·4(2·7)†	22(2·4)†

Values are mean(s.e.m.). *P=0·0012, †P=0·0006 *versus* control (Mann–Whitney U test)

The effect of SK on pulmonary seeding was dose related and significant in the absence of detectable systemic fibrinolysis. Reduction of seeding from circulating tumour cells following administration of SK may therefore be applicable in the perioperative period.

Mammographic microcalcification predicts resection margin involvement in screening breast biopsies

J. Walls, C.R.M. Boggis*, M. Wilson*, D.L. Asbury*, F. Knox†, J. Coyne†, A.D. Baildam, N.J. Bundred and R.E. Mansel, *Departments of Surgery, *Radiology and †Pathology, Withington Hospital, University Hospital of South Manchester, Manchester, UK*

The presence of tumour either at the resection margin or in the shavings of a malignant breast biopsy continues to pose therapeutic management problems.

The surgical and pathological results of 244 women from the authors' screening practice have been studied, 120 with and 124 without mammographic microcalcification (MM); 49 were found to have ductal carcinoma *in situ* (DCIS) and 195 invasive malignancy. Of those with MM, 83 (69 per cent) of 120 were shown to have tumour at the resection margin of the breast biopsy. Of the 49 patients with DCIS, 34 biopsies showed involved margins; significantly, 11 of 12 patients with multifocal DCIS had residual disease at further surgery compared with only seven of 22 with unifocal disease (P=0·003, χ^2 test). Of women with invasive malignancy, 49 (69 per cent) of 71 with MM compared with 54 (44 per cent) of 124 without had tumour at the resection margin (P=0·0001, χ^2 test). When the re-excised specimen was examined, 25 (35 per cent) of 71 specimens from patients with MM and 24 (19 per cent) of 124 without MM contained residual tumour.

	Margins involved	Residual re-excision disease	
		DCIS	Invasive
MM			
Present (n=120)	83	35	8
Absent (n=124)	54	13	11

In all cases (DCIS plus invasive malignancy) the presence of MM indicated that resection margin involvement with tumour was likely (P=0·0001), and that the re-excision specimen would probably contain residual disease (P=0·006). These observations were independent of tumour size and axillary node status.

The presence of microcalcification on the screening mammogram therefore indicates that a wider than usual surgical resection margin should be employed.

Cytotoxic drug fluorescence in human cancer cell lines: a model for drug sensitivity assays in tumour chemotherapy

M. Loizidou, S. Mudan*, A. Cooper*, D. Rew* and I. Taylor, *Department of Surgery, University College London and *University Surgical Unit, Southampton General Hospital, UK*

Adjuvant chemotherapy for most human solid tumours is arbitrary and empirical. Direct measurement of cytotoxic drug levels in cells might improve therapeutic drug monitoring. The intrinsic fluorescence of anthracycline-related drugs allows a simple and direct assay in cells, using conventional flow cytometry.

The authors have developed such an assay in human cancer models. Breast (MCF7) and colon (HT29) cell lines growing as monolayers were exposed to serial concentrations of Adriamycin and mitozantrone (MTZ). Disaggregated cells were transferred on ice for immediate assay (FACScan, FL3 detector) or viably frozen.

Drug accumulation was directly proportional to the external concentration up to 7 μg ml^{-1} for Adriamycin and 10 μg ml^{-1} for MTZ, saturating thereafter. Immediate (surface) binding represented 5 per cent of the total at 1 h. Fluorescence was conserved in live cells recovered from nitrogen. Drugs were measurable in cells exposed to estimated clinical extracellular concentrations, as supported by the demonstration of *in vivo* accumulated drug in blood leucocytes from patients with leukaemia (fluorescence equivalent to 1·5–5 μg ml^{-1} *in vitro* exposure).

	MTZ in MCF7 (μg ml^{-1})							
	0	1	2	5	12·5	25	50	100
F13 channel fluorescence	7(2·2)	27(3·9)	56(12)	139(16)	201(17)	263(47)	326(56)	395(65)

Values are mean(s.d.)

These results form the basis for detailed studies of cytotoxic accumulation in clinical material. They should encourage a re-evaluation of adjuvant treatment schedules using a sensitive direct flow cytometric assay of target cells.

Thrombotic mediators and prediction of early outcome following reconstructive vascular surgery

K.R. Woodburn, A. Rumley, J.G. Pollock, R.O. Quin and G.D.O. Lowe, *Unit for Peripheral Vascular Surgery and University Department of Medicine, Royal Infirmary and Surgical Unit, Gartnavel General Hospital, Glasgow, UK*

A total of 204 patients undergoing reconstructive vascular surgery have been studied prospectively to determine the relationship between potential thrombotic mediators and poor early postoperative outcome (hospital mortality or graft occlusion).

In 30 patients with a poor outcome following surgery (11 deaths, 19 graft occlusions), preoperative levels of fibrin degradation products (FDPs), fibrinogen and von Willebrand Factor (vWF) were raised and factor VII levels reduced compared with values in patients with a good postoperative outcome (P<0·005, Mann–Whitney U test).

	Good outcome	Poor outcome	P*
Fibrinogen (g l^{-1})	3·5 (2·9–4·4)	4·8 (4·4–5·5)	0·000002
FDPs (ng ml^{-1})	175 (104–344)	332 (220–532)	0·0005
vWF (units dl^{-1})	140 (99–182)	262 (199–349)	<0·000001
Factor VII (%)	106 (92–118)	91 (72–103)	0·004

Values are median (interquartile range). *Mann–Whitney U test

Poor outcome was more common in patients with critical limb ischaemia. Median age was similar in both groups, and there were no significant differences in concurrent pathologies between the two groups, with the exception of diabetes mellitus.

It is suggested that preoperative evaluation of thrombotic variables may enable the detection of high-risk patients. Further studies are required to develop a predictive index for poor outcome.

Cost–effectiveness of prophylaxis of deep vein thrombosis in general surgery

G. Ramaswami, C.M. Fisher, G. Geroulakos, E. Kalodiki and A.N. Nicolaides, *Academic Vascular Surgery, St Mary's Hospital Medical School, London, UK*

A meta-analysis was performed on published studies in which objective diagnostic tests had been used to determine the overall efficacy of methods of prophylaxis of deep vein thrombosis (DVT).

In 3848 patients (50 studies) belonging to control groups, the incidence of DVT was 21·2 per cent (95 per cent confidence interval (c.i.) 19·9–22·4 per cent). When graduated elastic compression (GEC) was used (ten studies, 863 patients), the incidence of DVT was 13·6 per cent (95 per cent c.i. 11·1–15·6 per cent). When intermittent pneumatic compression (IPC) was used (11 studies, 601 patients), the incidence was 6·8 per cent (95 per cent c.i. 4·8–8·8 per cent). With low-dose heparin (LDH) (59 studies, 7092 patients), the incidence was 8·1 per cent (95 per cent c.i. 7·1–8·7 per cent). When low molecular weight heparin (LMWH) was used (18 studies, 3558 patients), the incidence was 5·6 per cent (95 per cent c.i. 4·8–6·3 per cent).

Subsequently, the cost of 7-day treatment with each method was calculated. It was £5·94 for GEC, £6·58 for IPC, £16·80 for LDH and £38·00 for LMWH. On the basis of this, the cost of prophylaxis per 1000 patients for each prophylactic method has been calculated. The cost of every prophylactic method has been found to be less than the cost of no prophylaxis (i.e. cost for diagnostic investigations and treatment of those who develop clinical DVT), indicating that not only is DVT prevented but also that money is saved. The saving to the hospital per 1000 patients was approximately £3000 for LDH and £13 000 for IPC.

These figures should be borne in mind when units or hospitals plan their policy on prophylaxis of DVT.

Lovastatin reduces the proliferation of vascular smooth muscle cells by inhibiting isoprenoid but not cholesterol synthesis

E. Munro, P. Chan, M. Patel*, L. Betteridge*, K. Gallagher*, M. Schachter*, P. Sever* and J. Wolfe, *Departments of Vascular Surgery and *Clinical Pharmacology, St Mary's Hospital and Medical School, London, UK*

The inhibition of restenosis resulting from myointimal hyperplasia remains an unsolved problem following vascular intervention. Lovastatin is an inhibitor of hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase and has been found to reduce the incidence of restenosis in several animal models and in one human coronary restenosis trial. Its effect on cultured human vascular smooth muscle cells (VSMCs) ($n = 18$) was examined.

Growth rates of subcultured VSMCs were assessed by counting at 0, 3, 7, 10 and 14 days and the effects of adding lovastatin, mevalonate and cholesterol measured.

	Mean(s.e.m.) inhibition at 14 days (%)
Lovastatin (2 μmol l^{-1})	37(4)
Lovastatin plus mevalonate (400 μmol l^{-1})	0
Lovastatin plus cholesterol (10 μg ml^{-1})	36(2)

In separate experiments, [^{3}H]thymidine (^{3}H-T) uptake (an index of DNA synthesis) was measured, as well as the effects of the isoprenoids farnesol and isopentenyl adenine.

	Mean(s.e.m.) inhibition of ^{3}H-T uptake (%)
Lovastatin (10 μmol l^{-1})	48(3)
Lovastatin plus mevalonate (400 μmol l^{-1})	14(2)
Lovastatin plus farnesol (10 μmol l^{-1})	20(2)
Lovastatin plus isopentenyl adenine (50 μmol l^{-1})	48(3)
Lovastatin plus cholesterol (10 μg ml^{-1})	40(4)

The antiproliferative effects of lovastatin are prevented by mevalonate (the product of HMG-CoA reductase) but not by cholesterol ($P < 0·001$, Mann–Whitney U test). Furthermore, the mevalonate metabolite farnesol also reduces the effect ($P < 0·01$, Mann–Whitney U test), but not the isoprenoid end-product isopentenyl adenine, suggesting that lovastatin inhibits VSMC proliferation by depleting farnesol.

Further *in vitro* investigation of lovastatin as a possible therapeutic agent in restenosis is warranted.

Quality of life after infragenicular bypass

R.D. Sayers, M.M. Thompson, A. Reid, M.J. Underwood, D.A. Ratliff and P.R.F. Bell, *Department of Surgery, University of Leicester, Leicester, UK*

Infragenicular bypass may achieve high rates of limb salvage, but little attention has been directed towards the functional results of this procedure. The aim of this study was to assess the quality of life after femorodistal bypass objectively and to compare it with the quality of life achieved following primary limb amputation.

A self-assessment postal questionnaire containing scales measuring emotional disorder, social functioning and mobility was sent to 112 patients who had previously undergone femorodistal bypass ($n = 86$) or primary limb amputation ($n = 26$). The response rate was 94 per cent. The results are presented as median (95 per cent confidence interval); the lower the numerical value, the higher the quality of life.

	Maximum possible score	Femorodistal bypass	Primary amputation	P*
Anxiety	21	6 (5–7)	9 (6–10)	>0·1
Depression	21	6 (4–8)	9 (5–11)	<0·05
Social function	30	9 (7–11)	16 (10–19)	<0·01
Immobility	4	2 (1–2)	4 (2–4)	<0·01

*Mann–Whitney U test

Further analysis demonstrated that a secondary procedure (percutaneous transluminal angioplasty or graft revision) to maintain graft patency did not adversely affect the quality of life. Additionally, patients undergoing secondary amputation after graft failure had an identical quality of life to those undergoing primary amputation.

These data illustrate that the quality of life after successful femorodistal bypass is higher than after primary or secondary amputation. To attain the maximum quality of life in patients with critical ischaemia, femorodistal bypass should be performed whenever feasible.

Restoration of the endothelial monolayer decreases intimal hyperplasia after vascular reconstruction

M.M. Thompson, J.S. Budd, S. Eady, R.F.L. James and P.R.F. Bell, *Department of Surgery, University of Leicester, Leicester, UK*

Myointimal hyperplasia develops as a generalized response to vascular injury and may cause stenoses in 40 per cent of all peripheral arterial reconstructions. Disruption of the endothelial monolayer is a prerequisite for the development of intimal hyperplasia (IH) and may be the initiating event in the process. This study examined the hypothesis that restenosis following balloon angioplasty may be reduced by rapid restoration of the endothelial monolayer, achieved by endothelial seeding.

Bilateral iliac angioplasty was performed in 11 rabbits. A double-balloon catheter was used to seed one angioplasty site with autogenous endothelial cells; the contralateral site was sham seeded with culture medium and acted as a control. Arterial patency rates, the degree of IH, expressed as the ratio of the neointimal area to the normalized area enclosed by the internal elastic lamina (IEL), i.e. IH:IEL, and the extent of endothelialization were quantified at 1 ($n = 5$) and 3 ($n = 6$) weeks following balloon dilatation. Results from both time periods are presented as median (95 per cent confidence interval (c.i.)).

	Endothelial seeded	Control site	Difference (95% c.i.)
Patency rate (%)	100	64	1·0–53·6*
IH:IEL (%)	8·1 (0–17)	19·5 (5–28)	1·5–11·5†
Endothelialization (%)	64 (12–83)	0 (0–33)	10·5–62·5†

*χ^2 test; †Wilcoxon paired rank test

The data suggest that transluminal endothelial seeding may be a therapeutically applicable technique as it decreases myointimal hyperplasia and increases patency following angioplasty. This study also illustrates the protective effect of the vascular endothelium following arterial injury and indicates that intensive efforts should be made to preserve the endothelium during vascular reconstruction.

Human venous endothelium can promote intimal hyperplasia via a paracrine mediator

N.J.M. London, K.E. Allen, K. Varty, L. Jones, R.D. Sayers, P. Dunlop and P.R.F. Bell, *Department of Surgery, Leicester University, Leicester, UK*

Current theories on the aetiology of intimal hyperplasia invoke a central role for both endothelial and smooth muscle cells. The purpose of this study was to investigate the interaction between these cells using an organ culture system.

Saphenous vein from 30 patients was cultured in RPMI medium supplemented with 30 per cent fetal calf serum. For 20 of the veins, an intact segment and a segment from which the endothelium had been denuded by gentle abrasion were cultured separately. The same protocol was followed for the remaining ten veins, but in addition a co-culture was established comprising an intact and a denuded segment in culture together. After 14 days, intimal thickness was measured using an image analysis system.

The results from the 20 separate cultures showed that the median (range) intimal thickness for the intact veins was 24·5 (6·5–81·0) μm and for the endothelial denuded veins 2·5 (0·0–27·5) μm; this difference was significant ($P = 0{\cdot}0001$). The co-culture studies showed that endothelial-denuded veins cultured alongside intact veins developed significantly more intimal thickening than denuded veins cultured alone (median thickness 12 *versus* 0 μm, $P = 0{\cdot}001$). However, this thickening was less than that of intact segments cultured alone (median thickness 12 *versus* 28 μm, $P = 0{\cdot}01$). It is concluded that intimal hyperplasia of human saphenous vein can be promoted by an endothelium-derived mediator that acts in a paracrine fashion.

Hydrogen clearance as a non-invasive technique for measuring skin blood flow in critical ischaemia

P.T. McCollum, D.K. Harrison, R. Abi Raad, D. Newton and R.J. Holdsworth, *Vascular Laboratory, Ninewells Hospital and Medical School, Dundee, UK*

A new transcutaneous hydrogen (H_2) clearance technique has been developed for measuring skin blood flow (SBF) in patients with critical ischaemia. Measurements were carried out in the forearms of eight normal volunteers (group 1) and in the legs of ten patients with ischaemia (group 2), using protocols approved by the local ethical committee.

After stabilization of a specially prepared, but standard, electrode for measuring the transcutaneous partial pressure of oxygen ($P_{\mathrm{tcO_2}}$) at 40°C on the skin for 10 min, all subjects breathed 2 per cent H_2 in air for 15 min; the clearance was measured subsequently during breathing of room air. In group 1, laser Doppler flux (LDF) measurements (at 40°C) were carried out simultaneously at a neighbouring site. In group 2, ^{125}I-labelled 4-iodoantipyrine (IAP) clearance was measured immediately before and at the same sites as measurement of the transcutaneous partial pressure of H_2 ($P_{\mathrm{tcH_2}}$). The results of comparisons of the methods are given in the *Table*, which shows the regression of H_2 clearance against LDF and IAP: SBF ($P_{\mathrm{tcH_2}}$) = 7·9 LDF + 30·8; SBF ($P_{\mathrm{tcH_2}}$) = 1·39 SBF (IAP) + 6·8.

	No. of results	No. of subjects	r	P	Mean(s.d.) SBF ($P_{\mathrm{tcH_2}}$) (ml per 100 g)	Group
LDF	16	8	0·70	< 0·001	48·0(13·9)*	1
IAP	15	10	0·85	< 0·001	15·7(5·2)	2

*$P < 0{\cdot}001$ *versus* group 2 (Mann–Whitney U test)

There were significant correlations between H_2 clearance and LDF and IAP measurements. A highly significant difference in $P_{\mathrm{tcH_2}}$ SBF values was observed between groups 1 and 2.

Measurement of $P_{\mathrm{tcH_2}}$ is a new, reproducible, non-invasive methodology for assessing SBF. It correlates particularly well with radioisotope clearance, which it may ultimately supersede as the method of choice for assessment of SBF.

Falsely high pressure measurements in lower-limb ischaemia: an alternative approach

F.C.T. Smith, C.P. Shearman*, M.H. Simms* and B.R. Gwynn, *Departments of Surgery, Stafford District General Hospital and *Selly Oak Hospital, Brimingham, UK*

Ankle:brachial pressure indices (ABPIs), measured by sphygmomanometer and Doppler probe, are an accepted index of chronic leg ischaemia. However, tibial artery sclerosis or calcification decreases compliance, producing falsely raised cuff occlusion pressures. Arterial cannulation is invasive and impractical but, by elevating the foot and measuring the height at which the Doppler signal disappears, ankle systolic pressure is easily derived.

Using an 8-MHz Doppler apparatus and calibrated pole, ankle systolic pressures measured by sphygmomanometer and elevation were compared in 49 critically ischaemic legs (40 patients). In 20 legs undergoing vascular reconstruction, direct intra-arterial measurement of ankle systolic pressure was made via transducer. ABPIs were derived by dividing ankle systolic pressure by brachial pressure.

In 49 limbs the mean(s.d.) ABPI measured by cuff differed significantly from that derived by leg elevation (0·51(0·32) *versus* 0·22(0·10), $P < 0{\cdot}001$). In 20 patients studied at operation, the mean ABPI was 0·45 by cuff, 0·20 by elevation and 0·18 by transducer. Correlation of elevation with transducer-assessed pressure measurements ($r = 0{\cdot}88$, $P < 0{\cdot}001$) was closer than that obtained with cuff pressure measurements ($r = 0{\cdot}69$, $P < 0{\cdot}001$).

Pressures derived by leg elevation provide a more accurate index of ischaemia than sphygmomanometry. Falsely high ABPIs may underestimate the extent of disease in patients assessed for vascular reconstruction.

Accelerated peripheral thrombolysis with pulse-spray technique

S.W. Yusuf, S.C. Whitaker, R.H. Gregson, J. Astil, P.W. Wenham, B.R. Hopkinson and G.S. Makin, *University Hospital, Nottingham, UK*

Pulse-spray thrombolysis (PST) is a new technique for peripheral thrombolysis. Experience of 24 consecutive patients treated using this technique is presented. Details of patient age, duration of symptoms, length of occlusion and total dose of recombinant tissue plasminogen activator (rtPA) are shown.

Age (years)	74·5 (35–89)
Duration of symptoms (days)	6 (1–60)
Length of occlusion (cm)	23 (4–55)
Dose of rtPA (mg)	18 (10–35)

Values are median (range)

Severe ischaemia with sensory and motor deficit was present in 11 of 24 patients. rtPA was used in a concentration of 0·33 mg ml^{-1} in boluses of 0·2 ml every 30 s. Complete radiological lysis was achieved in 23 of 24 cases and the median duration of lysis was 137·5 (range 35–1125) min. This was an 11-fold reduction and was significantly lower ($P < 0{\cdot}001$, Mann–Whitney U test) than the median lysis time of 1545 (range 330–5760) min found in 120 consecutive patients treated with slow rtPA infusion in the authors' unit. The median ankle:brachial pressure index improved significantly ($P = 0{\cdot}002$, Mann–Whitney U test) from a prelysis value of zero to 0·8 following lysis.

PST rapidly restores vascular patency and may therefore become the treatment of choice in patients with acute limb ischaemia, including those at immediate risk of irreversible ischaemic damage, which would conventionally be treated with emergency surgical reconstruction.

SURGERY ABSTRACTS

Br. J. Surg. 1993, Vol. 80, November, 1486–1487

A selection from the October issue of the American journal, which was given over to papers presented at the 50th Annual Meeting of the Central Surgical Association in Cincinatti, Ohio, March 1993.

Awake patient monitoring to determine the need for shunting during carotid endarterectomy

Marshall E. Benjamin, MD, Michael B. Silva, Jr., MD, Cathleen Watt, MD, Michael T. McCaffrey, PhD, Adrienne Burford-Foggs, MD, *and* **William R. Flinn, MD,** *Chicago, Ill.*

Background. *The indications for shunt placement to prevent cerebral ischemia during carotid endarterectomy have been controversial. Some investigators have recommended empiric shunting for patients presumed to be at higher risk for cerebral ischemia with a recent stroke or severe stenosis or occlusion of the contralateral internal carotid artery.*

Methods. *Carotid endarterectomy was performed in 81 cases with cervical block anesthetic, monitoring the awake patient for the development of cerebral ischemia (unresponsiveness or paralysis) during carotid clamping. The need for shunting (based on awake response) was compared in patients with the arbitrarily defined empiric indications for shunting ($n = 29$) versus those who did not have such clinical or anatomic findings ($n = 52$).*

Results. *Cerebral ischemia requiring shunting was observed in five (17.2%) of 29 cases with the defined indications for empiric shunting. This was not different than the need for shunting in the control group where cerebral ischemia was seen in eight (15.4%) of 52 cases. No intraoperative neurologic events occurred in any case, but one (1.2%) patient suffered a postoperative transient ischemia attack and another (1.2%) had a postoperative stroke.*

Conclusions. *Empiric clinical or anatomic indications for shunting were not reliable predictors of cerebral ischemia that developed during carotid clamping in this study. Awake patient monitoring during carotid endarterectomy with regional anesthetic allowed prompt, accurate identification of patients with cerebral ischemia who would clearly benefit from placement of a shunt. (SURGERY 1993;114:673-81.)*

Histocompatibility and liver transplantation

Stuart J. Knechtle, MD, Munci Kalayoglu, MD, Anthony M. D'Alessandro, MD, Beth Mason, BS, John D. Pirsch, MD, Hans W. Sollinger, MD, Daniel C. Steen, RN, *and* **Folkert O. Belzer, MD,** *Madison, Wis.*

Background. *The role of histocompatibility between donor and recipient in liver transplant rejection is unclear because of a paucity of data. The influence of human leukocyte antigen (HLA) type on immunologic graft loss was examined for primary liver transplantations performed at this center.*

Methods. *Immunologic graft loss included patient death or retransplantation as a result of rejection or impending graft loss caused by either late hepatic artery thrombosis or severe, unremitting rejection requiring FK 506 rescue therapy. HLA A, B, and DR matching was available on 205 donor-recipient combinations, and an additional 31 patients had A and B matching only.*

Results. *A mismatch of class I antigens (HLA A and B) was predictive of immunologic graft loss ($p = 0.018$). DR mismatch did not correlate with graft loss. When the A and B loci were analyzed separately, an A mismatch correlated significantly with immunologic graft loss ($p = 0.02$), in contrast to a B mismatch ($p = 0.17$). Better matching significantly improved patient survival ($p = 0.02$) and overall graft survival ($p = 0.009$).*

Conclusions. *The beneficial effect of HLA class I antigen compatibility on liver transplantation outcome is in contrast to pancreatic and kidney transplantation in which class II antigen matching but not class I matching is beneficial. Immunologic mechanisms of hepatic allograft rejection may differ from those involved in kidney transplant rejection. (SURGERY 1993;114:667-72.)*

Two hundred consecutive simultaneous pancreas-kidney transplants with bladder drainage

Hans W. Sollinger, MD, PhD, Rutger J. Ploeg, MD, PhD, Devin E. Eckhoff, MD, Mark D. Stegall, MD, Ross Isaacs, MD, John D. Pirsch, MD, Anthony M. D'Alessandro, MD, Stuart J. Knechtle, MD, Munci Kalayoglu, MD, *and* **Folkert O. Belzer, MD,** *Madison, Wis.*

Background. *Since 1982, 288 pancreas transplantations have been performed at the University of Wisconsin. This report reviews our experience with 200 consecutive simultaneous pancreas-kidney (SPK) transplantations during a 7-year period.*

Methods. *Two hundred consecutive SPK transplantations were performed between December 1985 to October 1992. Immediate posttransplant function and surgical and infectious complications were evaluated. Frequency of rejection episodes were analyzed, as was 5-year patient and graft survival.*

Results. *All but four pancreas transplants functioned immediately after transplantation. Three pancreas transplants failed because of thrombosis and one from primary nonfunction. Five-year patient survival was 90.2%, kidney survival 80.3%, and pancreas survival 78.6%. There were 54 surgical complications. Fifteen patients have died since 1985. The most frequent cause of death was infection (three patients). A total of 678 infectious episodes were recorded. Urinary tract infection ($n = 344$) was the most frequent type of infection. Enteric conversion was necessary in 35 patients, with the most frequent indication being a leak of the duodenal segment.*

Conclusions. *We concluded from this series that SPK transplantation is associated with higher cost and morbidity as* *compared with kidney transplantation alone. However, excellent long-term survival in combination with the clearly demonstrated benefits for secondary diabetic complications indicate that SPK transplantation is the procedure of choice for carefully selected patients with diabetes. (*SURGERY *1993;114:736-44.)*

Endorectal advancement flap repair of rectovaginal and other complicated anorectal fistulas

Ira J. Kodner, MD, Amos Mazor, MD, Eli I. Shemesh, MD, Robert D. Fry, MD, James W. Fleshman, MD, *and* **Elisa H. Birnbaum, MD,** *St. Louis, Mo.*

Background. *Surgical correction of rectovaginal and complicated anal-perineal fistulas has been associated with high rates of complications and failure of repair.*

Methods. *This paper reports on 107 patients treated during the past 10 years by endorectal advancement flap repair. Ninety-two percent of the patients were women with mean age of 38 years (range, 20 to 71 years). Seventy-one had low rectovaginal, 28 had anterior anal-perineal, and 8 had posterior anal-perineal fistulas. The causes were obstetric injury, 48; cryptoglandular abscess-fistula, 31; Crohn's disease, 24; and trauma or after operation, 4. The technique completely preserves the sphincter muscle, covers the internal opening of the fistula tract with healthy rectal wall, and provides counter drainage to aid healing.*

Results. *No deaths occurred in the series. Persistent or recurrent fistula occurred in 17 patients (16%). Nine patients whose initial operation failed underwent a secondary successful operation. Continence status was unchanged in 80%, improved in 18%, and was unknown in two patients who still had intestinal flow diversion. Recurrence of the fistula did not result in destruction of the sphincter mechanism in those patients who underwent simultaneous reconstructive operation.*

Conclusions. *The endorectal advancement flap repair successfully treated 93% of the complicated anorectal fistulas, avoiding fecal diversion and improving, not injuring, sphincter function. (*SURGERY *1993;114:682-90.)*

Determination of malignancy of thyroid nodules with positron emission tomography

Allen D. Bloom, MD, Lee P. Adler, MD, *and* **Jerry M. Shuck, MD, DSc,** *Cleveland, Ohio*

Background. *Current noninvasive evaluation techniques of thyroid nodules are nonspecific. We studied the use of a new noninvasive imaging modality, positron emission tomography (PET), in the evaluation of thyroid nodules.*

Methods. *Nineteen patients were studied before operation with PET with [^{18}F]-2-deoxy-2-fluoro-D-glucose (FDG). Twelve patients had solitary thyroid nodules and seven had multinodular goiters. Fourteen overlapping transverse slices were acquired through the thyroid gland. A region of interest was drawn around the abnormal area and the maximum pixel value was calculated and corrected to produce a normalized value for FDG uptake.*

Results. *Four of the 12 nodules were malignant (three papillary and one follicular carcinoma), with the others being follicular adenomas. All of the multinodular goiters were benign. All of the malignancies had an FDG greater than 8.5 and all of the benign nodules had an FDG less than 7.6. The dose uptake ratio of FDG was 10.8 ± 3.2 (mean ± SD) for the malignancies and was significantly greater than the dose uptake ratio of either the follicular adenomas (4.3 ± 2.0) or the dominant nodule in multinodular goiters (3.0 ± 2.0).*

Conclusions. *The FDG uptake as measured by PET scanning successfully discriminated between all benign and malignant tumors. This technique appears useful in the evaluation of thyroid nodules. (*SURGERY *1993;114:728-35.)*

Transjugular intrahepatic portosystemic shunt in the management of variceal bleeding: Indications and clinical results

Maureen Martin, MD, FRCSC, Albert B. Zajko, MD, Philip D. Orons, DO, Gerald Dodd, MD, Harlan Wright, MD, Joannie Colangelo, RN, *and* **Ralph Tartar, PhD,** *Pittsburgh, Pa.*

Background. *Transjugular intrahepatic portosystemic shunt (TIPS) has proved to be a successful bridge to liver transplantation in the management of variceal bleeding. The safety and ease of this technique has now challenged standard surgical approaches to portal hypertension. To define the role of TIPS, we prospectively studied patients undergoing this procedure for variceal bleeding and/or ascites.*

Methods. *From September 1991 to September 1992, 45 patients entered a protocol that included assessment of liver chemistries, ammonia levels, coagulation profiles, liver synthetic function by caffeine-antipyrine clearance, ultrasonographic evaluation of hepatic and portal veins, portogram and direct measurement of portal vein pressures, upper endoscopy, computed tomography for liver volume and ascites, and formal neuropsychiatric evaluation. These studies were repeated at 3-month intervals or more frequently if bleeding or complications occurred.*

Results. *Technical success and control of bleeding were achieved in all patients with only three (7%) variceal rebleeds from recurrent portal hypertension. Complete and permanent control of clinical ascites was noted in all patients with this complication. Five of six deaths occurred from sepsis and multiorgan failure in intensive care unit-bound patients with Child class C liver disease. No serial changes were noted in liver chemistries; however, progressive loss of liver volume and prolongation of caffeine-antipyrine clearance was observed in most patients. In addition, hepatic vein stricture or shunt stenosis seen in nine patients (20%) required TIPS revision, whereas the frequent appearance of symptomatic encephalopathy was a main indication for transplantation in 11 of 14 patients.*

Conclusions. *TIPS successfully controls variceal bleeding and may serve as a novel approach to control of diuretic resistant ascites. The uncertain long-term patency and progressive decline in synthetic function emphasize the importance of initiating proper trials comparing TIPS with other management strategies before indiscriminate use of this technique is seen. (*SURGERY *1993;114:719-27.)*

Correspondence

Herniation at the site of cannula insertion after laparoscopic cholecystectomy

Letter 1

Sir

I read with interest the Case Report by Messrs McMillan and Watt (*Br J Surg* 1993; **80**: 915) concerning the herniation of small intestine through the site of insertion of a 10-mm cannula after laparoscopic cholecystectomy. Unfortunately this is not the first report of this acute complication, which has been recorded at least twice previously[1,2]. There have also been letters published casting doubt on their conclusion that fascial closure of the unextended 10-mm defect is required to prevent this occurrence[3,4].

All three of these patients were symptomatic within 3 days, and I have not yet seen a report of a similar herniation of small intestine at a later stage after laparoscopic operation. Thus it appears that the cause of herniation is likely to be perioperative and, as I have written previously[3], probably related to the method of cannula removal.

Messrs McMillan and Watt state that they expelled all the carbon dioxide before extraction of the subumbilical cannula, a practice that is normal at present in laparoscopic cholecystectomy. However, when this manoeuvre is performed there is a pressure gradient between the gas in the peritoneal cavity and the atmosphere, allowing small bowel or omentum to become attached to the end of the cannula and then held there by the pressure differential. The act of withdrawing the cannula will pull the attached bowel into the wound and cause the hernia.

In addition, the defect in the anterior abdominal wall fascia is produced by the dilating effect of the 10-mm trocar and this is then held open by the cannula. The removal of this cannula allows the defect to close suddenly, reducing the size of this small hole and causing it to act as a sphincter, holding any misplaced bowel within the wound. Obviously, if bowel or omentum is pulled far enough through the abdominal wall it will be seen and replaced immediately. It is when the viscus is trapped only within the deeper layers of fascia, where it cannot be seen, that the danger arises. Therefore in laparoscopic trocar wounds up to 10 mm that have not been extended, I suggest that careful digital examination of all the cannulation sites at the end of the operation is more likely to avoid this complication than attempted fascial repair of these very small defects.

Letter 2

Sir

We were interested to read the Case Report by Messrs McMillan and Watt regarding herniation at the site of cannula insertion after laparoscopic cholecystectomy (*Br J Surg* 1993; **80**: 915). We would like to communicate our own experience regarding this complication.

Of 780 patients operated on by a laparoscopic approach in our service, four developed herniation at the insertion site. Two patients who had undergone colorectal surgery presented with evisceration of the greater omentum. A cannula of 12 mm diameter had been used, and the insertion site was not extended. On the third day after operation they developed a painful small swelling deep to the insertion site. The wound was explored under local anaesthesia. The eviscerated omentum was reduced and the fascial defect was closed. The other two patients presented with small bowel herniation at the site where 10- and 12-mm cannulas had been inserted. They developed evidence of small bowel obstruction on day 4 after operation. Reoperation was carried out the same day, and intestinal resection was not necessary.

We believe that a careful exploration and closure of all 10- and 12-mm wounds is necessary, especially those situated in the infraumbilical region.

Letter 3

Sir

We read with interest the article by Messrs McMillan and Watt (*Br J Surg* 1993; **80**: 915). We have also had one case of uncomplicated herniation at the umbilical incision requiring repair. Thus, we have adopted a technique to lessen the risk of bowel herniation through the laparoscopic port incisions and reduce the risk of accidental injury to abdominal structures from the needle or trocar. We use a 'cut down' technique to the peritoneum and then place a no. 2 polyglactin purse string in the linea alba. After insertion of a reusable 10-mm cannula, the purse string is tightened and secured with one throw of a knot; the knot is held with an artery clip. At the end of the procedure, the pneumoperitoneum is deflated through the 10-mm cannula before its removal. The purse string is then tightened, and secured with two further knots.

The technique is slightly slower than using a Veress needle to establish pneumoperitoneum, but it has the advantage of placing the cannula under direct vision and providing secure closure. The latter is faster than repairing the fascial defect with a suture once the cannula is removed. Leakage of carbon dioxide around the purse string is minimal and if present can be reduced by placing a swab into the skin wound.

Letter 4

Sir

The recent interesting paper by Messrs McMillan and Watt (*Br J Surg* 1993; **80**: 915) prompts us to report a similar complication. A 74-year-old woman underwent an uncomplicated laparoscopic cholecystectomy but complained of abdominal pain and vomiting on the second day after operation. This settled with conservative treatment but on day 6 she developed small bowel obstruction and a swelling was noted beneath the subumbilical skin incision. This was explored and an obstructed loop of small bowel, surrounded by a small collar of peritoneum, was found. The subsequent recovery was uneventful.

We believe that a small umbilical hernia existed before operation and that the 10-mm port passed through it, facilitating herniation of the small bowel through the sac and into the subcutaneous tissue. We now close all fascial defects at 10-mm ports.

The article by Messrs McMillan and Watt generated much correspondence, with nine previously unreported instances of this complication coming to light. The matter is now, however, closed.

Editor

Laparoscopic cholecystectomy

Sir

We read with interest the Review on laparoscopic cholecystectomy by Messrs Macintyre and Wilson (*Br J Surg* 1993; **80**: 552–9). The authors state that one of the generally agreed contraindications to laparoscopic cholecystectomy is the presence of a cholecystoenteric fistula.

We have encountered five cholecystoduodenal fistulas in a series of 300 laparoscopic cholecystectomies, which we are reporting in *Surgical Laparoscopy and Endoscopy*. Of these, two were diagnosed before operation. One patient had a previous cholecystoduodenostomy and another had aerobilia on computed tomography. It was possible to deal with four fistulas laparoscopically. The fifth patient had to undergo conversion to laparotomy as the duodenum was inadvertently perforated during dissection. In the remainder it was possible to display the cholecystoduodenal fistula with a combination of careful blunt and sharp dissection. The fistula was divided and stapled at the same time by a single firing of an Endo-GIA30 stapler (US Surgical, Norwalk, Connecticut, USA) through an epigastric 12-mm cannula. Intraoperative cholangiography was performed in each patient to confirm biliary anatomy and detect bile duct stones.

We maintain that, with increasing expertise, better imaging and improved instrumentation, it is feasible to repair most cholecystoduodenal fistulas laparoscopically.

New adjustable knot for securing subcuticular running sutures

Sir

We read with interest the Surgical Workshop by Dr Di Saverio and colleagues on an adjustable knot for securing subcuticular sutures (*Br J Surg* 1993; **80**: 873). Careful adjustment of tension and a small knot might well reduce the problems associated with anchoring subcuticular sutures to the skin surface. However, where an absorbable suture is used, the marked skin and potential route of infection from the skin surface can be avoided by other techniques.

Ranabaldo[1] recently described a knotless technique involving several acutely angled passages through the subcutaneous tissue. Occasional immediate gaping was admitted, suggesting that the technique may be less suitable for low-friction monofilament sutures.

We believe that the problems of knot ulceration with absorbable subcuticular suturing can be avoided by using very light gauge material. Since 1992, one general surgeon (F.L.H.) has used 5/0 polydioxanone for all incisions except some on the face and scrotum. A three-throw conventional buried knot is used proximally and a three-throw Aberdeen knot distally. The cases include a large number of mastectomies and other breast procedures, laparotomy wounds and lower-limb amputations. The suture is also used by junior surgeons with no previous experience in subcuticular closure with such a small needle and fine material. Over 500 closures have been performed with no early wound dehiscence. Most major incisions have been reviewed in outpatients for other reasons, and no knot protrusion has been detected. The few wounds known to have dehisced were associated with infection among patients in whom a high incidence of wound problems might have been expected. Dehiscence occurred in a small part of a midline incision after proctectomy for Crohn's disease in an octogenarian with a low albumin level and recent steroid medication.

This suture dictates a meticulous technique, distributing tension over multiple small bites, and this contributes to a good cosmetic result.

Return to work after inguinal hernia repair

Sir

I read with interest the Short Note by Dr Rider and colleagues (*Br J Surg* 1993; **80**: 745–6). I was surprised at the decision to study this subject retrospectively over a 10-year period. Patient recall of subjective matters such as preoperative expectations of convalescence are strongly susceptible to bias at the best of times and cannot safely be analysed in retrospect, especially when the events being recalled may have occurred many years before. More objective data such as the length of time off work would still be difficult to evaluate unless corroborated by means of an independent source such as employment records or general practitioner's notes, and I can find no reference to this sort of information in the study. In the light of these methodological difficulties, which are to some extent inherent in retrospective analysis but accentuated in this study, I did not feel it is justifiable to draw the conclusion that the time off work following routine inguinal herniorrhaphy is reducing.

In a prospective study I conducted 2 years ago, for 101 patients from the Northern health region, the median time off work following inguinal hernia repair was 45 (interquartile range 23–83) days. This was of similar length to the figures quoted from earlier studies. Although there was a greater proportion of patients performing heavy work (37 *versus* 27 per cent), the same relationship between type of work and time off was not observed. Perhaps more significant was the observation that only 20 per cent of patients received advice concerning return to work before operation and 44 per cent after surgery. Some 63 per cent of patients made their own decision about when to return to work without consulting either their general practitioner (GP) or surgeon.

I agree with the authors that there is a great need for better preoperative education of patients (in particular) and GPs concerning the appropriate time of return to work, but I do not feel that they have presented adequate evidence to suggest that the current position is improving.

S. E. Stock

Department of Surgery
Newcastle General Hospital

UK

Authors' reply

Sir

We feel the strength of our study lies in considering inguinal hernia operations performed by only one surgeon, but we accept the shortcomings of its retrospective nature. Considering procedures performed by only one surgeon removes the influences on return to work of both variable hospital doctor advice (which does occur[1]) and differences in operation technique.

In Nottingham, time off work following routine inguinal herniorrhaphy appears to be reducing. In 1978 a mean of 78 (range 18–229) days convalescence was taken[2]. By 1991 this figure had fallen[2] to 28 (range 0–120) days. As previously suggested[1], it is possible that patients in Nottingham return to work today earlier than elsewhere.

Mr Stock's findings suggest that in the Northern health region, unlike elsewhere[1,3], views on when to return to work are correctly independent of the physical content of the patient's job.

Randomized study of the value of laparoscopy before appendicectomy

Sir

I read with interest the article by Dr Olsen and colleagues on the value of laparoscopy before appendicectomy in women (*Br J Surg* 1993; **80**: 922–3). The use of laparoscopy in the diagnosis and treatment of acute appendicitis is becoming widespread in this country and elsewhere in the world. Although this technique is very useful in confirming acute appendicitis and also in diagnosing other pathologies (especially gynaecological ones), practising surgeons must be wary of the 'laparoscopically normal' appendix.

Dr Olsen and colleagues used the criterion that appendicitis could be excluded 'if a normal appendix could be seen throughout its length'. However, a recent study by Grunewald and Keating[1] showed that, at open operation, surgeons diagnosed a normal appendix incorrectly in 26 per cent of patients when it was subsequently checked histologically. Furthermore, when the appendix appeared normal and no other pathology could be found, the false-reassurance rate rose to 29 per cent.

The laparoscope affords excellent views of much of the peritoneal cavity and allows visualization of the pelvic organs while causing minimal morbidity to the patient. It also magnifies the appendix, allowing very close inspection of this structure. Unfortunately, there are no data to show conclusively that laparoscopic assessment of the 'normal' appendix is any more accurate than inspection at open operation. My own attempts at assessing the turgidity of the 'normal' looking appendix via the laparoscope (the 'wobbly' sign) and comparing this with subsequent histological findings in an attempt to identify the hidden inflammation has shown no correlation.

Therefore, in the face of such a high false-reassurance rate it is inadvisable at present to leave a laparoscopically normal appendix, especially if the clinical picture is suspicious of appendicitis and no other cause of pain can be identified.

Detection and enumeration of circulating tumour cells in colorectal cancer

Sir

We read the article by Mr Leather and colleagues (*Br J Surg* 1993; **80**: 777–80) with great interest as we are conducting a similar study in patients with breast cancer. We have several comments to make.

First, the assumption made by the authors that tumour and mononuclear cells are deposited with equal efficiency at the interface following density-gradient centrifugation is probably incorrect. Previous work[1] has shown that the specific gravity of tumour cells ranges from 1·040 to 1·070 whereas that of mononuclear cells is between 1·060 and 1·075. The efficiency of cell recovery is therefore likely to be higher for mononuclear than tumour cells when Histopaque (Sigma Chemicals, Poole, UK; specific gravity 1·077) is used. Second, we are surprised to see that the authors detected as few as 10 tumour cells/ml in three of five attempts and achieved such a high rate of tumour cell recovery. Glaves[2] has reported an efficiency of tumour cell recovery as low as 16 per cent using a similar method with Percoll (Sigma Chemicals). Our own experience suggests a value that may be even lower. We used a similar method with Ficoll–Hypaque (Sterling Winthrop, Guildford, UK; specific gravity 1·077) and calculated the percentage of tumour cell recovery after adding a known number of tumour cells to blood from healthy volunteers. After the experiments were repeated 15 times, the mean tumour cell recovery was only 4 per cent. We are also interested to know the methodology used by the authors to count the relative number of tumour cells to mononuclear cells on cytospins. Sampling error can easily occur if the density of mononuclear cells varies between cytospins and between different areas on the same cytospin.

This is an important but difficult field of work, with major potential implications for clinical practice. This fact makes it all the more important that the methods used to study circulating tumour cells are extremely robust.

Vein-patch rupture after carotid endarterectomy: an avoidable catastrophe

Sir

We read with interest the article For Debate by Mr John and colleagues (*Br J Surg* 1993; **80**: 852–3) and agree with many of the points made within it. It has been our policy to use upper-thigh saphenous vein since 1990, when two cases of vein-patch rupture occurred after the use of lower-leg vein. A review of the literature convinced us of the advantages of upper-thigh vein and, until very recently, over 170 carotid endarterectomies had been performed with no recurrence of the problem.

However, we have now experienced our first case of upper-thigh saphenous vein-patch rupture following carotid endarterectomy. The patient, a 51-year-old man, presented with a history of recurrent transient ischaemic events in the left carotid territory. Carotid duplex scanning revealed 75 per cent stenosis of the left carotid artery and an occluded right carotid artery, on which endarterectomy had been performed 8 years previously. During the intervening period the patient had also undergone coronary artery bypass grafting, which had utilized all the long saphenous vein from the right leg. At operation the saphenous vein harvested from the left thigh was of small calibre for a man but considered acceptable for patching. A 30-min period of postoperative hypertension was controlled with intravenous labetalol infusion, and for the first 3 days the patient made a good recovery. On day 4 the vein patch ruptured; at operation it was found to have split down the middle in the characteristic axial direction[1].

This case underlines the importance of the diameter of the saphenous vein in patch rupture[1]. In patients whose saphenous vein is unsuitable to patch the carotid artery, several alternatives are available, although complications have been associated with all of them. Jugular vein is tempting because of its location, but the tensile strength of internal and external jugular vein is one-quarter that of large saphenous vein, and external jugular vein in particular has a very low rupture pressure[1]. Polytetrafluoroethylene (PTFE) patches can be used, but PTFE patch disruption has been reported[2] and cases of delayed postoperative bleeding from stitch holes have also occurred[3]. Woven Dacron (Du Pont, Stevenage, UK) is a useful alternative, but care must be taken to use material specified for the purpose as other forms of Dacron carry the risk of fraying. As with all artificial materials there is the risk of infection; we recently experienced a case of chronic carotid endarterectomy wound infection that was cured only by replacing the artificial patch with vein. Other sources of patch material such as superior thyroid artery have failed to gain popularity.

Vein-patch angioplasty for carotid endarterectomy has been shown to reduce the risk of early postoperative carotid thrombosis, long-term restenosis and recurrence of symptoms[4]. By contrast, there is a risk of patch rupture, which is a rare but serious complication. We agree with John and colleagues that this complication can be minimized by using good-quality upper-thigh saphenous vein, giving particular attention to the diameter of the vein. Nevertheless, we believe that the incidence of vein-patch rupture can be reduced by these guidelines but the complication probably never completely avoided.

'Car-crusher colon'

Letter 1

Sir

We read with interest the Case Report by Messrs Whiteley, Deardon and Pearson (*Br J Surg* 1993; **80**: 640). We recently treated a 40-year-old driver who was admitted to hospital after being injured by the jaws of a vehicle crane. An operating button had been pressed accidentally, and the patient's abdomen had been caught by the jaws of the crane. On examination he had left-sided abdominal pain and haemoperitoneum. Laparotomy revealed a ruptured spleen and a 'degloving' injury of the sigmoid colon. Around 6 cm of colon displayed an intact tube of mucosa. the injury to the mesentery was trivial; splenectomy and seromuscular repair of the sigmoid colon were performed. The patient made an uneventful recovery. Degloving injury of the bowel may not be rare and should be looked out for in patients with blunt abdominal injury.

Letter 2

Sir

I was interested by the report of Messrs Whiteley, Deardon and Pearson (*Br J Surg* 1993; **80**: 640) on a degloving injury to the colon. The authors stated:

> 'Degloving of the skin from limbs is familiar following shear forces but to our knowledge no such degloving event has been reported in the layers of the large bowel, although the mode of injury is certainly by "shear"'.

This type of injury, termed 'degloving', was reported by me[1,2] as early as 1981. I do not claim originality; I am certain that it would have been reported previous to my use of the term although, like the authors, I was unable to find the appropriate documentation.

Book reviews

Reconstructive Urology. Vols 1 and 2

G. Webster, L. King and B. Goldwasser (eds). 285 × 215 mm. Pp. 500 and 565. Illustrated. 1993. Oxford: Blackwell Scientific. £175.

Reconstructive Urology deserves to become the definitive text in this expanding area of surgery. In recent years there have been tremendous advances in this field and many of the leaders have contributed to these volumes.

Half of Volume 1 is devoted to the principles of reconstruction, reviewing physiology, anatomy, assessment and surgical techniques. Much of this is available in other books but its inclusion in this work is appropriate since there will be many occasions when the reader will wish to be reminded of basic principles. The book is well illustrated and produced in clear double-column text that makes for easy reading. It is comprehensive but there appears to be a blurring between conservation and reconstruction. While there clearly is an overlap in the management of urinary tract disorders, I found chapters on such topics as malignant kidney disease, retroperitoneal fibrosis and endoscopic management of ureteropelvic junction obstruction a little out of place. In this respect, Volume 2 is far more convincing and this is where the dedicated reconstructive surgeons will find much to interest them.

In the 1990s, for such a text to be economically viable it must serve an international market; this is the one area that I found irritating for it appears that good English words have been Americanized in an attempt to broaden the book's appeal. This makes part of the text appear stilted. I doubt, for example, that a British urologist really uses terms such as 'theoretic reason' and 'anatomic result'. However, these criticisms are minor and should not detract from what is a superbly produced book that deserves to become the reconstructive urologist's bible.

Transurethral Resection. 3rd ed.

J. Blandy and R. Notley. 250 × 190 mm. Pp. 169. Illustrated. 1993. Oxford: Butterworth–Heinemann. £39·50.

The third edition of this well written book has been updated to include more details of closed-circuit television for the urologist, new information on the transurethral resection (TUR) syndrome and comments on the medical and surgical alternatives to TUR of the prostate that are in fashion. The outline of the book is unaltered. There is an interesting historical introduction, followed by a review of the basic physics of the technologies enabling the urological surgeon to perform TUR. The armamentarium is described, and the indications and investigations are discussed. The greatest strength of this book, however, remains its detailed description of technique. Although the teaching of TUR is now much easier with the introduction of closed-circuit television, the surgeon in training nevertheless must still have a thorough grasp of the surgical principles and basic technical steps. Nowhere are these more thoroughly described or more beautifully illustrated (the black and white illustrations are much more informative than the colour plates). Readers can enjoy the prose, which makes for easy and pleasurable reading. Postoperative care, and the prevention and management of complications are covered comprehensively. In a book of this size it is not surprising that there is no room to include comments on prostatic screening, transrectal ultrasonography and prostate-specific antigen. These controversial topics may be included in a fourth edition which will undoubtedly be required in due course, since this book is destined both to remain essential reading for every urologist in training, and to maintain its place on the bookshelves of every urology department.

Minimally Invasive Surgery

J. Hunter and J. Sackier (eds). 285 × 220 mm. Pp. 358. Illustrated. 1993. Maidenhead: McGraw–Hill. £71·50.

If predictions that 70 per cent of all surgical operations will be performed by minimally invasive techniques by the turn of the century come true, this will be a very important book for surgeons. The editors – both pioneers in the field – work in the United States but acknowledge their British training and influence. It is disappointing therefore to see that only one contributor (Professor Cuschieri) comes from the UK, compared with seven from France and 36 from the States, reflecting perhaps the relative contributions that each of these countries has made to the new technology.

Early chapters are appropriately devoted to the new technologies that have made the surgical revolution possible. Consecutive chapters deal with fibreoptics, ultrasound, lasers, electrosurgery and surgical polymers. The bulk of the book is devoted to the description of individual techniques; due prominence is given to laparoscopic suturing and anastomosis. The layout of the book is pleasing, with double columns and effective use of subheadings. The quality of the illustrations is high and the line drawings of operative procedures in particular are models of clarity. Minimally invasive procedures within the abdomen and pelvis are comprehensively covered along with a short chapter on thoracoscopic surgery. In addition, endoluminal endoscopic techniques of the gastrointestinal tract merit chapters in their own right, as does endovascular surgery.

This is a clear, comprehensive, well illustrated and well referenced textbook. For this reviewer it is the best so far produced in the field and is highly recommended.

Surgical Decision Making. 3rd ed.

L. W. Norton, G. Steele Jr and B. Eiseman (eds). 220 × 280 mm. Pp. 342. Not illustrated. 1993. Philadelphia, Pennsylvania: W. B. Saunders. £55.

This is an excellent book. Assimilation of complex methods of treatment in general surgery is becoming increasingly difficult, particularly as specialization continues a pace. The essential form of this book is to keep each chapter to two pages facing one another. The basis of each chapter is an algorithm beginning with history, examination and investigations, and extending – depending on the findings – into the various management options. The algorithms are always on the right-hand page and at major decision points there are keys enabling the reader to refer to items of text on the left-hand page. Each chapter also contains a handful of good up-to-date references. The whole book works extremely well, partly because the editors have exploited a large number of specialists to deal with each of the sections. In all there are 334 chapters divided into 11 sections: general, head and neck, cardiopulmonary, gastrointestinal, breast and soft tissues, vascular, paediatric, transplantation, urological, gynaecological and orthopaedic. The book is well indexed.

I found this volume easy to use and the algorithms were thoughtful, up to date and well laid out. Inevitably, there will be aspects with which not every reader will agree, but in principal there was little I could find to fault. This book will be extremely useful for those undertaking specialist examinations and those involved in undergraduate and postgraduate teaching. It may also be helpful for the busy clinician. The success of such a book demands that it remain up to date, incorporating new data as they arrive; I am not surprised that it is in its third edition. This volume should be found in every postgraduate medical library – it is a pity that it is not available in paperback.

Atlas of Surgical Pathology

J. Turk and C. Fletcher. 315 × 255 mm. Pp. 346. Illustrated. 1992. London: Gower Medical. £99.

In 1985 Gower Medical commissioned a slide atlas comprising eight volumes of colour transparencies of the magnificent collection of pathological specimens in the museum of The Royal College of Surgeons of England, which dates back to 1799 when parliament bought John Hunter's collection. Each eight-volume set cost over £1000 but they sold quite well to medical schools that had not yet built up their own pathology museums. Over 1000 of these photographs have now been published in full colour, together with their accompanying text.

Many of the more bizarre congenital malformations, which have little educational value, have been omitted, but there are few surgically important lesions – adult respiratory distress syndrome is one – that are not represented. From time to time I wished that the photograph of the gross specimen had been accompanied by a photomicrograph, but no doubt that would have doubled the price.

This is not a 'coffee table' book, but a serious volume of surgical pathology. I am not sure which to admire most, the skill of the photographer or the erudition of the text writer. Each photograph is accompanied by a description of the specimen, its provenance and clinical history (if they are known), and a teaching paragraph that is quite enough to satisfy the requirements of the examiners for Fellowship of any of the Royal Colleges. Despite this, I am not sure for whom the book is intended; at £99 it is beyond the means of most Fellowship candidates. Nevertheless, it is a superb book that is worth saving up for, and it will not go out of date.

Atlas of Vascular Surgery – Basic Techniques and Exposures

R. Rutherford. 285 × 220 mm. Pp. 267. Illustrated. 1993. Philadelphia, Pennsylvania: W. B. Saunders. £57.

In the preface the author confesses to a longstanding disappointment with surgical atlases, largely because they focus on the final stages without demonstrating the essential intermediate steps. To counteract this Dr Rutherford has written an atlas of vascular surgery and divided it into two sections, the first of which deals with basic vascular technique and the second with vascular exposure. In the first section the historical background is described along with instruments and suture material. The section then goes on to discuss vascular exposure and control, haemostasis and anticoagulation, vascular incisions, closures and anastomoses. The remainder of this section deals with preparation of grafts, tunnelling, thromboembolectomy, endarterectomy and perioperative arteriography. The illustrations are beautifully drawn and well annotated; the descriptive narrative is clear and concise. This section is aimed as an introduction to basic techniques and clearly accomplishes its task. The second section deals with vascular exposure and is once again well illustrated with clear and simple diagrams. In particular the approach to the suprarenal aorta is lucidly described. There is also an interesting section on the lateral approach to the popliteal artery that is seldom used in this country. At £57 this book represents excellent value, not only for beginners in vascular surgery but also for those actively engaged in its practice. It also complements admirably Rutherford's *Text Book on Vascular Surgery*.

Surgery for All. A View from the Developing World

M. Ahmed, R. J. W. Blanchard, B. Eklof, T. S. Harrison, F. Moazam, S. K. Suleman, J. Talati and S. Tibblin. 250 × 190 mm. Pp. 419. Illustrated. 1992. Lahore: Arkash Publishing. £15.

This is a difficult book to review and I am left in some doubt as to the target readership the multiple authors had in mind when assembling the chapters. The foreword does little to clarify the situation as it consists largely of a series of quotes from the text. The chapters cover both general surgical and specialty topics in the context of the country of origin of the author. It was interesting to be reminded of some of the infective agents causing general surgical problems in the Third World, but the specialty chapters are not detailed enough to form a useful reference text or instructive enough for a practical manual.

I did enjoy (and indeed could relate better to) the more general chapters. Particularly informative were those on prioritizing surgical care in Africa and surgery for the effects of chronic violence, which describes the evolution of the acute surgical services at the American University Hospital in Beirut as the Lebanon conflict escalated.

Peruse this book if you want to familiarize yourself with some of the acute surgical problems of the developing world. The colour photographs are of reasonable quality and enhance the text, although you may well be frustrated by the not so infrequent patches of poor English. However, I cannot recommend you to buy a copy for your personal library, although it is reasonably priced for a hardback volume.

Instructions to authors

The British Journal of Surgery publishes original articles, reviews and leading articles. Short notes, case reports and surgical workshops are also accepted. All manuscripts are submitted to editorial review.

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another journal, has not been accepted for publication elsewhere and has not already been published. **Any detected attempt at dual publication will lead to automatic rejection and may prejudice acceptance of future submissions.** Articles and their illustrations become the property of the Journal unless rights are reserved before publication. The title page should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies of original articles and other editorial matter to: The Senior Editor, *The British Journal of Surgery*, Blackwell Scientific Publications Ltd, 25 John Street, London WC1N 2BL, UK. Telephone: 071-404 1831. Facsimile: 071-404 1927.
Books for review should be sent to the same address.

A covering letter must accompany all submissions and must be signed by all authors. The covering letter should state if an abstract of the work has been published and whether the authors wish the manuscript and/or illustrations to be returned if the work is not accepted. The first named author is responsible for ensuring that all authors have seen and approved the manuscript and are fully conversant with its contents.

Rejected manuscripts will not be returned to the authors, unless this is specifically requested.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached. Written consent must be obtained from the patient, legal guardian or executor for publication in *The British Journal of Surgery* of any details or photographs which might identify an individual. Evidence of such consent should be submitted with the manuscript.

Preparation of manuscripts

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; **296**: 401–5 or the *Annals of Internal Medicine* 1988; **108**: 258–65, or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from The Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR, UK (cost £1·00 per copy).

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. **When quoting specific materials, equipment and proprietary drugs, authors must state in parentheses the name and address of the manufacturer.** Failure to do so will result in delay in publication as the Journal considers that this information is essential for any reader who wishes to obtain similar material. Generic names should normally be used.

Original articles

Original articles should normally be in the format of introduction, methods, results, discussion. Each manuscript should contain a summary on a separate page. Authors are reminded that there is considerable pressure on editorial space in the Journal. Lengthy manuscripts are likely to be returned to authors for shortening. The discussion in particular should be clear and concise, and should be limited to matters arising directly from the results. Authors should avoid discursive speculation.

Reviews

The Editorial Board of *The British Journal of Surgery* encourages submission of review articles on topics of interest to its readers. Any topic will be considered, but priority will be given to those addressing a major current problem. The author of each accepted review will receive an honorarium. Potential authors seeking advice on the suitability of review topics are advised to contact: Mr J. A. Murie, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK.

Leading articles

The Editors commission signed leading articles to *The British Journal of Surgery*. These articles are 600–1000 words in length, address controversial topics of current interest and are supported by key references. Submissions may be subjected to external review and assessment by the Editorial Board before acceptance. The Editors retain the right to alter style and shorten material for publication. An honorarium is payable on publication.

Short notes

These are original observations presented in brief form. They should follow the standard format of introduction, methods, results and discussion, but no summary is required. Short notes should not exceed 500 words with a maximum of five references and one table or one figure.

Case reports

The British Journal of Surgery receives an increasing number of case reports each year. Space within the Journal remains at a premium and the rejection rate is high. Case reports should be no more than 400 words (300 if accompanied by a figure), with no more than five references and one illustration.

Surgical workshops

These describe technical innovations or modifications which may be useful in surgical practice. These articles should be less than 500 words long; they may be accompanied by no more than two figures and up to five references.

Typescripts

It is *essential* that manuscripts be clearly reproduced with adequate space for editorial notes. **Papers must be typewritten or printed on A4 paper (210 × 297 mm) on one side of the paper only with double spacing and 4 cm margins. Manuscripts which do not conform to these requirements will be returned to the authors for recasting.** Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations. The text should usually follow the standard sequence of introduction,

methods, results and discussion. These sections should run sequentially through the text, avoiding blank space between them.

Title page

The title page should give: (1) the title of the article; (2) the name and initials of each author; (3) the department and institution to which the work should be attributed; (4) the name, address, and telephone and facsimile numbers of the author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; and (6) the category in which the manuscript is being submitted (original article, case report etc.).

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytical methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Three copies of all illustrations and tables should be submitted. Each table with an appropriate brief title should be typed on a separate page. At least one set of illustrations (line drawings, radiographs, photomicrographs etc.) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Photocopies should be of sufficient quality to enable the Journal's referees to judge their content and value. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers of patients involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full. Permission to use published work must be obtained from the original author and the publisher before submission.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension. Abbreviations should be used consistently throughout the text and must be clearly defined on first use.

Numbers and units

The decimal point, not a comma, is used, e.g. 5·7. A space and not a comma follows thousands and multiples thereof, e.g. 10 000. SI units (International System of Units) should be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points.

References

References should be typed with double spacing and cited in the Vancouver style (see above: Uniform Requirements for Manuscripts Submitted to Biomedical Journals). Reference to abstracts from meetings is discouraged; reference to unpublished communications is not acceptable. Personal communications should be cited in the text, in parentheses. The first author is responsible for confirming the acceptability of the material quoted with the originator.

In the text, references should be numbered consecutively by superscript: ^{1,2} or $^{1-3}$. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication; volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; **66**: 184–6. The sequence for the chapters of a book should be: author(s); chapter title; editors; book title; place of publication; publisher; year of publication; page numbers. For example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In: Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications*. New York: Springer-Verlag, 1981: 123–63.

Statistics

For detailed guidance on the handling of statistical material, authors should consult *The British Journal of Surgery* 1991; **78**: 782–4. The Editors and statistical referees in evaluating a manuscript will consider the *design* of the study, the *presentation* of the data, the *analysis* of the data, and the *interpretation* of the results.

Design

Authors should set out clearly the objectives of the study, should identify the primary and secondary hypotheses, and should explain the rationale for the choice of sample size.

Presentation

Whenever possible a graphical presentation should be used to illustrate the main findings of a study. The use of standard deviation and standard error should be clearly distinguished. The use of the '±' symbol should be avoided; these statistics should be presented in parentheses after the mean value.

Analysis

There should be a clear description of which methods were used for which analyses, and any methods not in common usage should be supported by references. Results of statistical tests should be reported by stating the value of the test statistic, the number of degrees of freedom and the P value. For example, '$t = 1{\cdot}34$, 16 d.f., $P = 0{\cdot}20$' might be reported. Actual P values should be reported, to two decimal places, especially when the result is not significant, rather than stating 'not significant'.

Whenever possible, the results of the primary analyses should be reported using confidence intervals instead of, or in addition to, P values.

Interpretation

Statistical significance should not be confused with clinical significance. In particular, 'negative' findings should be interpreted through the use of confidence intervals.

Authors should beware of placing undue emphasis on secondary analyses, especially when they were suggested by an inspection of the data.

COMPLICATIONS OF LAPAROSCOPY AND HYSTEROSCOPY

Edited by R S Corfman, M Diamond and A DeCherney

086542201X, Hardback, £45.00, Jan-93,
288 pages, 86 illustrations

Many surgical procedures in gynaecology are now performed by means of endoscopy or 'keyhole surgery' rather than by traditional surgery, thereby reducing hospital stays and cutting costs. The number and difficulty of such procedures is growing constantly. This book deals with potential complications of such techniques and how to avoid and rectify them.

The contents deal with all the major procedures, including sections on: preoperative and postoperative considerations, anesthesiology, intraperitoneal insufflation and trocar placement, complications arising from vaginal placement of accessories, operative laparoscopy, specific gynecological procedures, hysteroscopy, general surgery and other surgical complications. Their complications are addressed in detail to help the practitioner better understand each procedure and its potential problems.

- covers all the major procedures;
- deals with increasingly popular and complicated techniques;
- enables the practitioner to operate more safely;
- responds to the growing trend towards day case surgery.

scribing information
sentation: Ampoule containing 5ml of
% aqueous solution of dopexamine
lrochloride (50 mg).
es: Short term intravenous administration
the treatment of heart failure associated with
diac surgery.
sage and Administration: Dopacard must
diluted before use and administered
ravenously via a cannula or catheter into a
ntral or large peripheral vein. A device which
vides accurate control of the rate of flow of
ision is essential.Full instructions are given in
data sheet and package insert.
paration: The contents of four ampoules
uld be injected aseptically into one of the
owing: 0.9% Sodium Chloride Injection or
Dextrose Injection (500 or 250ml).
commended dosage for adults including the
erly: Infusion should begin at a dose of 0.5
kg/min and may be increased to 1μg/kg/min
l then in increments (0.5-1 μg/kg/min) up to
g/kg/min at not less than 15 minute intervals,
ording to the patient's haemodynamic and
iical response. The rate of administration
l duration of therapy should be adjusted
ording to the patient's response as determined
heart rate and rhythm (ECG), blood pressure,
ne output and, whenever possible,
asurement of cardiac output. Extended
rapy beyond 48 hours has not been fully
iluated. It is recommended that the infusion
Dopacard is reduced gradually.
ntra-indications, Precautions, Warnings:
ntra-indications: Known hypersensitivity
dopexamine hydrochloride or excipients
sodium edetate). Concurrent MAOI
ninistration, left ventricular outlet obstruction
ch as hypertrophic obstructive
diomyopathy or aortic stenosis),
aeochromocytoma, thrombocytopenia.
cautions: If any correction of hypovolaemia
equired this should be achieved before the
ninistration of Dopacard.
rnings: Dopacard should be administered
h caution to patients with a clinical history
schaemic heart disease especially following
ite myocardial infarction or recent episodes of
gina pectoris. A small, reversible fall in
culating platelet numbers has been observed in
ne patients. No adverse experiences
ributable to alterations in platelet count have
en seen in clinical studies. Plasma potassium
y decrease and blood glucose may increase
ing Dopacard administration and care is
uired in its use in patients with, or at risk of,
pokalaemia or hyperglycaemia. In patients
h a marked reduced systemic vascular
istance, Dopacard should not be used as a
ect substitute for pressor agents or other
tropes. If cardiac arrhythmia should occur,
dosage should be reduced or infusion
continued. There have been occasional
orts of partial tolerance, with some
enuation of the haemodynamic response
eloping during long term infusions of
pacard. The safety and efficacy of Dopacard
use in children has not been established.
e in Pregnant and Lactating Women:
pacard is not currently recommended for use
pregnant and lactating women.
e effects: Dose-related increases in heart
e may occur during infusion of Dopacard; in
st cases these are not clinically significant.
casionally excessive tachycardia or ventricular
rasystoles, and, more rarely, atrial fibrillation,
ve been noted during the infusion,
cessitating reduction or temporary
continuation of the infusion. Tachycardia
y be more pronounced in patients with pre-
sting atrial fibrillation. The following side-
ects have been reported infrequently, in most
es at high dosage: Nausea, vomiting,
potension, dyspnoea, headache, hypertension,
mor, chest pain, cardiac failure, increased
eating, angina pectoris.
eractions: Dopacard may potentiate the
ects of exogenous noradrenaline and may
enuate the inotropic effects of higher doses of
pamine. Caution in the concomitant use of
- adrenergic and dopamine receptor
agonists because of possible attenuation of the
rmacological effects of Dopacard.

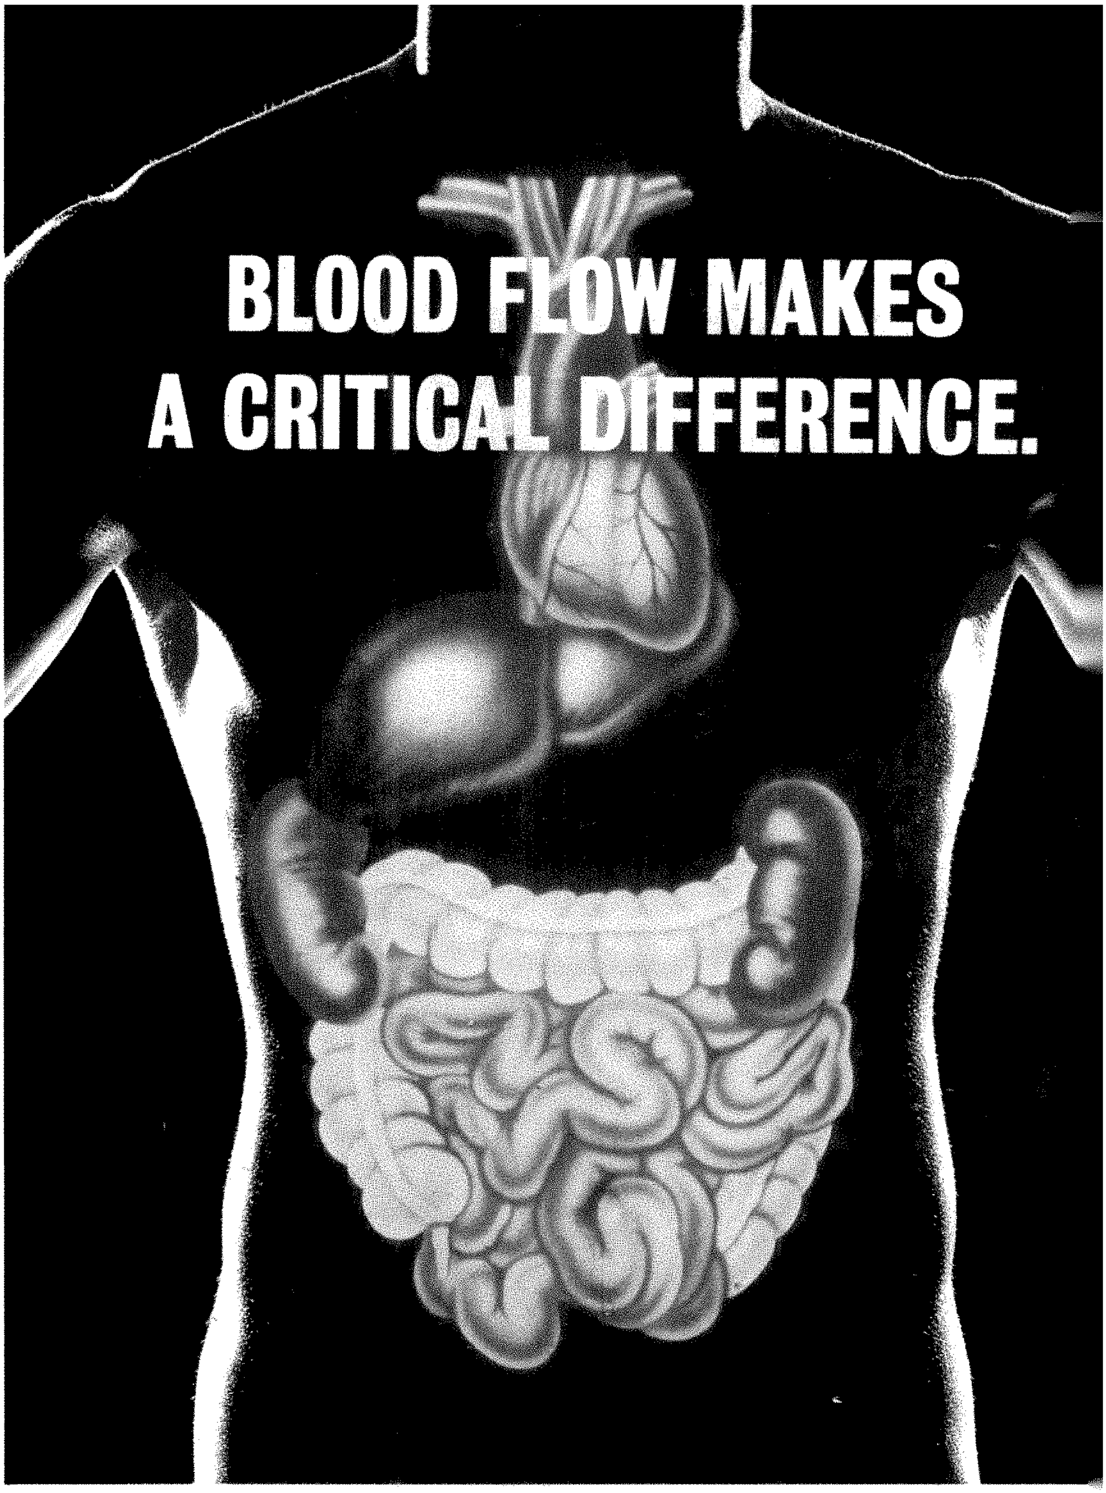
ence holder.
te of preparation October 1993

PORTON



DOPACARD increases cardiac output and enhances both renal and mesente
blood flow. This combined activity makes it of value for patients with low ca
output associated with cardiac surgery.

DOPACARD achieves its effects by combining dopaminergic and β_2 adrenerg
agonist activities. Substantial cardiac output increases are frequently obtaine
mostly by afterload reduction, with no significant change in myocardial
oxygen consumption.

The distribution of the increased cardiac output to vascular beds such as the
kidney, liver and gut, without the risk of vasoconstriction, offers improved blc
flow to these vital organs.

DOPACARI
dopexamine hydrochlor

Increasing Renal and Hepato-Splanchnic blood flo

Prescribing information

Presentation: Ampoule containing 5ml of a 1% aqueous solution of dopexamine hydrochloride (50 mg).

Uses: Short term intravenous administration for the treatment of heart failure associated with cardiac surgery.

Dosage and Administration: Dopacard must be diluted before use and administered intravenously via a cannula or catheter into a central or large peripheral vein. A device which provides accurate control of the rate of flow of infusion is essential.Full instructions are given in the data sheet and package insert.

Preparation: The contents of four ampoules should be injected aseptically into one of the following: 0.9% Sodium Chloride Injection or 5% Dextrose Injection (500 or 250ml).

Recommended dosage for adults including the elderly: Infusion should begin at a dose of 0.5 µg/kg/min and may be increased to 1µg/kg/min and then in increments (0.5-1 µg/kg/min) up to 6 µg/kg/min at not less than 15 minute intervals, according to the patient's haemodynamic and clinical response. The rate of administration and duration of therapy should be adjusted according to the patient's response as determined by heart rate and rhythm (ECG), blood pressure, urine output and, whenever possible, measurement of cardiac output. Extended therapy beyond 48 hours has not been fully evaluated. It is recommended that the infusion of Dopacard is reduced gradually.

Contra-indications, Precautions, Warnings:

Contra-indications: Known hypersensitivity to dopexamine hydrochloride or excipients (disodium edetate). Concurrent MAOI administration, left ventricular outlet obstruction (such as hypertrophic obstructive cardiomyopathy or aortic stenosis), phaeochromocytoma, thrombocytopenia.

Precautions: If any correction of hypovolaemia is required this should be achieved before the administration of Dopacard.

Warnings: Dopacard should be administered with caution to patients with a clinical history of ischaemic heart disease especially following acute myocardial infarction or recent episodes of angina pectoris. A small, reversible fall in circulating platelet numbers has been observed in some patients. No adverse experiences attributable to alterations in platelet count have been seen in clinical studies. Plasma potassium may decrease and blood glucose may increase during Dopacard administration and care is required in its use in patients with, or at risk of, hypokalaemia or hyperglycaemia. In patients with a marked reduced systemic vascular resistance, Dopacard should not be used as a direct substitute for pressor agents or other inotropes. If cardiac arrhythmia should occur, the dosage should be reduced or infusion discontinued. There have been occasional reports of partial tolerance, with some attenuation of the haemodynamic response developing during long term infusions of Dopacard. The safety and efficacy of Dopacard for use in children has not been established.

Use in Pregnant and Lactating Women: Dopacard is not currently recommended for use in pregnant and lactating women.

Side effects: Dose-related increases in heart rate may occur during infusion of Dopacard; in most cases these are not clinically significant. Occasionally excessive tachycardia or ventricular extrasystoles, and, more rarely, atrial fibrillation, have been noted during the infusion, necessitating reduction or temporary discontinuation of the infusion. Tachycardia may be more pronounced in patients with pre-existing atrial fibrillation. The following side-effects have been reported infrequently, in most cases at high dosage: Nausea, vomiting, hypotension, dyspnoea, headache, hypertension, tremor, chest pain, cardiac failure, increased sweating, angina pectoris.

Interactions: Dopacard may potentiate the effects of exogenous noradrenaline and may attenuate the inotropic effects of higher doses of dopamine. Caution in the concomitant use of β_2 - adrenergic and dopamine receptor antagonists because of possible attenuation of the phamacological effects of Dopacard.

FRAGMIN®
Abbreviated Prescribing Information

Presentation: Single dose disposable syringes containing dalteparin sodium 2,500 I.U. (anti-Factor Xa)/0.2ml or 5,000 I.U. (anti-Factor Xa)/0.2 ml. No preservative present. **Indication:** Peri- and post-operative surgical thromboprophylaxis. **Dosage:** Adults only. *Moderate risk of thrombosis.* Fragmin 2,500 I.U. administered subcutaneously (s.c.) 1-2 hours prior to surgery and thereafter 2,500 I.U. s.c. once-daily for five days or until the patient is fully ambulant. *High risk of thrombosis* eg. elective hip replacement, extensive operations, patients with malignant disease. Fragmin 2,500 I.U. administered s.c. 1-2 hours prior to surgery, and the same dose is administered 12 hours later. Thereafter 5,000 I.U. s.c. once-daily for five days or until the patient is fully ambulant. **Contraindications:** There are no known absolute contraindications to Fragmin. However, caution should be exercised in patients with an increased risk of bleeding complications. **Precautions:** Caution in patients with severely disturbed hepatic or renal function, thrombocytopenia, or defective platelet function and in patients receiving drugs affecting coagulation/platelet function; patients with known heparin hypersensitivity. Fragmin, when administered in doses of 2,500-5,000 I.U./day, does not generally accumulate and, therefore, monitoring of anti-Factor Xa levels is not usually necessary. **Side effects:** High doses of Fragmin with serum anti-Factor Xa levels greater than 1.5 I.U./ml may cause bleeding. Slight to moderate increase in liver enzymes. The following heparin side effects cannot be excluded as Fragmin is a derivative of heparin: thrombocytopenia, allergic reactions, osteoporosis. **Overdose:** 100 I.U. Fragmin is inhibited by 1mg protamine: see data sheet for full prescribing information. **Legal Category:** POM. **Packs:** Fragmin 2,500 I.U./0.2ml: basic NHS price of £ 25.95, pack of 10 single dose syringes. 5,000 I.U./0.2ml: basic NHS price of £ 36.95 pack of 10 single dose syringes. **P. L. Numbers:** 2.500 I.U./0.2ml 0022/0076. 5,000 I.U./0.2ml 0022/0077. ' TABLETS
data sheet before prescribing)
tion White tablets containing the
of either 250mg, 500mg or 750mg
acin. **Uses** Ciprofloxacin is
for the treatment of single or mixed
caused by susceptible organisms.
icated for prophylaxis against
n elective upper gastro-intestinal
nd endoscopy where there is an
d risk of infection. **Dosage and**
tration The tablets should be
ed whole with liquid. ***Adults***:
mg twice daily. In surgical
xis a single 750mg tablet
ered 60–90 minutes before the
re (but see interactions with oral
ants). ***Duration of treatment*** For
ctions the usual treatment period is
days, except in cases of acute
cated cystitis where treatment is
vice daily for 3 days. Generally, in
d chronic infections where sensitivity
, treatment should be continued for
days after the signs and symptoms
on have disappeared. ***Elderly*** No
justment. **Contra-indications**
nsitivity to ciprofloxacin or other
es; also in children and growing
ents except where the benefits of
t outweigh the risks. **Warnings and**
ons Use with caution in epileptics
ents with a history of CNS disorders.
it could result in impairment of ability
or operate machinery. Crystalluria
n reported so patients should be well
d and excessive urine alkalinity
. As haemolytic reactions with
acin are possible in patients with
nd actual defects in glucose-6-
te dehydrogenase activity, use with
. **Drug interactions** Increased
levels of theophylline have been
d following concurrent administration
ofloxacin. The dose of theophylline
be reduced and plasma levels of
line monitored. Where monitoring of
levels is not possible, avoid the use
ofloxacin in patients receiving
line. Particular caution is advised in
atients with convulsive disorders.
tions have also been noted with
ulants and cyclosporin. The tablets
ot be administered within 4 hours of
tions containing magnesium,
um or iron salts. High doses of
nes have shown an interaction with
in animals leading to convulsions.
stration of quinolones and
amide simultaneously can potentiate
ect of glibenclamide, resulting in
ycaemia. Opiate premedicants or
l anaesthetic agents must not be
tered concomitantly with ciprofloxacin
sed for surgical prophylaxis. **Use in**
ancy and lactation Not
mended. **Side-effects** Gastro-
nal, CNS, hypersensitivity/skin
s, musculoskeletal and special sense
ances. Renal and hepatic
ances. Effects on haematological
eters. Also reported vasculitis,

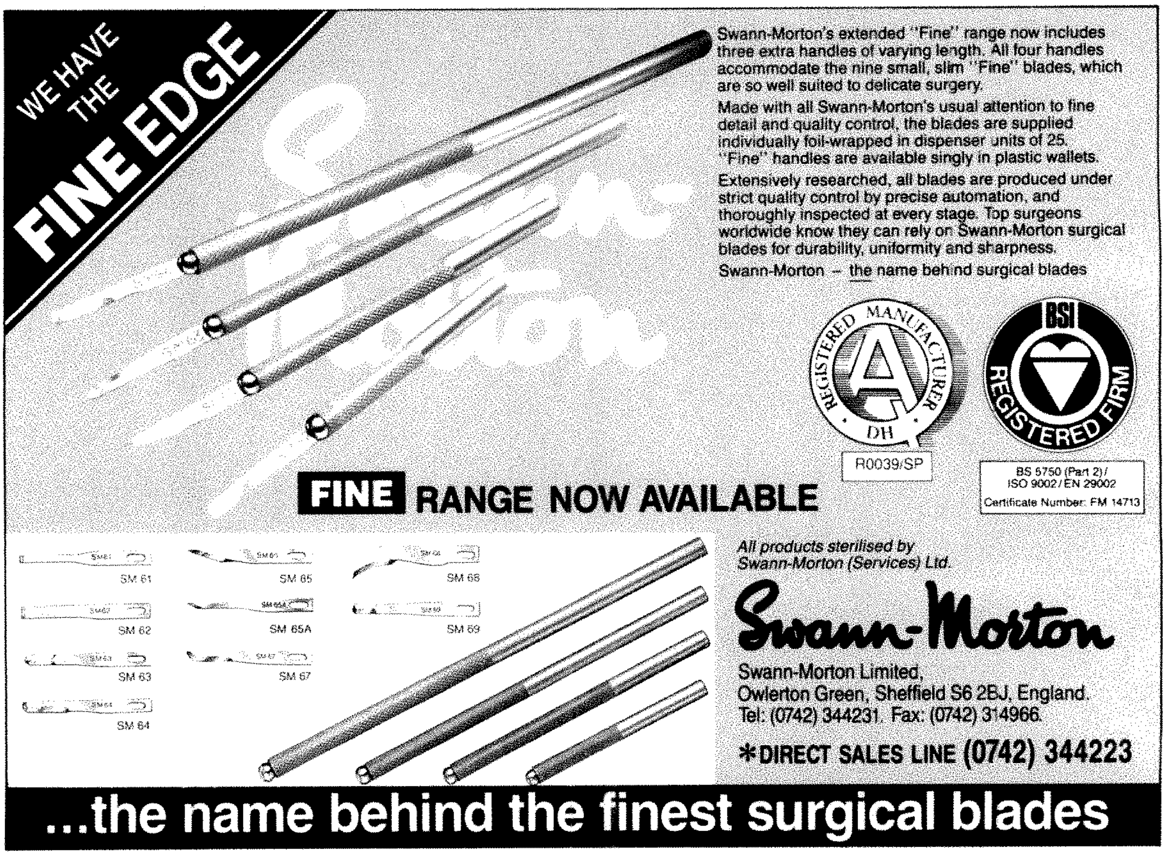
Now indicated for upper GI Surgical Prophylaxis



Swann-Morton's extended "Fine" range now includes three extra handles of varying length. All four handles accommodate the nine small, slim "Fine" blades, which are so well suited to delicate surgery.

Made with all Swann-Morton's usual attention to fine detail and quality control, the blades are supplied individually foil-wrapped in dispenser units of 25. "Fine" handles are available singly in plastic wallets.

Extensively researched, all blades are produced under strict quality control by precise automation, and thoroughly inspected at every stage. Top surgeons worldwide know they can rely on Swann-Morton surgical blades for durability, uniformity and sharpness.

symposium

BLOOD TRANSFUSION IN CANCER SURGERY

Friday, January 28, 1994, Leiden, the Netherlands

Leiden University & Erasmus University Rotterdam

The purpose of the symposium is to discuss the results of recent clinical trials concerning the possible detrimental effects of blood transfusion on cancer prognosis, taking into account the many retrospective studies. The symposium will try to reach a consensus on the subject by bringing together all disciplines dealing with blood transfusion in cancer surgery. Separate sessions will deal with the complications of blood transfusion, the effect of blood transfusions on the immune system and how to prevent blood transfusion.

FOR THE SERIOUS RESEARCHER

ROODEPLAAT RESEARCH LABORATORIES OFFER YOU......

- Pharmacokinetic, pharmacodynamic and toxicological studies in large laboratory animals, specialising in cardiovascular, neuropharmacology and male fertility (semen quality).
- Fully equipped theatres, including well organised anaesthetic, X-ray and intensive care facilities for research on non-human primates and dogs.
- Superb facilities as a research and training centre for minimal invasive surgery.
- Support by our own, modern, well-equipped laboratories for clinical biochemistry, haematology, blood gas analyses and microbiology.
- Metabolic studies in different animal species.
- All enquiries and projects are handled in strict confidence

All work is done according to OECD guidelines for GLP.

RRL
ROODEPLAAT RESEARCH LABORATORIES (PTY) LTD

SITUATED:

Just 25 km north of Pretoria, South Africa, 45 minutes from Jan Smuts International Airport, near to three large medical universities and three other reputable research organisations.

RRL is a privately owned, totally independent contract research centre, with no affiliations with any large organisation.

STEP Distance Learning Course for FRCS (Part II) Examination

A new distance-learning course for SHOs preparing for the CSiG (Part II) examination of the FRCS. Students follow a structured nine-month programme comprising workbooks, audiotapes and regular MCQs & self assessment exercises, as well as having the opportunity to attend 3 study days at the College. All major topics are covered and guidance is given on how to direct and focus textbook reading. SHOs can follow the course alongside their normal clinical duties, choosing the most convenient time and place to study.

Course fee: £575

Courses commence: 31 January, 9 May, 29 August
(Students are advised to apply at least one month in advance of their proposed date of commencement).

香港大學

THE UNIVERSITY OF HONG KONG

Senior Lecturer in the Department of Surgery

(Ref: 93/94-17)

Applications are invited for the post of Senior Lecturer in the Department of Surgery, tenable from January 1994. The appointment will be made on a fixed-term contract of two or three years in the first instance, with the possibility for further extension.

Applicants should be specialized surgeons of some seniority and be clinically competent in the broad field of vascular surgery. They should possess a strong commitment to undergraduate teaching and registrar training. Additionally, proven research achievement should be evident.

Annual salary [non-superannuable but attracting 15% (taxable) terminal gratuity] is on an 11-point scale, with starting salary depending on qualifications and experience: HK$952,800 - HK$1,173,600 (approx. £82,850 - £102,050; sterling equivalents as at October 28 1993). At current rates salaries tax will not exceed 15% of gross income. Annual leave, medical benefits, and a monthly cash allowance of 60% of basic salary will be provided.

Further particulars and application forms may be obtained from Appointments (42300), Association of Commonwealth Universities, 36 Gordon Square, London WC1H OPF, UK (tel. 071 387 8572 ext. 206; fax 071 383 0368); or from the Appointments Unit, Registry, The University of Hong Kong, Hong Kong (fax: (852) 559 2058; E-mail: APPTUNIT@HKUVM1.HKU.HK). Closes **14 January 1994.**

LAPAROSCOPIC COMMON BILE DUCT EXPLORATION

ADVANCED HANDS-ON COURSES

Trinity College & Adelaide Hospital, Dublin

~~November 20-21 1993~~ NOW FULLY BOOKED

February 26-27 1994

Laparoscopic minimally invasive surgery has, so far, seen its greatest application in the biliary tract. Advances in technology now afford the experienced laparoscopic surgeon the opportunity to deal with more complicated biliary problems. Stone clearance from the common bile duct may be achieved laparoscopically at the time of cholecystectomy and intra-operative ultrasound now assists in the laparoscopic evaluation of the biliary and pancreatic systems, and is an effective means of staging intra-abdominal disease.

Hosted by Mr Frank Keane of Dublin's Adelaide Hospital, with a faculty including Mr W. Arthur Tanner and Mr Peter Gillen, these advanced two-day courses will provide ample opportunity to apply, in practical situations, the techniques gained through simulator sessions.

DAY 1

Hands-on operating experience in a laboratory setting; Laparoscopic suturing; Intra-corporeal and extra-corporeal knot tying techniques; Simulator-assisted laparoscopic choledochoscopy; Choledoscopic stone extraction; Hands-on experience of laparoscopic ultrasound imaging.

DAY 2

Live surgery demonstrations of laparoscopic techniques; Common bile duct stone clearance; Laparoscopic intra-operative staging using ultrasonography; Full CCTV and two-way audio link between theatre and seminar room, using the latest imaging and audio-visual technology.

Previous delegates on this course have benefited considerably from the practical mix of closely assisted tuition and demonstration, using the latest techniques and instrumentation.

For more details and an application form, please contact:
Miss Janice Wilkinson, Course Co-ordinator, KeyMed,
KeyMed House, Stock Road, Southend-on-Sea, Essex SS2 5QH.

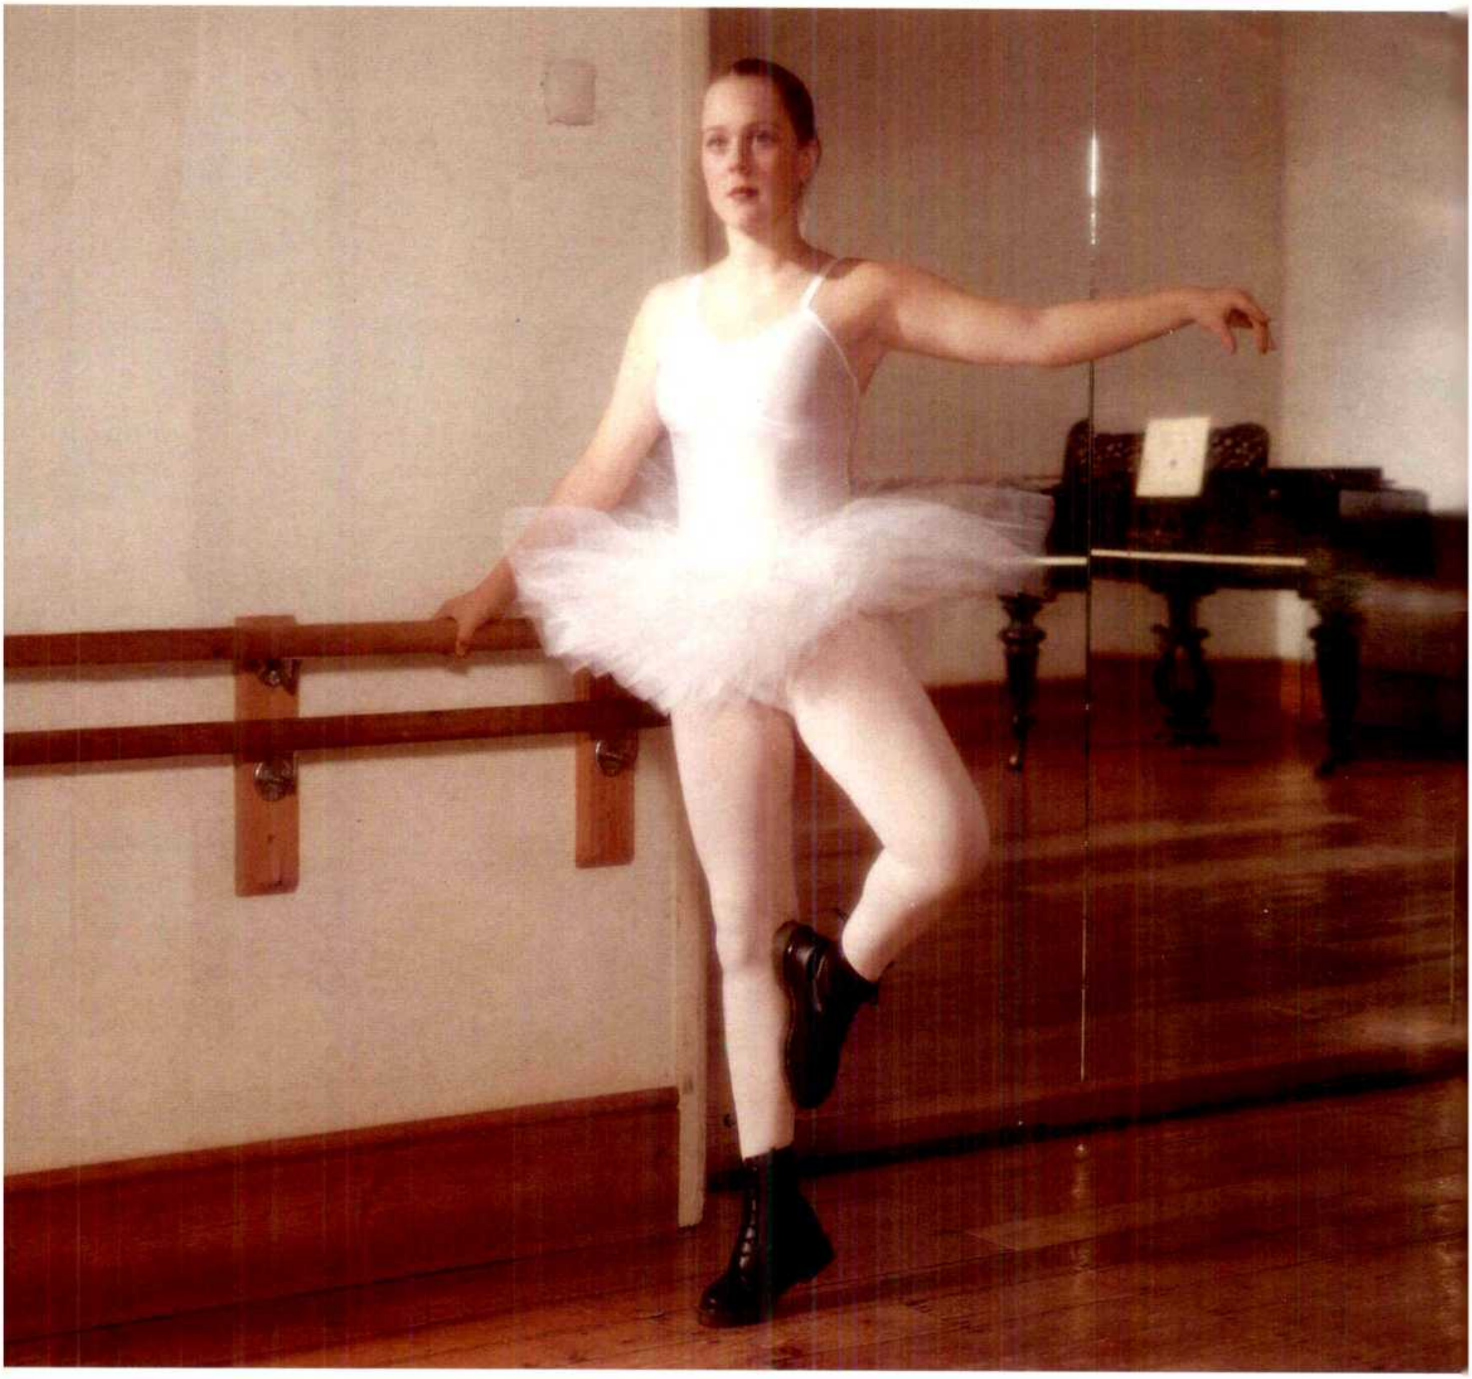
TO ACHIEVE THE PERFECT PERFORMANC
USE THE CORRECT EQUIPMENT.



Keeping in step with today's *ELECTROSURGICAL* procedures can be hard work without the correct equipment.

In fact, when it comes to the precision of minimal invasive surgery, your procedure can turn on the most delicate points – so you certainly won't want any sudden pirouettes during the performance.

Which is why it's good to know that with Eschmann products, your own expertise is backed by years of experience in surgical practices and *ELECTROSURGICAL* technology. We've also collected more than a few bouquets for our standards of performance and safety.

We can even choreograph our product range to suit the specialist concerned, including a choice of bipolar and monopolar generators, a wide range of output modes and an impressive list of accessories.

And since all Eschmann products are backed by the highest quality standards, full service back-up and a unique range of safety features… our name is likely to be music to your ears.

ESCHMANN
EQUIPMENT

YOU'RE NOT PROPERLY EQUIPPED WITHOUT US.

Eschmann Equipment Division, Peter Road, Lancing, West Sussex BN15 8TJ, England. Telephone (0903) 753322. Telex: 877075. Fax (0903) 766793.

Further Board Members from around the world.

Member of Council

MR CHRISTOPHER RUSSELL

(London)

Ronald Christopher Gordon Russell (born 1940) is a consultant surgeon at the Middlesex Hospital, London, where he graduated MB BS in 1963. Obtaining his FRCS in 1966 and MS (London) in 1979, he became a senior registrar at the Central Middlesex Hospital and later a consultant senior lecturer at St Mary's Hospital, London. His special interest is in hepatobiliary and pancreatic surgery. Chris Russell has been a loyal servant of *The British Journal of Surgery* for many years. He first joined the Editorial Committee and Council of the BJS Society in 1977, becoming Assistant Editor in 1978, Associate Editor in 1981 and then Joint Editor with David Carter from 1986 to 1991. We welcome him back to the Editorial Committee and Council and are counting on his further advice and support.

DR STEPHEN LOWRY

(USA)

Stephen F. Lowry (born 1947) is Professor of Surgery and Director of the Laboratory of Surgical Metabolism at Cornell University Medical College. He graduated from the University of Michigan in 1973 and completed his general surgical training at the University of Utah. He was a Clinical Associate and Investigator at the National Cancer Institute and a Surgical Fellow at the Memorial Sloan–Kettering Cancer Center, where he also holds an appointment. His research interests lie in nutritional biochemistry, oncology and infection; he has made several contributions to the emerging area of cytokine biology in surgical disease.

MR JACK COLLIN
(Oxford)

Jack Collin was born in 1945, qualified with Honours at Newcastle upon Tyne in 1968 and trained in Newcastle and the Mayo Clinic, USA. He is Reader in Surgery at the University of Oxford and a consultant surgeon at the John Radcliffe Hospital. At The Royal College of Surgeons of England he has been Arris and Gale Lecturer (1976), Jacksonian Prize winner (1976) and Hunterian Professor (1988). He has also been Moynihan Fellow (Association of Surgeons) and James IV Travelling Fellow. His clinical and research interests are in vascular surgery.

PROFESSOR ULF HAGLUND
(Sweden)

Ulf Haglund was born in 1944 and graduated from Göteborg University in 1971. He trained in Göteborg, where he obtained a PhD, then moved to Lund as Associate Professor (1982–1987). He took up his present post as Professor and Chief of Surgery at the University Hospital, Uppsala in 1988. His clinical interests are centred on the upper gastrointestinal and pancreatobiliary tracts, and he has a strong research interest in septic shock. He is current President of the Swedish Surgical Society.

Acute pancreatitis: the value of life

Those of us who work in the financially constrained and increasingly cost-conscious National Health Service are all too well aware of the increasing need to justify our use of resources. Two papers in this issue of the *Journal* address the important question of cost–benefit relationships in the treatment of patients with acute fulminant or necrotizing pancreatitis, a severe and life-threatening disease that is estimated to account for some 15 per cent of all attacks of acute pancreatitis[1]. In recent years there have been significant advances in our ability to detect and assess the severity of necrosis, notably by dynamic contrast-enhanced computed tomography (CT); improvements in patient care and surgical management have resulted in mortality rates that may be as low as 8 per cent[2] but which are generally of the order of 25 per cent[3]. These patients often remain grievously ill for prolonged periods, require intensive care and/or high-dependency nursing, and frequently need multiple operations and related procedures. Is it all worthwhile?

From the outset, it is incontestable that patients with acute necrotizing pancreatitis consume a great deal of resource. Fenton-Lee and Imrie[4] from Glasgow have attempted to cost the management of ten such patients admitted in the 12-month period to August 1991. The patients appear representative of UK practice in this context in that they had a median age of 63 years, gallstones were implicated in seven cases and alcohol in three, and all had severe disease on admission as assessed by scoring of prognostic factors. All had pancreatic or peripancreatic necrosis on bolus intravenous contrast-enhanced CT, although the extent of involvement was not defined, and in six patients there was proven infected necrosis. Consumption of resources was predictably high and was reflected in a median stay in intensive care of 7 days and a hospital stay ranging from 40 to 150 days. Our own record for hospital stay in such patients currently stands at 226 days, and I suspect that many readers will be able to furnish even more impressive evidence of the fortitude and indestructibility of the human organism.

With regard to costing, one still has misgivings about the current degree of sophistication of hospital cost computation in this country, feelings underlined by the admission that the cost of endoscopic procedures in the Glasgow experience was not available from the health board concerned. Nevertheless, within the limits of computational error, the total estimated cost per patient in the Glasgow series averaged no less than £18 441 (range £9296–£33 796), two-thirds of this being attributable to hospitalization excluding the cost of investigations, operations and procedures.

The Glasgow group also attempted to relate outcome to the quality of life achieved by patients by a brave foray into the minefield of the quality-adjusted life year (QALY). As always in such endeavours, one must take a great deal on trust. The key disability and distress index at the time of admission was assessed by the senior surgeon whereas, in the ideal world, a disinterested third party might be preferred. It is assumed that all patients would have died without treatment, a contention that might be challenged by some with respect to those with sterile necrosis[5], and that all patients who survived would have a normal life expectancy of 75 years, a postulate that might give rise to some doubts in the case of the 29-year-old Glasgow man with necrotizing pancreatitis attributable to alcohol. Within these stated restrictions, the authors estimated that the mean number of QALYs obtained was 8·55, at a mean cost per QALY of £2157. In my admittedly less than objective view as a surgeon with a major interest in pancreatic disease this seems a perfectly reasonable use of resources and one that the patients, their relatives and the community in general would almost certainly endorse. As with all blunt instruments, the analysis must be wielded carefully, and I have no doubt that recipients of renal transplants and their relatives would not warm to the notion that the management of acute necrotizing pancreatitis is 'more favourable' in cost–benefit terms than that of kidney transplantation at a 1988 price of £6072 per QALY gained.

The second paper dealing with this question moves away from the treacherous ground of QALYs to assess a series of Finnish patients an average of 6·2 years after an attack of fulminant pancreatitis[6]. The two patient populations are not strictly

0007-1323/93/121499–02 © 1993 Butterworth–Heinemann Ltd

comparable; the Finnish patients were recruited over a longer period, alcohol was the aetiological factor in three-quarters of cases and patients were younger. In addition, fewer than 60 per cent of the Finnish patients had severe disease on Ranson scoring and conservative treatment with peritoneal lavage was the mainstay of therapy, at least in the first instance. No fewer than one-third of patients died in hospital, underlining the potentially lethal nature of this disease. Of the 37 survivors assessed, 30 were regarded as in 'good' or 'normal' condition but, more reliably, 24 were working. Diabetes was present in 20 patients of whom nine needed insulin, and the paper emphasizes the fact that formal resection should now be avoided in favour of blunt necrosectomy if surgical intervention becomes necessary. Not only is resection the more dangerous option[3], it is clear that it often results in inappropriate removal of viable pancreas in patients who may prove to have little functional pancreatic reserve. These factors have particular importance in patients with alcohol-associated disease, in which it is now appreciated that there may be underlying chronic damage and that the gland often does not return to anatomical and functional normality. It is noteworthy that, of the patients with frank diabetes or abnormal glucose tolerance at follow-up in the Finnish experience, no fewer than 88 per cent had suffered from alcohol-associated pancreatitis.

It is clear that the great majority of patients can now be expected to survive an attack of acute necrotizing pancreatitis, and in my view the expenditure and use of resources seem eminently justifiable. Long-term survival and acceptable quality of life can be anticipated, and one must agree with the Finnish authors when they conclude that patients with acute fulminant pancreatitis are 'definitely worth treating'. In many ways the need to make such statements is a sad commentary on the current requirement to defend management decisions in an era when the accountant reigns supreme. It is now being debated whether some patients with 'self-inflicted' disease attributable to tobacco smoking or alcohol abuse should be denied treatment when resources are restricted. Patients with alcohol-induced pancreatitis are in danger of falling into this modern trap; it is salutary to learn that in the Finnish experience two-thirds of the previously heavy drinkers had either reduced their intake considerably or had become abstainers. Assuming that Finnish patients are to be trusted when asked about their alcohol consumption, it may be that surviving an attack of acute necrotizing pancreatitis leads to a radical adjustment of lifestyle which results in increased longevity and improved life quality. Life is surely so precious that resources must continue to be made available to patients with acute necrotizing pancreatitis.

'Damage control' in trauma surgery

The introduction of increasingly complex surgical solutions to severe truncal injuries was a salient feature of trauma surgery during the 1960s and 1970s. Major operations, such as formal hepatic resection or pancreatoduodenectomy, were reported with an acceptable mortality rate, reflecting the prevailing belief that complex surgery, when necessary, is a feasible option in difficult trauma situations. Advances in modern anaesthesia, autotransfusion and critical care contributed to this view.

During the past decade, it gradually became apparent that the results of these prolonged and extensive procedures in the critically injured were often poor, even in experienced hands[1]. Despite technological advance, the operating room remains a physiologically unfavourable environment for the severely injured patient. This is because laparotomy for major trauma involves dissipation of body heat and blood loss requiring massive replacement. The result is rapid development of hypothermia, coagulopathy and metabolic acidosis[2]. A vicious circle is set up in which these three elements augment each other, leading to death from an irreversible physiological insult[3]. The triad of hypothermia, coagulopathy and metabolic acidosis effectively marks the limit of the patient's ability to cope with the physiological consequences of injury; crossing this limit will frustrate even the most technically successful repair. Unfortunately, in severe trauma the time available for repair of injuries is inversely related to their severity.

These observations have led to the development of a new surgical strategy that sacrifices the completeness of the immediate repair so as adequately to address the combined physiological impact of trauma and surgery. During the initial operation, the surgeon does only the absolute minimum necessary rapidly to control exsanguination and to prevent spillage of intestinal content and urine into the peritoneal cavity. Complex or time-consuming procedures, such as formal resection and reconstruction, are deliberately avoided in haemodynamically unstable patients[4]. Definitive repair of the injured organs is postponed until reoperation can be performed on a stable, non-bleeding and warm patient with optimized oxygen delivery. This management concept has been termed 'damage control' or 'planned reoperation'.

Techniques for abbreviating the surgical procedure in unstable patients are very straightforward. One traditional method for the management of major liver injuries is packing. There is no reason why the same method should not apply to other technically challenging situations such as retrohepatic venous injury[5] or retroperitoneal and pelvic haemorrhage[6]. Examples of simple techniques to buy time besides packing include temporary closure of the lumen of injured bowel without resection[4], tying off or rapid exteriorization of an injured ureter, non-anatomical lung resection with a linear stapler, insertion of temporary vascular shunts[7] and balloon tamponade of bleeding cavities or inaccessible vessels[8]. Since the patient will require reoperation, formal closure of the chest or abdomen is unnecessary; skin closure using only a running stitch or towel clips saves valuable time[9]. The fascia is left untouched and preserved until a later formal closure. In some patients, massive visceral oedema will prevent skin approximation. Under these circumstances, temporary abdominal closure with a soft plastic sheet[4,9] or synthetic mesh[10] is the only practical option.

Despite its simplicity and logic, this new approach is being adopted only slowly. This is because the abrupt termination of an operation to prevent an as yet unapparent physiological insult seems to contrast with traditional surgical values. It is only during the past 2 years that reports have started to emerge on the use of 'damage control'[4,6,9–12].

The original application of this concept was in critically ill patients who already exhibit intraoperative warning signs such as coagulopathy, indicating that they are approaching or have passed their physiological limits. It seems that the key to successful application of the planned reoperation approach hinges on an early decision to employ it within the first few minutes of the initial operation, when the surgeon estimates that the patient will not tolerate a definitive procedure. This decision must be based on realistic evaluation of the extent of the necessary repair and of the patient's physiological reserves.

Adoption of this new management strategy brings with it a host of medical and logistic problems. Accident and emergency referral centres must make arrangements for a strategy that includes a quick primary operation followed by a prolonged stay

0007-1323/93/121501-02 © 1993 Butterworth-Heinemann Ltd

in the intensive care unit and planned – or sometimes unplanned – reoperation(s). Some patients continue to bleed after surgery, requiring a decision about the feasibility of re-exploration. In others, increased intra-abdominal pressure from distended and oedematous bowel impairs ventilation and renal function, requiring immediate decompression[12,13]. All of this translates into a vast investment of hospital resources in a small group of severely injured patients and, although the results obtained using the new approach are superior to those of the traditional method, the mortality rate is still 30 per cent or higher[4,6,10–12].

The principles of planned reoperation for trauma are eminently applicable to hospitals in rural areas, to surgeons who encounter major trauma infrequently, and to field surgery during war. A short life-saving procedure, followed by transfer to an accident and emergency referral centre for continued management and planned reoperation, is clearly in the patient's best interest under these circumstances.

The new 'damage control' concept is likely to modify the management of the critically injured. Surgeons from all specialties involved in trauma care will adapt to the new strategy by developing appropriate surgical solutions for injuries in their respective fields. All medical personnel caring for wounded patients should be familiar with this new concept and its surgical and logistic implications.

Role of the leucocyte in the pathogenesis of vascular disease

The leucocyte plays a key role in the local and systemic tissue injury that results from peripheral arterial disease and chronic venous insufficiency. Despite the apparent dissimilarities between limb ischaemia and chronic venous ulceration, in both diseases macrovascular abnormalities lead to microvascular leucocyte trapping and activation. Activated leucocytes adhere to and damage adjacent endothelium by expressing adhesion molecules and releasing harmful moieties such as proteases and free radicals. Subsequent loss of endothelial integrity and the migration of activated leucocytes outwith the circulation leads to destruction of surrounding tissue. Leucocytes and their products are also involved in the systemic manifestations of ischaemia such as multiple organ failure and coagulopathy. An overview of leucocyte biology as it pertains to peripheral arterial and venous disease is presented. The opportunities for novel therapeutic interventions based on a better understanding of this biology are also discussed.

A. W. Bradbury,
J. A. Murie and
C. V. Ruckley

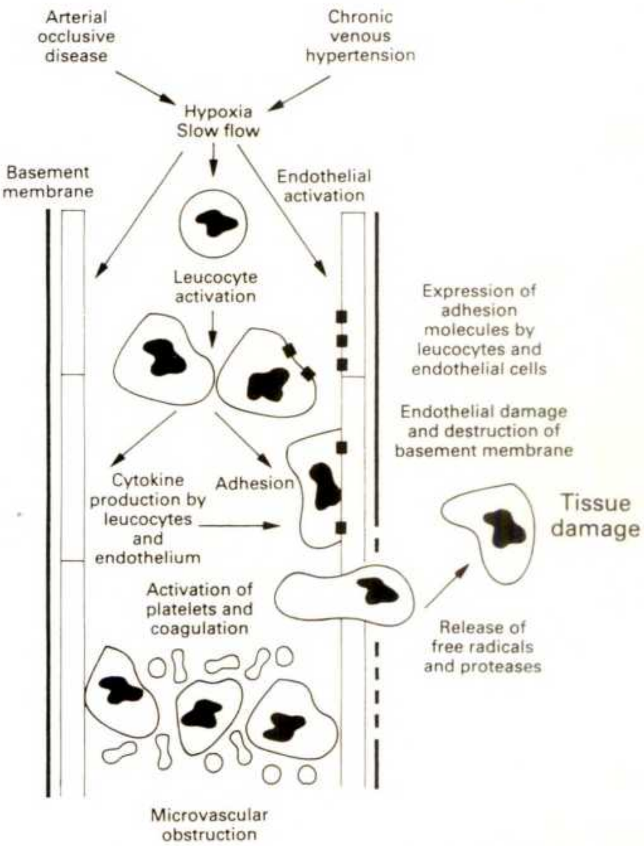
Vascular Surgery Unit, University Department of Clinical Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK

Correspondence to:
Mr A. W. Bradbury

Little is known of how peripheral arterial disease and chronic venous insufficiency lead to the local tissue destruction seen so commonly in everyday clinical practice. The systemic manifestations of vascular disease such as multiple organ failure and coagulopathy are also poorly understood. It is thus not surprising that our ability to limit these processes, while corrective surgical measures are undertaken, is extremely restricted. For example, compression therapy for venous ulceration is associated with a high rate of recurrence[1], and for the majority of patients with critical limb ischaemia the only hope of arresting progressive tissue loss rests with some form of local surgical reconstruction. Nevertheless, the commonly observed mortality from myocardial infarction and stroke in patients with peripheral arterial disease clearly indicates that this is a generalized condition that requires systemic treatment[2].

Increasing evidence points to a central role for abnormal leucocyte–endothelial cell interactions in the pathogenesis of, and tissue destruction resulting from, these conditions[3–5]. Although the present review deals solely with peripheral arterial and venous disease it is likely that similar mechanisms are involved in myocardial and cerebral ischaemia. It has been known for some time that a raised white cell count is associated with vascular disease in the coronary, cerebral and peripheral circulations[6,7]. This association appears to be independent of other known risk factors, such as smoking, that also promote leucocytosis[8]. More recently, it has been discovered that leucocytes are sequestered in ischaemic muscle and in the legs of patients with chronic venous insufficiency (*Figure 1*). In both situations sequestration is postulated to lead to (or result from) activation of leucocytes, which in turn results in the generation of free radicals[9], proteases, histamine[10], neutrophil chemoattractants[11] and complement[12]. These substances destroy the endothelium and its basement membrane, increase vascular permeability and derange microcirculatory flow[13,14]. Such chronic recurring inflammation may also be important in the development of atherosclerosis itself[15,16]. Activated leucocytes also interact with platelets, erythrocytes and components of the coagulation–fibrinolysis pathways to promote microvascular thrombosis[17,18]. Leucocytes also mediate the systemic complications of vascular disease such as adult respiratory distress syndrome (ARDS)[19–21], endotoxaemia[22] and disseminated intravascular coagulation[23]. Activated endothelial cells play an equally important role in these pathological processes by releasing substances such as platelet-activating factor (PAF), thromboxanes and cytokines that attract and activate leucocytes and platelets.

It is the aim of this paper to review leucocyte biology as it pertains to the pathogenesis of local and systemic tissue damage



Arterial occlusive disease
Chronic venous hypertension
Hypoxia Slow flow
Basement membrane
Endothelial activation
Leucocyte activation
Expression of adhesion molecules by leucocytes and endothelial cells
Endothelial damage and destruction of basement membrane
Cytokine production by leucocytes and endothelium
Adhesion
Tissue damage
Activation of platelets and coagulation
Release of free radicals and proteases
Microvascular obstruction

consequent on peripheral arterial disease and chronic venous insufficiency. In particular, novel therapeutic interventions that might act through modifying leucocyte activity are discussed.

Leucocyte–endothelial cell pathophysiology

A complex and finely balanced relationship exists between the cellular and humoral components of blood and the endothelial cells that line the vasculature. This relationship plays a vital role in preserving normal blood flow and in orchestrating appropriate, as well as preventing inappropriate and potentially harmful, inflammatory and thrombotic responses[24].

Mononuclear and polymorphonuclear leucocytes

Mononuclear phagocytes arise in the bone marrow, circulate in the blood as monocytes and then enter the tissues to become macrophages. Both cell types may become activated in response to a variety of stimuli, following which they are capable of phagocytosing and destroying antigen. Activated cells also present antigen to lymphocytes, so allowing a specific immune response to be initiated. Polymorphonuclear granulocytes account for 50–70 per cent of all circulating leucocytes and neutrophils comprise 90 per cent of all granulocytes. Like mononuclear cells, neutrophils normally circulate in a quiescent state but when activated are capable of adhering to endothelium, entering tissues and releasing a variety of noxious substances recognized for their ability to cause tissue damage. For example, neutrophil elastase digests elastin, fibronectin, fibrinogen and collagen, and leads to destruction of the basement membrane, increased endothelial adhesiveness and permeability and oedema. In addition, because they are much less deformable than erythrocytes[25,26] and because they adhere to endothelial cells[27,28], activated leucocytes may obstruct the microvasculature[29,30].

Endothelial cells

Endothelial cells release a wide range of biologically active factors such as endothelium-derived relaxing factor (EDRF), which relaxes smooth muscle[31], endothelin, a powerful vasoconstrictor[32], thrombomodulin and prostacyclin, which maintain a non-coagulant surface[33], cytokines, such as interleukin (IL) 1, which attract and activate leucocytes, and adhesion molecules that mediate interaction with leucocytes. Together these moieties control blood flow, coagulation and fibrinolysis, as well as leucocyte margination, activation and diapedesis. Some or all of these properties may be lost or modified in the presence of hypoxia and in low-flow states[34–36].

Cytokines

The cytokines are a family of low molecular weight peptides that are released by and act on a wide range of cells including leucocytes and endothelial cells[37,38]. They play a central role in generation of the inappropriate inflammatory responses resulting from the abnormal leucocyte–endothelial cell interactions present in vascular disease. For example, IL-1 and tumour necrosis factor (TNF) are released from activated mononuclear cells and act on endothelial cells to suppress anticoagulant activity, induce procoagulant activity and promote the production of PAF, colony-stimulating factor (CSF)[39] and IL-6[40]. IL-1 causes neutrophilia, thrombocytosis[41] and vasodilatation through stimulating endothelial cells to produce nitric oxide and EDRF[42]. IL-1 is also implicated in the pathogenesis of atherosclerosis through promoting vascular smooth muscle proliferation and the formation of fatty plaques[43]. TNF increases endothelial cell susceptibility to immune attack, is directly toxic to capillary endothelium[44], promotes the release of CSF by endothelial cells and is angiogenic[45]. Both IL-1 and TNF stimulate neutrophil and lymphocyte adhesion to endothelial cells[46,47]. They also stimulate transendothelial migration of neutrophils and act as modulators of prostacyclin synthesis by endothelial cells[48]. IL-2 may increase prostacyclin synthesis and enhance leucocyte adhesion and endothelial cell growth. IL-4 may be an important regulator of endothelial cell morphology and proliferation as well as acting as a potent lymphocyte growth factor[49]. IL-6 is produced by endothelial cells in response to IL-1 and TNF, and is a major stimulus of the acute-phase response. IL-6 also primes neutrophils for their respiratory burst and release of free radicals[50]. This interleukin is likely, therefore, to be important in the pathogenesis of the systemic manifestations of ischaemia[51]. IL-8 may also be important in the development of such systemic manifestations. Cultured endothelial cells have receptors for transforming growth factors and these peptides appear to have an inhibitory action on endothelial cell growth, as well as reducing the increase in adhesivity of endothelial cells for leucocytes caused by IL-1 and TNF. Endothelial cells also produce interferons, in response to which they increase expression of the class I major histocompatibility antigens and their adhesivity for lymphocytes. Interferons also inhibit endothelial cell growth and induce the expression of other cytokines, complement factors and adhesion molecules. Granulocyte and monocyte CSF are mitogenic for endothelial cells[52].

Complement

The complement cascade is a series of plasma proteins that are sequentially activated by a range of stimuli such as bacterial infection and tissue hypoxia. Two main products, the anaphylotoxins C3a and C5a, increase vascular permeability, activate leucocytes and interact with the kinin, coagulation and fibrinolytic systems to promote intravascular thrombosis and inflammation. Complement activation may also be important in the systemic effects of ischaemia such as ARDS[53]. Ischaemia–reperfusion injury of skeletal muscle also results in the activation of complement[54,55].

Adhesion molecules

Leucocytes and endothelial cells express adhesion molecules that control leucocyte adhesion within the circulation and migration into perivascular tissue[56–61]. Adhesion molecules on leucocytes comprise the selectins and integrins, whereas endothelial cells express selectins and adhesion proteins belonging to the immunoglobulin family[62]. Binding of adhesion molecules is also the trigger for leucocyte degranulation, the oxidative burst and generation of free radicals[63]. Expression of adhesion molecules changes rapidly with the activation status of both leucocytes and endothelial cells[64]. For example, stimulation of neutrophils by chemoattractants rapidly activates the integrins and endothelial expression of adhesion molecules is increased by thrombin[65] and various cytokines such as IL-1 and TNF[66]. Expression of adhesion molecules leads to leucocyte emigration within inflamed vessels *in vivo*[67]. Adhesion molecules may also be shed from the cell and increased levels are found in the serum of patients with septic shock; in these circumstances they may be a measure of excessive or inappropriate endothelial or leucocyte activation[68].

Free radicals

Free radicals are generated by phagocytes, through the action of membrane-bound oxidases and myeloperoxidase, and by endothelial cells through the action of xanthine oxidase, which is formed from xanthine dehydrogenase in hypoxic conditions. As ischaemia progresses, adenosine 5′-triphosphate is degraded to hypoxanthine. This is then converted to uric acid by xanthine oxidase with production of the highly reactive superoxide anion. Free radical damage may be particularly important during reperfusion of ischaemic muscle or skin as levels of xanthine and oxygen are both high at this time.

Free radicals damage cells through peroxidation of membrane phospholipids and denaturation of macromolecules[69]. Free radicals impair endothelial function by reducing prostacyclin and increasing thromboxane production, promoting the breakdown of EDRF, inhibiting antithrombin III activity and promoting cholesterol deposition[70]. Free radicals may therefore be involved in both acute and chronic arterial disease[71]. Free radical toxicity is normally limited by scavengers such as superoxide dismutase, glutathione and caeruloplasmin. In ischaemic tissue, levels of these protective substances are reduced and evidence of excess lipid peroxidation and increased plasma viscosity can be detected in patients with peripheral vascular disease. For example, limb swelling after femoropopliteal bypass has been attributed to the generation of free radicals[72]. Free radicals may also be involved in the pathogenesis of venous ulceration[73].

Platelets

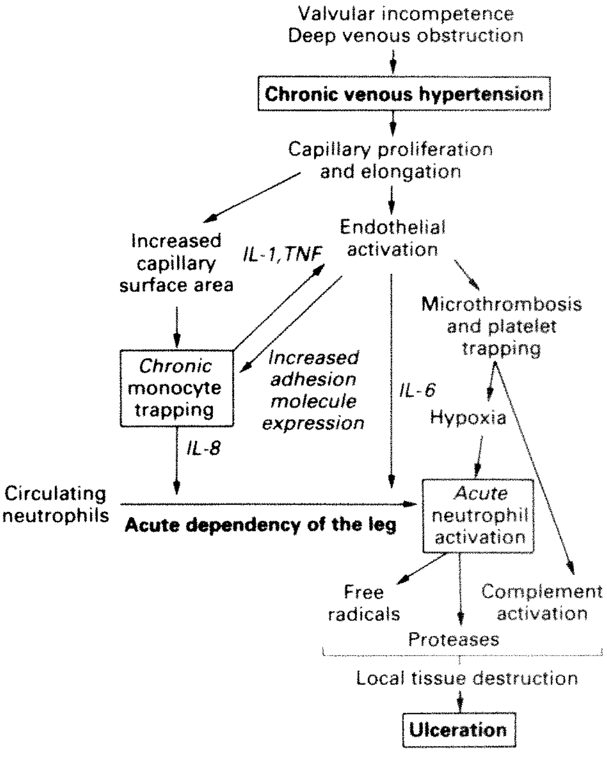
There is a complex interaction between platelets, leucocytes and endothelial cells in both health and disease[74]. Normal endothelial cells produce a range of 'protective' moieties such as prostacyclin, EDRF, adenosine diphosphatase and thrombomodulin that prevent platelet adhesion. Although EDRF production is constitutive it is also inducible by cytokines[75] such as IL-2. EDRF production is reduced in peripheral vascular disease because of both decreased synthesis and increased degradation such that vessels are incapable of endothelium-dependent vasodilatation. Adenosine diphosphatase breaks down adenosine 5'-diphosphate, a powerful cofactor in platelet stimulation by plasmin, to inactive adenosine 5'-monophosphate[76]. Thrombomodulin is an endothelial cell surface protein that inactivates thrombin, so preventing it from activating platelets, and activates protein C, a natural anticoagulant[77]. By contrast, platelets bind readily to damaged endothelial cells and subendothelial tissue. Adhesion is partly dependent on expression by endothelial cells of platelet–endothelial cell adhesion molecules[78]. Platelets also bind to endothelial cells indirectly by first adhering to activated neutrophils and monocytes, which in turn bind to endothelial cells via their own adhesion molecules[79]. Platelets also influence endothelial cell function by generating vasoactive substances such as lipoxin A_4, a vasodilator, and leukotriene C_4, a vasoconstrictor, from neutrophil precursors[80]. Platelets release plasminogen activator inhibitor 1, which neutralizes endothelium-derived plasminogen activator so reducing fibrinolysis. Platelet activation also enhances the production of endothelin 1 from activated endothelial cells. Endothelin 1 is a powerful vasoconstrictor and its levels are raised in atherosclerosis[81]. Activation of endothelial cells leads to the release of PAF, which causes vasoconstriction, platelet aggregation, and platelet and neutrophil adhesion to endothelial cells[82].

Venous disease

Venous ulceration results from sustained venous hypertension, which in turn arises from deep and/or superficial valvular incompetence. These macrovascular abnormalities lead to disruption of the microvasculature and a wide variety of abnormalities have been described in the tissues surrounding venous ulcers[83]. Dermal capillaries become tortuous and elongated (and thus may appear more numerous) and so present an increased surface area of endothelium to the circulating blood[84,85]. Intravascular thrombosis and platelet trapping[86], pericyte disruption[87], increased capillary permeability and abnormalities of lymphatic drainage have also been described. How these abnormalities are related to the process of skin ulceration is uncertain. The validity of early theories implicating skin hypoxia secondary to either stagnant desaturation, arteriovenous shunting or the formation of a fibrin cuff has been questioned[88–90]. More recently, it has been discovered that normal subjects sequester white cells in the legs if these are held dependent and motionless[91]. In similar studies patients with chronic venous insufficiency trapped far more leucocytes than normal controls[92]. This led to the proposal that venous hypertension leads to morphological changes in the microvasculature such that leucocytes are trapped and activated[3]. Trapped cells are poorly deformable, adhere to activated and damaged endothelium, and release proteolytic enzymes and free radicals that are directly harmful to tissues. This process has been likened to a form of ischaemia–reperfusion injury. Interestingly, compression hosiery appears to reduce leucocyte trapping within the leg, although it is not clear how this is achieved. The precise mechanism by which leucocytes become trapped within the legs of patients with chronic venous insufficiency and ulceration remains poorly defined. It is uncertain, for instance, whether leucocytes enter an abnormal microcirculation and become activated *in situ* or whether there is a degree of systemic activation that predisposes them to trapping within the leg. It is also unclear whether the trapped cells are predominantly monocytes or neutrophils. Most studies to date have examined leucocytes derived from the venous outflow of the leg, although it would not be unreasonable to presume that the maximally activated leucocytes, and thus those most worthy of study, remain in the affected area. Furthermore, although derangement of endothelial function is likely to be the primary abnormality, endothelial cell biology has been the subject of relatively little study. Immunohistochemical studies have confirmed that there is an excess number of leucocytes, predominantly monocytes and lymphocytes, in the skin of the gaiter area of patients with lipodermatosclerosis and healed venous ulcers[93,94]. However, in acute experimental venous hypertension, levels of products specific to neutrophil activation such as lactoferrin are raised in the effluent blood. One might therefore speculate that venous hypertension results in *chronic* monocyte trapping in the postcapillary venules of the leg, which in turn leads to generation of a range of cytokines that, perhaps following dependency, causes *acute* recruitment of neutrophils and subsequent tissue damage (*Figure 2*). Monocytes also appear to use neutrophils as the final instruments of tissue destruction in ischaemic tissue damage, as discussed below. Further studies examining the local milieu in terms of cytokine and adhesion molecule expression by leucocytes and endothelial cells are required to clarify these points.

Arterial disease

In addition to the macroscopically apparent effects of atherosclerosis, vascular spasm, platelet thrombus and embolism, ischaemic tissue damage occurs as a result of



Valvular incompetence
Deep venous obstruction
Chronic venous hypertension
Capillary proliferation and elongation
Increased capillary surface area
Endothelial activation
IL-1, TNF
Microthrombosis and platelet trapping
Chronic monocyte trapping
Increased adhesion molecule expression
IL-6
Hypoxia
IL-8
Circulating neutrophils
Acute dependency of the leg
Acute neutrophil activation
Free radicals
Complement activation
Proteases
Local tissue destruction
Ulceration

Figure 2 *The pathogenesis of venous ulceration: a hypothesis. IL, interleukin; TNF, tumour necrosis factor*

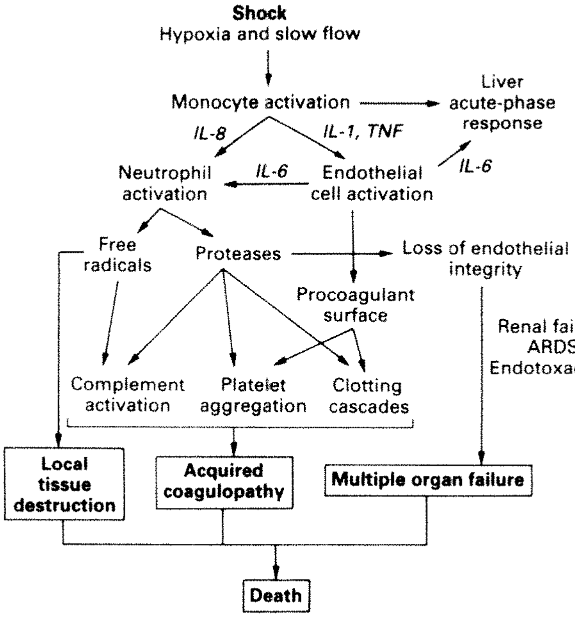


Figure 3 *The pathogenesis of multiple organ failure and coagulopathy in patients with ruptured aortic aneurysm: a hypothesis. IL, interleukin; TNF, tumour necrosis factor; ARDS, adult respiratory distress syndrome*

microvascular changes not unlike those found in chronic venous insufficiency. Although it has been known for many years that ischaemic infarction is associated with rapid neutrophil accumulation, recent evidence suggests a wider and earlier role for leucocytes in ischaemic disease. There is good evidence for a state of chronic white cell activation in patients with arterial disease; raised plasma thiol and thromboxane levels, an increased leucocyte count, depressed fibrinolytic activity, and activation of complement and free radicals are found both before and after prosthetic vascular reconstruction[95]. The histamine and alkaline phosphatase content of leucocytes is increased in ischaemic disease[10]. Patients with vascular disease therefore suffer from a prolonged but low-grade 'acute-phase reaction'[96]. As in venous disease, one of the key events in ischaemic tissue damage appears to be microvascular obstruction by activated leucocytes. Neutrophils are 2000 times less deformable than red blood cells and in ischaemic conditions extend pseudopodia, aggregate and demonstrate increased endothelial adhesiveness[97]. Once lodged in the microcirculation, activated neutrophils cause loss of endothelial integrity, secondary thrombosis and irreversible vessel occlusion.

In animal models neutrophil rolling, endothelial swelling and vascular leakage occur following experimentally induced claudication. Similar changes are seen in the contralateral unaffected leg, suggesting a systemic response to local ischaemia[98]. In patients with intermittent claudication, exercise is associated with increased urinary albumin excretion (a reflection of vascular permeability), decreased neutrophil filterability, and increased serum lysozyme activity[99,100]. Claudicants demonstrate a rise in levels of serum thromboxane A_2 and urinary thromboxane metabolites after exercise[101,102]. Calf pain in patients with claudication is associated with a significant decrease in leucocyte deformability[103,104]. These exercise-related manifestations of systemic inflammation and neutrophil activation disappear after successful arterial bypass. Patients with critical limb ischaemia leading to amputation also demonstrate neutrophil activation and loss of deformability[105,106]. White cell rheology returns to normal following surgery and healing.

In addition to the period of ischaemia it is clear that significant tissue damage is sustained following reperfusion. Thus, even after apparently successful revascularization, muscle ischaemia and infarction may progress[107]. Revascularization also flushes harmful leucocyte products into the systemic circulation. These undoubtedly contribute to multiple organ failure, which may account for up to 20 per cent of postoperative deaths associated with emergency vascular surgery[108]. Patients undergoing aortic aneurysm surgery, both electively and as an emergency for rupture, show evidence of leucocyte activation. Baigrie and colleagues[109] examined plasma levels of IL-1, IL-6 and TNF in 22 patients undergoing elective aneurysm repair and found that a brief rise in IL-1 concentration preceded an IL-6 response. Three patients who developed postoperative complications showed significantly higher IL-6 responses. IL-6 levels also correlated with acute physiology scores. This study was unable to show a rise in TNF concentration. The authors postulated that IL-6 levels might prove to be a useful predictor of outcome. In a further study[110] the same authors reported increased levels of IL-6 in portal venous blood but found no clear relationship with portal endotoxaemia. This led them to conclude that the portal circulation draining the colon was a major source of the previously observed systemic rise in IL-6 levels. Elective aortic aneurysm repair is associated with an increase in urinary albumin excretion, indicating a generalized increase in vascular permeability. This rise correlated with the development of pulmonary complications[111]. Aortic surgery is also associated with a rise in systemic thromboxane levels. In a series of 38 patients randomized to receive mannitol or saline before cross-clamping, mannitol reduced neutrophil activation (as measured by free radical production), thromboxane production and postoperative rises in creatinine level and pulmonary shunting[112]. Soong and colleagues[113] found that diarrhoea after aneurysm surgery was associated with low intramucosal pH and high serum endotoxin and TNF levels.

Complex acquired coagulopathies also develop following aortic aneurysm rupture, and thrombocytopenia and a raised prothrombin ratio are associated with a greatly increased postoperative mortality rate[114]. Although the basis of this coagulopathy is poorly understood, the release of leucocytes and leucocyte products from ischaemic tissue is strongly implicated[115]. Clotting is only one of several cascades that proceed through the sequential activation of proteolytic enzymes on leucocyte, and particularly monocyte, membranes[116]. With respect to ruptured aortic aneurysm it is postulated[117] that shock may cause activation of monocytes and the release of IL-1, IL-8 and TNF. This in turn leads to the recruitment and activation of neutrophils and endothelial cells[118]. Activated endothelial cells and leucocytes inappropriately activate circulating platelets and clotting cascades to produce disseminated intravascular coagulation[119]. Neutrophil elastase increases the adhesivity and procoagulant activity of endothelial cells and activates complement. The end result is local tissue destruction, coagulopathy and multiple organ failure (*Figure 3*).

Therapeutic intervention

Peripheral arterial disease and chronic venous insufficiency appear, at least superficially, to be very different. However, in terms of the pathological processes leading to tissue damage they clearly share important features. In both conditions primary macrocirculatory disease results in secondary microcirculatory changes that cause leucocyte and endothelial cell activation. Furthermore, in both diseases reperfusion may be as damaging as ischaemia. The effects of both arterial and venous disease may therefore be successfully ameliorated by normalizing leucocyte and endothelial cell function. Several drugs in current use, such as heparin, warfarin and aspirin, may indirectly affect leucocyte function, but this is not perceived as their main therapeutic action[120]. A number of newer therapies aimed specifically at modulating leucocyte–endothelial interaction are now being evaluated[121–124].

Inhibition of leucocyte adhesion

Monoclonal antibodies to adhesion molecules have been used to prevent neutrophil adhesion and so attenuate ischaemia–

reperfusion injury[125]. The antibody 60.3 directed against the human neutrophil adhesion molecule CD18 reduces neutrophil-mediated endothelial cell damage *in vitro* and *in vivo*. Antibody treatment reduces the incidence of multiple organ damage and improves survival in animal models of ischaemia–reperfusion injury including primates subjected to haemorrhagic shock followed by fluid resuscitation[126], a situation akin to ruptured aortic aneurysm. Perhaps surprisingly, treatment does not appear to increase the mortality rate from septic shock in animals with abdominal sepsis[127]. Elastase inhibitors and selective platelet depletion also reduce neutrophil adhesion and accumulation in ischaemic tissue[128,129].

Antiplatelet strategies

The most well known antiplatelet strategy modifies prostanoid synthesis such that prostacyclin release is augmented while thromboxane/leukotriene synthesis is relatively reduced[130]. This is discussed separately below. Another possibility is to use PAF antagonists[131]. PAF levels are raised in ischaemia of many organs including the brain, liver, mesentery, heart and lung. PAF increases neutrophil chemotaxis, adhesion to endothelial cells, and elastase and free radical production[132–135]. PAF antagonists protect animals from the consequences of shock caused by haemorrhage, septicaemia, burns and visceral ischaemia[136].

Secondary messenger modulation

Platelet and leucocyte–endothelial cell interactions may also be affected by manipulating secondary messenger systems. Protein kinase C (PKC) mediates the effects of several ligands on platelets and endothelium and, as the enzyme exists as a number of isozymes, it may be possible to develop selective inhibitors[137]. The activation of endothelial cells by IL-1 and TNF is mediated by PKC, and a specific inhibitor (H-7) reduced the adherence of polymorphonuclear leucocytes to IL-1- and TNF-stimulated human endothelial cells *in vitro*[138]. Adenosine 3′,5′-cyclic monophosphate (cAMP)-dependent protein kinase is also implicated in the control of adhesion molecule expression and its different isoforms are selectively inhibited and stimulated by various cAMP analogues[139,140].

Prostaglandin analogues

Protaglandin analogues possess a number of actions that would seem beneficial in arterial disease. They exert an antiatherosclerotic action through inhibiting smooth muscle and fibroblast proliferation by suppressing the release of growth factors from endothelial cells and leucocytes[141,142]. They possess profibrinolytic and antithrombotic properties, inhibit intimal cholesterol accumulation in the vascular wall[143] and inhibit neutrophil degranulation, free radical production, chemotaxis, adhesion and neutrophil-dependent thrombosis and platelet activation[144–150]. They also exert a direct cytoprotective effect on endothelial cells by reducing calcium influx, oxidative metabolism and the production of toxic metabolites[151], and by preventing the hypoxia-induced loss of endothelial defences such as reduced EDRF and prostacyclin production[152–154]. In summary, prostacyclin analogues may preserve function in the hypoxic microvasculature through limiting leucocyte activation and endothelial cell dysfunction. In a multicentre randomized double-blind controlled trial, the prostaglandin (PG)I_2 analogue iloprost was found to be significantly better than placebo in terms of the requirement for amputation in 151 patients with ischaemic ulcers and gangrene[155]. Similar trials have reported reduced amputation and mortality rates following treatment with iloprost in patients with critical limb ischaemia[156,157]. Prostanoids may also be of value in other clinical settings. For example, PGE_1 may attenuate the abnormalities seen in lung function after aortic surgery[158], and iloprost may improve graft flow following femorodistal bypass[159,160] and be of value in chemotherapy-induced digital ischaemia[161]. Another way of modulating prostanoid levels is through the use of thromboxane synthetase and lipo-oxygenase inhibitors, and thromboxane and leukotriene antagonists[162]. The thromboxane synthetase inhibitor OKY-046 and the lipo-oxygenase inhibitor diethylcarbamazine were found to reduce white cell activation and infarct size in an animal model of limb ischaemia[11,163].

Endothelium-derived relaxing factor

Treatment with L-arginine, the substrate for nitric oxide synthetase in the production of EDRF, has been reported to correct endothelial cell dysfunction in an animal model of atherosclerosis[164] and in patients[165]. In addition, as EDRF is inactivated by free radicals, antioxidant agents may also improve endothelial cell function by increasing EDRF activity[166]. Nitric oxide, which is thought to be (or at least very closely related to) EDRF, has recently been reported to be of clinical benefit in patients with ARDS[167]. It is postulated that nitric oxide may act not only through its vasodilator action but also by inhibiting the neutrophil-, platelet- and cytokine-dependent 'systemic inflammatory response syndrome' that accompanies a range of severe illnesses including ischaemia[168].

Free radical inhibition

Various methods of limiting free radical injury have been evaluated including control of reperfusion flow and oxygenation, use of free radical scavengers and intervention aimed at preventing, or at least limiting, leucocyte and/or endothelial cell activation[169] (*Table 1*). In a recent animal study haemofiltration using a combination of mannitol, superoxide dismutase, methylprednisolone, heparin and α-tocopherol (a free radical scavenger) was found to protect against reperfusion renal failure and muscle damage after ligation of the aorta and inferior vena cava[170]. In another study the radical scavenger oxpentifylline was found to be significantly better than placebo in reducing recovery time, as measured by transcutaneous oxygen tension, in a group of 30 patients with intermittent claudication. These effects were also associated with a significant improvement in leucocyte filterability, leucocyte pseudopodia formation and serum oxidant activity[176]. Free radical inhibition may also be of value in preventing the systemic manifestations of ischaemia. Allopurinol inhibited arteriolar disruption in a mesenteric ischaemia–reperfusion model[177] and mannitol has been shown to be effective in limiting the neutrophil activation that follows aortic surgery. This is thought to result from inhibition of thromboxane synthesis initiated by free radicals released from ischaemic tissue[180]. Allopurinol and another scavenger, dimethyl sulphoxide, may also be of value in the treatment of venous ulceration. In a double-blind controlled study, use of these drugs with compression bandaging healed over 93 per cent of ulcers at 3 months compared with only 70 per cent of ulcers treated with compression therapy alone[73].

Oxpentifylline

Oxpentifylline, a drug that has been advocated for the treatment of both arterial and venous ulcer disease, appears to modulate

Table 1 *Methods of preventing ischaemia–reperfusion injury*

Control of reperfusion flow and oxygenation[170]
Free radical scavengers (mannitol, prednisolone, heparin, superoxide dismutase, vitamin E)[171,172]
Xanthine oxidase inhibitors (allopurinol)[73]
Haemofiltration[172]
Adhesion molecule blockade by specific antibodies[173]
Leucocyte depletion[174,175]
Inhibition of leucocyte activation[122,124]
Inhibition of free radical production[176,177]
Inhibition of leucocyte–endothelial cell adhesion[126,148]
Inhibition of thromboxane production[162,178]
Prostacyclin infusion[11,179]
Complement activation inhibition by cobra venom[54]

Table 2 *Actions of oxpentifylline*

Increases mononuclear phagocyte and granulocyte filterability through artificial membranes[185]
Reduces leucocyte–endothelial cell adhesion[186]
Inhibits thrombin- and complement-induced leucocyte adherence to endothelial cells[187]
Inhibits free radical production[187]
Inhibits phagocytosis[188]
Inhibits the ability of platelet-activating factor to activate neutrophils[189]
Inhibits the activating and adhesion-promoting effects of cytokines (tumour necrosis factor, interleukin 2)[184,190] on leucocytes *in vitro* and *in vivo*
Inhibits endotoxin-induced pulmonary neutrophil sequestration[191]
Inhibits platelet aggregation through changes in adenosine 3′,5′-cyclic monophosphate levels, reduction in thromboxane and increase in prostacyclin synthesis[192]
Increases red blood cell deformability[192]
Decreases blood fibrinogen level, and whole blood and plasma viscosity[192]
Inhibits platelet adhesion to vascular endothelium[193]
Reduces endothelial permeability[193]
Increases fibrinolysis[194]

leucocyte and endothelial cell function through a number of different mechanisms[181–184] (*Table 2*). Several early studies indicated that oxpentifylline can improve ankle artery blood pressure, walking distance, rest pain, and muscle blood flow and oxygenation in patients with arterial occlusive disease. However, it has been argued that many of these studies are small and poorly designed, and oxpentifylline is not widely used in the UK for the treatment of peripheral arterial disease. Nevertheless, in a recent double-blind multicentre trial of 150 patients, the drug was found to be statistically superior to placebo[195], especially in those with an ankle:brachial pressure index below 0·8. Oxpentifylline has also been shown to promote the healing of venous leg ulcers in a multicentre double-blind placebo-controlled study of 80 patients, confirming the results of earlier uncontrolled trials[196]. The effects of this agent on white cell activation, deformability and endothelial adhesion appear, therefore, to be of benefit in arterial and venous disease, supporting the contention that similar pathological processes are involved in both.

In addition to its local effects, oxpentifylline may attenuate the neutrophil-mediated systemic response to ischaemia–reperfusion injury. In a double-blind placebo-controlled trial oxpentifylline was found to reduce albumin excretion after exercise significantly relative to creatinine in a group of 20 patients with intermittent claudication[197]. This led the authors to conclude that the deleterious systemic effects of localized ischaemia could be attenuated by the drug. Oxpentifylline also preserves intestinal microvascular flow and may protect against ARDS following shock[184,198]. These effects are at least partly mediated through inhibition of TNF and IL-2 and by optimizing flow dynamics between leucocytes and endothelial cells in the microcirculation. For example, oxpentifylline suppresses TNF gene transcription in acute endotoxaemia[199].

Cytokine modulation

Cytokines represent a potential target for intervention through either the development of specific receptor antagonists or the interruption of secondary messenger pathways[200,201]. In the case of IL-1, a naturally occurring specific receptor antagonist has been discovered[202]. Recombinant IL-1 receptor antagonist is currently being evaluated in the treatment of a range of medical conditions including septic shock[42,203]. With respect to vascular disease IL-1 receptor antagonist inhibits neutrophil accumulation, endothelial–leucocyte adhesion, leucocyte cytokine production and release of free radicals[204,205]. There is also evidence that diets rich in fish oils decrease IL-1 production by leucocytes and inhibit the development of atherosclerosis[206]. IL-1 could also be inhibited by neutralizing antibodies, by preventing synthesis of its active form[207] and through the development of soluble IL-1 receptors[208]. A naturally occurring soluble form of the receptor has been found in body fluids although its biological function is unknown[209]. Another approach might be through the use of inhibitory cytokines that downregulate the production of proinflammatory cytokines[210] such as IL-1 and TNF. For example, IL-10 inhibits antigen presentation and cytokine (IL-1, IL-6, IL-8, TNF, CSF) production by cells of the macrophage–monocyte lineage. IL-10 also inhibits adhesion and the production of oxygen metabolites but upregulates expression of IL-1 receptor antagonist. IL-10 protects mice from death caused by endotoxaemia[211].

Aprotinin

The clinical importance of coagulopathy and the role played by activated leucocytes after aortic aneurysm rupture have already been discussed. Aprotinin is now widely used to reduce the bleeding associated with cardiopulmonary bypass. The drug also reduces blood loss during and after elective aortoiliac surgery[212]. Aprotinin is a protease inhibitor and is thought to act on fibrinolysis, kallikrein and complement activation[213]. There is also evidence that the drug may affect neutrophil function after major vascular surgery. Lord and colleagues[214] found that perioperative aprotinin therapy maintained significantly better postoperative white cell function in terms of morphology, unstimulated nitroblue tetrazolium reduction and chemotaxis. Blood loss was also significantly decreased. The present authors are currently involved in a trial to determine whether perioperative aprotinin treatment can reduce blood loss, prevent coagulopathy and ultimately improve survival in patients presenting with ruptured aortic aneurysm.

Conclusions

The reason for conducting primary scientific research into vascular, and indeed all, disease is the hope that a better understanding of basic pathological processes will result in novel methods of treatment. The ultimate aim must be the development of systemic treatments specifically aimed at key points in these processes that will prevent or at least limit tissue damage. At present, understanding of leucocyte, platelet and endothelial cell biology is in its infancy but potential targets for such specific intervention are already becoming apparent. It may be that such intervention will enable control of many aspects of both arterial and venous disease.

Cocaine 'body packers'

N. E. Beck and J. E. Hale

Department of Surgery, East Surrey Hospital, Three Arch Road, Redhill, Surrey RH1 5RH, UK

Correspondence to:
Mr N. E. Beck

Intracorporeal drug smuggling, particularly of cocaine, is increasing. The so-called 'body packers' present a difficult clinical problem, particularly as no coherent management policy has been formulated. The various methods of diagnosis and the treatment options available are presented and discussed.

'Body packers' or 'mules' are drug traffickers who attempt to smuggle drugs, mainly cocaine or heroin, by intracorporeal concealment. Packages containing the drug are usually swallowed or inserted into the rectum to be retrieved after the trafficker has cleared customs. 'Body stuffers' or 'quick swallowers' are drug dealers who ingest packages or vials of drugs when suddenly confronted by the authorities.

Although the gastrointestinal tract is the preferred site for intracorporeal drug concealment, almost no orifice has been overlooked. The insertion of illicit drugs into the vagina[1,2] and even the ear[3,4] has been described. While the majority of body packers do not require medical attention, the detection of body packing is important because the practice has resulted in bowel obstruction[5,6] and acute drug toxicity[7–12]. Fatalities are particularly common following cocaine intoxication[7,9,10]. Since the first reports[5,13–15] of gastrointestinal drug smuggling in the 1970s, most reported cases have been from the United States or continental Europe. However, this technique of smuggling is being used with increasing frequency and body packers are becoming an increasing problem in the UK[16,17]. The majority of patients have been apprehended at international airports by customs officials and are then transferred to hospital only after developing complications. Some body packers become frightened and present to an accident and emergency department directly. The greatest management problems are caused by cocaine ingestors.

Cocaine

Cocaine (methylbenzoylecgonine) is an alkaloid, prepared from the leaves of the *Erthroxylon* plant[18,19], that is currently marketed in the form of crystals, granules or a white powder. The systemic effects of cocaine are probably mediated by alterations in synaptic transmission; it blocks the presynaptic re-uptake of the neurotransmitters noradrenaline and dopamine, which produces an excess of transmitter at the postsynaptic receptor sites. Sympathetic activation by this mechanism produces vasoconstriction, an acute rise in arterial pressure, tachycardia and a predisposition to arrhythmia, seizures, hyperglycaemia and hyperthermia[19,20]. For cocaine, the median lethal dose fatal to 50 per cent of human test subjects is said to be 500 mg after oral ingestion[21], but the fatal dose[19] can be as low as 20 mg. A relatively rapid increase in blood level may be as important in determining a fatal reaction as the peak blood concentration[10,22]. This may be of particular relevance in the context of the body packer.

Cocaine packages

The number of packages recorded as swallowed[6,23,24] ranges from 15 to over 200, each package containing 3–15 g cocaine[6,11,23,24]. The packages are constructed in a variety of ways (*Figure 1*), but generally consist of cocaine powder wrapped in cellophane and three or four layers of latex tied with a non-absorbable surgical ligature. McCarron and Wood[23] classified packages into three types (*Table 1*). While rupture of a single package can lead to massive fatal cocaine poisoning[9], the packages do not have to break open to cause death. The wrapping may serve as a semipermeable membrane, allowing fluid from the gastrointestinal tract to permeate the wall of the package; cocaine hydrochloride, being a salt, dissolves and diffuses out[1]. It has been estimated that 25 per cent of packages are highly susceptible to breakage or leakage[23].

Clinical presentation

There is a broad spectrum of presentation, from the entirely asymptomatic but anxious body packer who arrives at an accident and emergency department, to the packer with acute cocaine intoxication. The typical body packer is a young man recently arrived from South America[7,8,14,15]. Predictably, a good history is not always available[23] but, if the patient is confronted with the fact that cocaine metabolites have been positively identified in the urine, in the authors' experience they will often admit to how many packages they have swallowed. In asymptomatic patients initial examination is also often unhelpful[11]. Most body packers are not cocaine users

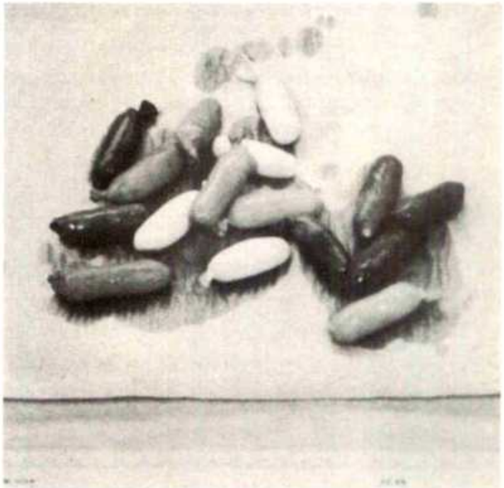

Figure 1 *Cocaine packages. In this case toy balloons were used as the packaging material*

Table 1 *Classification of cocaine packages*[23]

Characteristic	Type 1	Type 2	Type 3
Cocaine	Loose powder	Matted powder	Paste
Packaging	Condoms, toy balloons or fingers of latex gloves	Tubular latex	Aluminium foil and tubular latex
No. of layers	2–4	5–7	3–5
Risk	Susceptible to breakage	Resistant to breakage	Resistant to breakage

0007-1323/93/121513-04 © 1993 Butterworth-Heinemann Ltd

themselves and features of intravenous drug abuse or chronic cocaine abuse are absent[11]. Small mobile packages may occasionally be felt on abdominal or rectal examination.

Anticholinergic drugs

The body packer may have taken anticholinergic agents, for example up to 20 tablets of Lomotil (atropine sulphate 0·025 mg, diphenoxylate hydrochloride 2·5 mg; Gold Cross Pharmaceuticals, High Wycombe, UK) per day, to slow the transit time of the ingested packages during a long flight from South America[23–25]. Symptoms such as a dry mouth, mydriasis and accommodation difficulties may therefore be evident.

Obstruction

Obstruction may be the first presenting feature[5,6]. Obturation obstruction of the bowel probably occurs when the cocaine-filled packages become entangled[5]. The most common sites are the pylorus, ileocaecal valve and splenic flexure[6]. Previous surgery may increase the likelihood of obstruction if adhesions have led to extrinsic areas of narrowing.

Acute cocaine intoxication

Signs and symptoms of acute cocaine intoxication should always be sought, although they are often absent when the patient first presents[23]. Classically, intoxication is manifested by agitation, diaphoresis, tachycardia, palpitations, hypertension, hyperthermia, disorientation, hallucinations and paranoid behaviour[20]. After the massive doses that may be absorbed when a package breaks, the patient may develop arrhythmia, seizures and metabolic and respiratory acidosis. Such cases are usually fatal[1,7,9,10,26,27].

Investigations

As the initial history and examination are often not helpful the diagnosis is established largely by a combination of urine analysis and radiology.

Urine analysis

Detection of opiates and benzoylecgonine, the major metabolite of cocaine, in the urine is possible by enzyme immunoassay[24,28]; a result can be available[28] within 10 min. There is a good correlation between the presence of drugs in the urine and cocaine packages in the body[24,29]. Gherardi *et al.*[29] tested the urine of 50 cocaine body packers and detected benzoylecgonine in 49. The sensitivity of the benzoylecgonine test is greatest (up to 97 per cent) on the first day of admission to hospital, but the accuracy of the test progressively decreases as the ingested cocaine packages are spontaneously eliminated[24]. The test is often positive, even if the packages have remained intact. This may be because some packages are semipermeable or because contamination of the outside of the packages occurred when they were made[24,28].

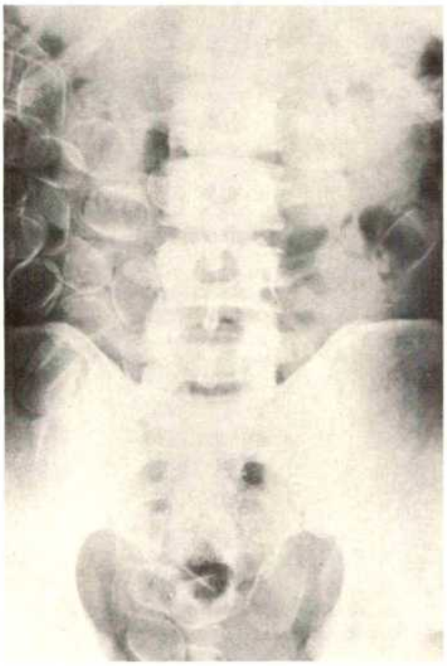

Figure 2 *Plain abdominal radiograph showing cocaine packages in the bowel*

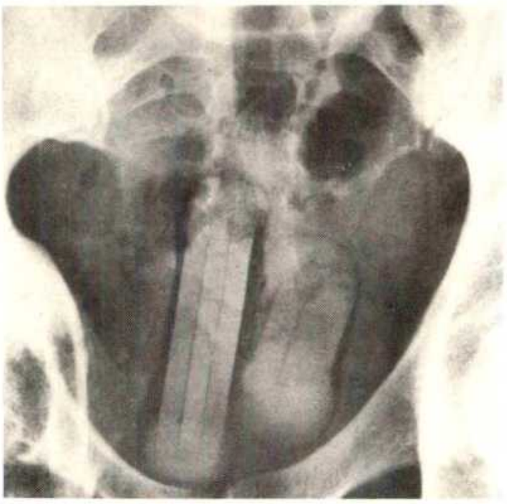

Figure 3 *Plain abdominal radiograph showing cocaine packages inserted in the rectum*

Radiology

The usefulness of plain abdominal radiography in the diagnosis of cocaine body packers is well established[6,23,25,30–32] (*Figures 2* and *3*). The drug may be detected in the gastrointestinal tract as a consequence of the way in which it is packaged. Air trapped between layers of condoms may be seen; this is the 'double condom' sign first described by Pinsky *et al.*[33]. Air trapped in the outer package at the end where the knot has been tied may be seen as a 'rosette' shape[23,31]. Radiographs are taken not only to establish diagnosis but also to determine the type of package and its position in the gastrointestinal tract. Packages are easier to identify in the stomach as the gastric air bubble acts as a contrast agent; however, the most common location in which they are identified is the ascending colon[31]. False-negative results can occur, but plain abdominal radiography will lead to a correct diagnosis in 83–92 per cent of cases[6,31].

Contrast study of the bowel has been variably reported as unreliable or useful[11,23,29,30,34]. Those who advocate its use point out that, as water-soluble contrast medium is osmotically active, it accelerates the spontaneous elimination of packages by acting as a purgative. Ultrasonography has not been shown to increase significantly the detection rate of packages[35].

Other investigations

Routine blood investigations are invariably taken, although they do not often contribute to establishing a diagnosis. Arterial blood gas analysis may confirm acidosis if cocaine intoxication is present[26] and blood should be taken for assay of serum cocaine levels[7,8]. Cardiac events related to cocaine intoxication are well described and electrocardiography should be performed[20,36–39].

Management

The aim of any form of management is to attempt to prevent death or complications from acute cocaine poisoning or obstruction. The retrieval of packages for legal purposes is not an indication for intervention. Management depends on the type of package ingested, their location in the gastrointestinal tract, the length of time elapsed since ingestion and, most importantly, the physical findings, in particular the presence or absence of cocaine poisoning or obstruction.

Surgery

The risk of rupture of a package has not been determined in any large series, but surgical removal of all packages from all body packers is almost certainly an invasive over-reaction. On the other hand, most authors agree that obstruction and evidence that the ingested packages are disintegrating are both absolute indications for operation[5,6,11,16,23,25,31,34]. If the packages are poorly constructed or of the type most likely to leak (McCarron–Wood[23] type 1), surgical intervention should also be considered. The type of package may be determined radiologically but analysis of one that has already been passed is, of course, more reliable. The risk of disintegration of packages is increased if they have been present in the gastrointestinal tract for a prolonged period. Failure to eliminate the packages is, therefore, a relative indication for operation[1].

At laparotomy a single enterotomy is usually sufficient as the packages can be 'milked' to the enterotomy site and evacuated manually. Occasionally more than one enterotomy is required[5,25].

Bowel ischaemia has been reported secondary to ingestion of cocaine[40,41], although not yet in a body packer. Although at present this remains only as a theoretical risk, with the increasing frequency of intracorporeal cocaine concealment it should be considered as a possibility.

Endoscopy

Upper gastrointestinal endoscopy has been used both to confirm the diagnosis and to remove packages[34]. However, packages may be damaged as they are snared and so this technique is not recommended[7,11,23,26].

Induced emesis and purgation

Induced emesis is of most use in quick swallowers. The hastily ingested packages are particularly susceptible to leakage and quick evacuation of the stomach contents is therefore the aim[11,12,27,42–44]; 15 ml ipecacuanha after drinking 200 ml water is recommended, and a second dose may be given[42]. The present authors have found the same regimen useful in retrieving packages from the stomach in body packers.

Purgation will be successful in the majority of patients without obstruction[6,11,23,30]. Caruana *et al.*[6] describe a study of 50 cocaine body packers: six chose elective surgery, three had emergency surgery for obstruction and 41 were successfully managed by purgation. A clear liquid diet was given and the patients commenced on mineral oil 30 ml four times a day. In this study none of the patients presented with or developed signs or symptoms of cocaine intoxication[6]. Similar results have been obtained with a regimen of 100 ml oral paraffin twice daily[11]. Enemas should be avoided, as packages within the rectum may be damaged by insertion of the enema nozzle[26]. A single instance of whole bowel irrigation has been described[34] in which all packages were successfully eliminated without complication. The patient was required to drink 20 litres of polyethylene glycol electrolyte lavage solution.

Management of cocaine intoxication

Survival is rare after massive cocaine poisoning[7,9,10,20,26]. Most deaths are attributed to generalized convulsions, cardiac arrhythmia or respiratory failure, but the precise sequence of events leading to death is poorly understood[20]. Medical management largely involves treating complications as they arise. The patient developing signs and symptoms of cocaine intoxication should be transferred to an intensive care unit for monitoring. Propranolol 1 mg per min intravenously may specifically antagonize the sympathomimetic effects of cocaine[45–47]. Pretreatment with diazepam 2·5–5·0 mg or high-dose chlorpromazine has been used effectively to prevent seizures and, in addition, it has been suggested[26,48,49] that this drug will counteract the sympathomimetic effects of cocaine on the heart. Nitrendipine may also be an effective antagonist to the cardiotoxic effects of cocaine[50]. Hyperthermia may not respond to standard evaporative cooling methods and in such circumstances dantrolene sodium 1 mg/kg intravenously over 10–15 min has been used, albeit with variable success[17,51–53]. Once the patient has been stabilized, any remaining packages are also at risk of disintegration and should be removed surgically.

Conclusions

Body packing should be considered as a diagnosis in any international traveller who presents with signs or symptoms compatible with cocaine intoxication. For asymptomatic patients, a trial of conservative management will lead to the uncomplicated elimination of all packages in the majority. However, rupture of a single package can lead to death and so early surgical intervention is probably the safest policy if there is evidence that the packages are disintegrating or are likely to do so. Obstruction or acute cocaine intoxication are absolute indications for operation once the patient has been stabilized.

SURGERY TODAY
The Japanese Journal of Surgery

Br. J. Surg. 1993, Vol. 80, December, 1517–1518

The July to September issues of Surgery Today (The Japanese Journal of Surgery) *form the basis for this quarter's digest by that journal's Editor-in-Chief, Professor Yoshio Mishima.*

Oncology

Kase *et al.*[1] investigated the modulating effect of folinic acid (leucovorin) on the antitumour action of 5-fluorouracil (5-FU) against C-1 human colonic carcinoma cells *in vitro* and Co-4 human colonic cancer xenografts in nude mice. The modulating effect of folinic acid on 5-FU was optimal at a concentration of 40–80 μg/ml *in vitro* as determined by a colorimetric 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2H tetrazolium bromide (MTT) assay. An optimal dose of 200 mg/kg was observed in the nude mouse system. The modulating effect of folinic acid increased according to the extent of thymidylate synthetase inhibition *in vivo*. Since the pharmacodynamics of folinic acid in nude mice given the drug at 200 mg/kg were similar to those in patients treated at a dose of 100 mg/m^2, this method of administration was thought to be adequate for modulating the antitumour activity of 5-FU in clinical practice.

Oka *et al.*[2] studied the natural killer (NK) activity of peripheral blood mononuclear cells and serum immunosuppressive acidic protein (IAP) levels in patients with oesophageal or gastric cancer before and after surgery. Patients with stage IV oesophageal or gastric cancer had significantly lower NK cell activity (mean(s.d.) 39·5(14·8) and 37·0(11·6) per cent respectively) and higher serum IAP levels (mean(s.d.) 778(264) and 633(156) μg/ml respectively) than corresponding controls (50·0(5·6) per cent and 375(26) μg/ml). Patients with oesophageal or gastric cancer who underwent curative resection had high NK cell activity (mean(s.d.) 54·8(11·6) and 54·8(8·0) per cent respectively) and low IAP levels (mean(s.d.) 471(116) and 490(42) μg/ml) compared with those undergoing palliative resection, and this effect was seen 1 month after surgery. Mononuclear cells in the regional lymph nodes and tumour specimens showed significantly lower NK cell activity than those in the peripheral blood and spleen. Thus, NK cell activity and IAP level reflected the immunocompetence, clinical course and surgical curability of these patients. NK cells appeared not to have significant antitumour activity in the regional lymph nodes or in the tumour itself, although they were still active in the peripheral blood.

Toge *et al.*[3] investigated the role of lymphocyte surface binding sites for wheat germ agglutinin (WGA) in the negative regulation of disease in patients with malignancy. The number of WGA binding sites on the surface of each lymphocyte ranged from 10^7 to 10^8. Fluorescein isothiocyanate-conjugated WGA bound to the majority of peripheral blood lymphocytes with two peaks of fluorescent intensity (dim and bright). The increase in the proportion of lymphocytes with bright fluorescence ('WGA-bright' lymphocytes) correlated significantly with the number of WGA binding sites. The suppression of lymphocyte proliferation mediated by purified soluble suppressor factor correlated significantly with an increase in the size of the WGA-bright lymphocyte population ($P < 0·05$). A significantly greater number of WGA-bright peripheral blood lymphocytes was found in patients with oesophageal, gastric, breast and colonic cancer than in those with benign disease or healthy controls. An increase in the number of WGA-bright lymphocytes was found in subsets expressing the antigens CD8 dimly or CD16. The number of WGA binding sites may therefore increase on the surface of effector cells such as NK and CD8-positive killer T cells in patients with cancer, triggering the negative regulation mediated by soluble suppressor factor.

Gastric cancer

Ichikura *et al.*[4] studied 318 patients undergoing curative resection for gastric cancer, 168 with and 150 without prognostic serosal invasion, to determine the prognostic importance of clinicopathological factors and identify which patients were at high risk of recurrence. Multivariate analysis of survival using a Cox proportional hazards model was carried out to determine important prognostic factors. In patients with prognostic serosal invasion these emerged as lymph node involvement, the classification of gross tumour appearance, macroscopic serosal invasion and interstitial connective tissue. Lymph node involvement, macroscopic serosal invasion and venous invasion were important factors in patients without prognostic serosal invasion. A risk score for recurrence was derived based on the results of further multivariate analysis (Hayashi's Quantification Analysis II)[5], in which recurrence was chosen as an objective variable with the prognostic factors mentioned as explanatory variables. Some 84 per cent of patients with prognostic serosal invasion and a score of 0 or higher and 83 per cent of those without such invasion and a score of +6 or more developed recurrence. This score may thus be useful for identifying patients at high risk of recurrence, who should receive intensive chemotherapy after curative resection.

Breast cancer

Narita *et al.*[6] investigated the utility of serum levels of procollagen type III N peptide and the type IV collagen 7S domain as markers of recurrence and metastasis in 199 patients with breast cancer. Serum levels of N peptide and the 7S domain were significantly higher in patients with postoperative recurrence, with 76·9 per cent of N peptide-positive patients with cancer and 68·0 per cent of those with malignancy positive for the 7S domain having metastases in the bone and/or liver. Furthermore, 66·7 per cent of all patients with metastases in the bone and/or liver were positive for N peptide and 75·6 per cent for the 7S domain. Patients with liver metastases were either N peptide or 7S positive and levels were higher than those in patients with bone secondaries. These findings suggest that serum levels of both collagen peptides are useful markers of recurrent and metastatic breast cancer, especially in the bone and/or liver.

Liver transplantation

An animal model of split liver transplantation using pigs is described by Tanaka *et al.*[7]. The donor liver was divided into two grafts, the right graft consisting of the right medial and lateral segments with the caudate lobe, the left of the left lateral and medial segments. To make implantation easier a distal part of the donor inferior vena cava (IVC) was isolated and attached to the left graft with anastomosis between the orifice of the renal vein and the graft hepatic vein. The left graft thereby contained a newly constructed retrohepatic IVC for anastomosis to the recipient. During the anhepatic phase, no conventional bypass procedure was used, but abdominal aortic clamping in combination with general hypothermia was employed. Ten pigs were used as donors and 20 liver transplants performed; no immunosuppressive drugs were given. Ten of the 20 recipients survived more than 2 days, the mean survival time being 4·7

0007-1323/93/121517-02 © 1993 Butterworth-Heinemann Ltd

(range 2–14) days. The survival time of animals receiving left grafts was much longer than that of those given right grafts, although no technical problems such as graft kinking or hepatic vein occlusion were encountered in either group. This is the first report of split liver transplantation in animals. The advantages of the infrahepatic IVC graft include stability of the graft and safe hepatectomy. This model will therefore be useful for the experimental study of split liver transplantation and the method may be employed clinically in the future.

Endoscopic surgery

Lifting of the abdominal wall is a means of producing space between the anterior abdominal wall and the intra-abdominal organs during laparoscopic surgery. Hashimoto *et al.*[8] devised a hanger lifting procedure for the anterior abdominal wall to avoid complications and reduce the costs related to pneumoperitoneum. Fifty patients underwent laparoscopic cholecystectomy with this abdominal wall-lifting procedure. Initially cholecystectomy by pneumoperitoneum was used but eventually the insufflator was discarded. There was no incidence of conversion to pneumoperitoneum and a relatively good operative view was achieved enabling trouble-free laparoscopic cholecystectomy.

Coronary artery bypass

Histopathological and biochemical studies were conducted by Kobayashi *et al.*[9] on the severity of arteriosclerosis of the internal mammary artery (IMA), as used for coronary artery bypass grafting. Twenty-six bilateral IMAs and 13 left anterior descending coronary arteries (LADs) obtained in full length from 13 autopsies were studied. In no case had the patient died from atherosclerotic heart disease. The ratio of the thickness of the intima to that of the media was used as an index of atherosclerosis. IMAs and LADs were classified as grades I–IV according to this index. The atherosclerosis index of the IMAs was approximately one-tenth that of the LADs ($P < 0{\cdot}01$). Most IMAs showed a low atherosclerosis grade, with no variation along the length and a low index in all segments. No difference was found between right and left IMAs. Biochemical studies were carried out on 12 IMAs and 11 LADs obtained from 12 different unselected autopsies. The lipid content of the vascular wall was determined to evaluate the severity of atherosclerosis. The mean(s.d.) lipid levels of the IMA and LAD for total cholesterol were 5·5(1·8) and 17·8(13·6) μg per mg wet weight respectively ($P < 0{\cdot}05$), for triglyceride 90·4(90·3) and 114·4(117·2) μg/mg (P not significant) and for phospholipid 7·4(3·9) and 11·2(3·9) μg/mg ($P < 0{\cdot}05$). The authors concluded that atherosclerosis of the IMA is mild compared with that of the LAD in the same individual.

Soft tissue sarcoma

In a second series of articles on soft tissue sarcoma, Dosluoglu *et al.*[1] review treatment options for extremity sarcoma with particular emphasis on wide local excision and compartment resection. Wide local excision represents removal of the primary tumour with at least a 2-cm margin of normal tissue. After this procedure high-grade tumours will show a local recurrence rate of up to 50 per cent and therefore require additional chemotherapy or radiotherapy. For low-grade tumours wide local excision appears to be sufficient if all gross tumour is removed and the margins are free from microscopic disease. Compartment resection, in contrast, requires removal of all soft tissue that constitutes the anatomical compartment in which the tumour resides, together with the fascial sheath. Overall results of this treatment are similar to those of extremity amputation, with recurrence rates of 15–20 per cent; compartment resection should be preferred if surgical treatment alone is considered for high-grade sarcoma (for example, radiation-induced sarcoma). Compartment resection may be difficult for tumours located in the groin, popliteal fossa or distal forearm, because there is little surrounding tissue, and preoperative radiochemotherapy with wide local excision may be preferable. Amputation may be necessary for large tumours in these locations. In the thigh, compartment resection may produce specific functional deficits. Potential aids to overcome or ameliorate sequelae of operative treatment are presented. Although functional deficits following compartment resection of the upper extremity are usually more severe than in the lower limb, the remaining function is preferable to that following forearm or forequarter amputation for sarcoma in this location.

Combined treatment of high-grade sarcoma including preoperative, intraoperative or postoperative radiotherapy may result in good local tumour control and preservation of limb function. Wide local excision is the treatment of choice for low-grade sarcoma or small (less than 5 cm) high-grade sarcoma. Postoperative radiotherapy should be considered if margins are less than 2 cm. For high-grade sarcoma and for lesions of more than 5 cm, preoperative intra-arterial chemotherapy is recommended. Tumours larger than 10 cm, fixed lesions or those adjacent to the neuromuscular bundle should be treated by preoperative radiochemotherapy to avoid primary amputation.

Current management of retroperitoneal sarcoma is reviewed by Siewert *et al.*[2], who recommend abdominal computed tomography (CT) with intravenous and enteral contrast media to delineate the tumour and establish its precise anatomical relation to surrounding organs and vessels. CT of the chest is recommended to detect pulmonary metastases. Angiography should be used to detect feeding vessels and local vascular invasion by the tumour. Preoperative needle biopsy guided by ultrasonography or CT was successful in 85 per cent of patients, providing information on cell type and grade. Complete resection of the tumour with clear margins was achieved in approximately 50 per cent of patients. Growth of retroperitoneal sarcoma is not restricted by fascial sheaths and complete removal requires clearing of the quadrant or side on which the lesion is located. This is more often achieved on the left since the hepatoduodenal ligament, the mesenteric root and infiltration of the vena cava may restrict resectability on the right. Multiorgan resection was performed in 34 of 40 patients. Complete tumour removal was possible in half and the perioperative mortality rate was 8 per cent. The median survival of patients with high-grade sarcoma was 12 months. The 5-year survival rate of patients with grade I or II tumours was 56 per cent, whereas no patient with a grade III lesion survived 5 years. Multivariate analysis identified complete removal of macroscopic tumour ($R_{0/1}$ resection) and grade as independent prognostic factors. Over a median follow-up of 38 months the local recurrence rate was 43 per cent. The authors emphasize that on prolonged follow-up approximately 90 per cent of patients who have received R_0 resection will develop local recurrence, while only 30 per cent develop distant metastases within 10 years. No clear advantage of adjuvant radiotherapy or chemotherapy could be determined from a review of the literature.

Large bowel

Several conditions, such as familial adenomatous polyposis (FAP), ulcerative colitis and low rectal cancer, may require total proctocolectomy or excision of the rectum with the need for subsequent restoration of intestinal continuity. Parc and Sales[3] review surgical options to restore continence and report experience with ileoanal pouch construction, coloanal pouch anastomosis and coloanal anastomosis.

Between 1983 and 1991, 156 patients with ulcerative colitis were treated by ileal pouch–anal anastomosis. There were no postoperative deaths. A three-stage procedure was performed in 34 per cent of patients and 28 per cent had postoperative complications. The morbidity rate was lower after three-stage than two-stage operations (17 *versus* 39 per cent). Overall, 10 per cent of patients required reoperation. Nine patients developed a fistula and seven stenosis. Three patients required pouch removal for persistent fistula and in two of these Crohn's disease was diagnosed after operation. During a 6-year period 114 patients with FAP were treated by ileoanal pouch construction. The authors observed no complications or mortality. More than 90 per cent of patients reported full continence and only 15 per cent required dietary restrictions.

Between 1984 and 1990 the same authors performed coloanal J pouch anastomosis in 162 patients with low rectal cancer. The operative mortality rate was 0·6 per cent. All patients had a temporary diverting colostomy. Pelvic sepsis and anastomotic leakage were recorded in 3 per cent of patients and treated conservatively in all. After 1 year, 52 per cent of patients were fully continent and 40 per cent reported minor problems. Some 25 per cent of patients required enemas or suppositories to facilitate bowel movements. The 5-year survival rate was 79 per cent and the recurrence rate 7 per cent.

Defining the exact extent of an anorectal fistula may be difficult on clinical examination or during operation. Hancke *et al.*[4] studied the value of magnetic resonance imaging (MRI) in 17 patients with anorectal fistula in whom clinical examination including proctoscopy and rectoscopy failed to define the extent of the lesion. Nine patients had Crohn's disease and two ulcerative colitis. Nine of the 17 patients had had previous surgery for the fistula. In six of the 17 patients MRI revealed additional tracks that had not been detected by clinical examination and in a further three abscess formation that had been missed by clinical examination was found. Intraoperative findings confirmed the lesions demonstrated by MRI in all but

0007-1323/93/121519-03 © 1993 Butterworth-Heinemann Ltd

one patient. Seven of the nine patients with additional findings on MRI had Crohn's disease. The authors conclude that MRI of the pelvis is an important diagnostic tool to evaluate the extent of complex anorectal fistula.

Hernia repair

Repair of inguinal hernia remains one of the most frequently performed operations. Töns and colleagues[5] conducted a postal survey to determine the status of hernia surgery in Germany. A total of 1656 questionnaires were sent out with a return rate of 66·2 per cent, covering 27 991 operations per year. Just over half of surgeons (54 per cent) indicated that the operation was performed under general anaesthesia, while 40 per cent preferred spinal or epidural anaesthesia. Only 6 per cent of surgeons preferred local anaesthesia. Absorbable sutures were employed by 67 per cent of surgeons and the rest used non-absorbable sutures. Surprisingly, 63 per cent of surgeons advocated subcutaneous placement of the spermatic cord for primary hernia repair irrespective of other technical aspects. When the results of this survey are compared with those of a study conducted 10 years ago the majority of surgeons (54 per cent) now prefer the Shouldice technique for primary and recurrent hernia repair, whereas this was used by only 0·4 per cent in 1982. Only 0·7 per cent of surgeons used any laparoscopic techniques for primary hernia repair. Recurrent inguinal hernia repair was performed laparoscopically in only 1·1 per cent of departments, but 8·6 per cent of surgeons considered the use of mesh as an alternative in the treatment of recurrent herniation. When asked specifically about laparoscopic herniorrhaphy, 87·6 per cent of surgeons documented strong reservations, because this was 'not an established form of treatment' (72 per cent), because conventional repair was considered to be a safer procedure (47 per cent), because it was laborious and expensive (20 per cent) and because it was considered an unphysiological approach or for other reasons (18 per cent). Day surgery for herniorrhaphy was offered by 21 per cent of hospitals and the average stay after repair was 8 days for primary and 10 days for recurrent inguinal hernia.

Vascular surgery

In a prospective randomized trial Bernert and Balzer[6] tested various bifurcation grafts inserted for aortoiliac occlusive or aneurysmal disease. In all, 100 patients were randomized to four groups receiving Dacron (Du Pont, Wilmington, Delaware, USA) prostheses with or without velour and with or without gelatin coating. The operations were performed in 1983 and 1984. Intraoperative blood loss was lowest in patients receiving a gelatin-coated velour prosthesis (878 ml), but the differences between groups were not significant. Ten patients died after operation; the cause of death was myocardial failure in all ten. No patient had evidence of prosthesis infection or perigraft reaction in the postoperative period. Thirteen late deaths were unrelated to the operation or graft and 23 patients refused follow-up examination. Long-term follow-up results after 5·5 years were available for 54 patients, who were examined clinically and by ultrasonography. The latter revealed that 87 per cent of prostheses had increased in diameter by a mean of 17·3 per cent. No significant differences were established for different graft materials. The late amputation rate was 4 per cent and unrelated to the material used. The cumulative primary patency rate(s.e.) was 83(9) per cent at 72 months. The authors concluded that only the highly subjective criterion of ease of intraoperative handling conferred some advantage to the velour prosthesis. No advantage of gelatin coating could be demonstrated.

Oesophageal carcinoma

Cancer of the oesophagus remains a major challenge to all surgeons of the alimentary tract. Nürnberger and colleagues[7] report experience with this disease. Between January 1988 and December 1991, 122 patients with squamous cell carcinoma of the oesophagus were evaluated prospectively. The primary resectability rate was 52 per cent (64 patients). Twenty-two patients with locally inoperable tumours were referred for preoperative radiochemotherapy with 28–45 (mean 37) Gy and a combination of cisplatin (20 mg/m^2, days 1–5), 5-fluorouracil (400 mg/m^2, days 1–5) and folinic acid (100 mg/m^2, days 1–5). The chemotherapy cycle was repeated on day 29. A tumour response was recorded in 16 of the 22 patients and 14 of the 16 responding underwent secondary surgery. The 30-day mortality rate was 9 per cent, but the overall hospital mortality rate was 19 per cent for patients undergoing primary resection and 21 per cent for those treated by radiochemotherapy followed by secondary surgery. Reporting the 30-day mortality rate alone may conceal data and this should not be accepted as a measure of postoperative mortality. The incidence of surgical complications was comparable for the two groups (25 *versus* 21 per cent). Although general and, in particular, pulmonary complications were not specified, the authors concluded that preoperative radiochemotherapy for irresectable squamous cell carcinoma of the oesophagus does not increase postoperative mortality or morbidity rates.

Complications of anticoagulation therapy

A recent survey demonstrated that most hospitals in Germany rely on postoperative low-dose heparin treatment for the prophylaxis of deep vein thrombosis (DVT). Schmidt and associates[8] highlight two types of heparin-associated thrombocytopenia that may occur irrespective both of the type of heparin used and the route of administration, and which often go unrecognized. Type I has an incidence of 1–15 per cent and is a relatively harmless condition in which the platelet count falls temporarily. It is caused by inhibition of adenylate cyclase, resulting in decreased intracellular levels of adenosine 3',5'-cyclic monophosphate. Platelet counts are usually not lower than 10^{11}/l and will recover spontaneously even when heparin treatment is continued. This condition does not require specific treatment.

Type II heparin-associated thrombocytopenia has an estimated incidence of 0·6–10 per cent. An immunological mechanism is believed to cause platelet aggregation, resulting in a fall in platelet count to below 10^{11}/l. The condition may develop immediately following the first dose of heparin in already sensitized patients or 6–14 days after the first treatment in those not previously exposed to the anticoagulant. Up to 50 per cent of patients with type II thrombocytopenia develop arterial or venous thromboembolic complications. Thrombi consist mainly of fibrin–platelet aggregates, so-called 'white clots'. The condition is associated with a 25–30 per cent mortality rate from myocardial infarction, pulmonary embolism or mesenteric infarction, and the morbidity rate from arterial embolism, DVT, ischaemic infarction or paraparesis may be as high as 60 per cent. When heparin therapy is discontinued the platelet count returns to normal within 1 week. Treatment of overt thromboembolic complications consists of standard regimens including embolectomy and thrombolysis with streptokinase or urokinase. The authors recommend monitoring of platelet counts on alternate days to recognize the condition and list a number of sophisticated laboratory tests for verification. Anticoagulation may then be achieved by use of aspirin or dicoumarol.

The American Journal of Surgery®

Dr Hiram C. Polk Jr, Editor of The American Journal of Surgery, *has this month selected from the July to September issues of that journal for his digest. A summary of the best of the* BJS, *written by Professor John Farndon, appears in the American journal.*

Br. J. Surg. 1993, Vol. 80, December, 1521–1522

Sepsis

There have been few subjects of broader interest over the past decade than the study of peritonitis and intra-abdominal abscess formation. Much has been learned about the process, although major clinical application of some of the new concepts has not yet been achieved. Simmen and Blaser[1] report interesting observations on 59 patients with infection; these indicate that infected peritoneal fluid is often acidic and relatively hypoxic compared with that from patients undergoing elective laparotomy. The diagnostic predictive value of this work may be far less important than its simple and direct contribution to the understanding of peritoneal infection. The significance of the relationship between these observations and *in vitro* susceptibility or antibiotic activity remains to be determined.

Upper gastrointestinal tract

The group of van der Mijle and associates[2] from Groningen in the Netherlands contributes further to the growing understanding of malfunction of the jejunal Roux limb, especially for reconstruction following gastric surgery. Earlier papers in *The American Journal of Surgery* indicated a motility disorder in the Roux limb itself that has little to do with the status of the residual gastric pouch. It is interesting to speculate whether an 'uncut' Roux limb would have the same characteristics.

Breast

Reconstruction of the female breast carried out following surgical treatment of breast cancer is very prevalent in North America and often employed as an index of quality of care. There has been concern that early complications and late tumour recurrence would be unfavourably influenced by this additional, often very extensive, procedure. O'Brien and associates[3] define these risks in a significant population of patients in a most reassuring way.

Cardiovascular

Some clinical reports have value, just for the simple fact that they remind the clinician of important and/or often overlooked relationships. Buchbinder and associates[4] describe the discovery of a variety of curious lesions in the evaluation of patients with relatively simple lower-extremity venous disease. The lesson of looking for the underlying disease process continues to be valid.

The surgical approach to brachiocephalic stenotic vascular lesions continues to be reported through a trickle of patients from some very busy centres. The principles that are evolving from a few large units are very important and directly influence safety, expense and extent of requisite care. Salam and associates[5] point out that extrathoracic bypass procedures for symptomatic proximal common carotid stenosis or occlusion were safe and well tolerated, with a 3-year patency rate in the range of 90 per cent and apparent protection against further carotid-related neurological deaths. With an ageing population, more and more of whom are seeking low-risk care, these kinds of observations are at least reassuring.

The number of operations performed in North America for cardiac disease has grown in a dramatic fashion over the past two decades and the indications for surgery have, more often than not, been extended. Lower-extremity arteries have been required as access for devices, especially the intra-aortic balloon pump, and a higher proportion of such patients develop leg ischaemia. This influences the outcome of the primary cardiac surgical procedure with significant morbidity and a mortality rate[6] that approaches 50 per cent. As indications for interventional less invasive surgical procedures are expanded, so the evaluation of the peripheral circulation is increasingly important to minimize such adverse outcomes.

Debate has continued over the management of carotid artery occlusion by endarterectomy. DeLaurentis and associates[7] studied this prospectively in 261 patients and found that a palpable stump pulse, pressure in the stump of the carotid artery and retrograde flow were accurately reflective of collateral blood flow, permitting them to carry out shunting in a selective fashion with excellent results.

0007-1323/93/121521-02 © 1993 Butterworth-Heinemann Ltd

Growth factors and interleukins

Baigrie and colleagues[8] studied the utility of interleukins as markers in response to surgery of the abdominal aorta, notably excision and replacement. They postulated that portal endotoxaemia and related colonic ischaemia may be major contributors and related to interleukin (IL) 6 release. The majority of patients undergoing aortic surgery did not develop clinically significant colonic ischaemia but the study demonstrated a significant clinical correlation between frank ischaemia and altered IL-6 level, which may be helpful in the interpretation of the new physiological mediators.

The significance of growth factors in surgical illness and physiology is poorly understood. Their order of administration, dose and route of delivery are obviously critically important, but none of them appears at this time to represent anything like the pervasive influence of penicillin on Gram-positive coccal infection 50 years ago. The report by Ness and associates[9] addresses proliferative growth factors in breast cyst fluid and provides a degree of understanding in the illness of truly cystic breast disease. The therapeutic potential is discussed.

Colorectal cancer

Yamamoto and associates[10] examined some clinicopathological variants of mucinous carcinoma of the colon and rectum. This tumour is known to be associated with a poor prognosis, due largely to its tendency to invade directly into adjacent viscera and a propensity to more extensive lymph node involvement. The authors recommended extensive surgical excision when mucinous adenocarcinoma is discovered. Long-term results to test this hypothesis are awaited.

Trauma

For a very long time, the League of Nations' classification of cancer of the uterine cervix stood alone as a clinical scoring system with direct relevance to patient care. Recently there has been a proliferation of scores and grading systems for many surgical conditions, for example haemorrhoids and liver injury. This has been most clearly justified in the field of trauma, where standardization of protocols and evaluation of the impact of new treatment are critically dependent on the classification of the severity of injury. Increasing objectivity in grading that injury is vitally important. Rutledge and associates[11] from the University of North Carolina studied 428 consecutive victims of trauma and determined that intensive care unit and hospital outcomes were best predicted by the Acute Physiology and Chronic Health Evaluation II score. They caution that no combination of scoring methods is a substitute for clinical assessment and that scores are best employed alongside clinical judgements made by the clinician experienced in the field. This suggests that a number of the discrepancies seen in previous reports may be a reflection of the wisdom and experience of the attending surgeon.

Transcranial Doppler ultrasonography was used to evaluate serially the changes in middle cerebral artery blood flow velocity (MCAV) in 37 consecutive patients during the first 72 h after carotid endarterectomy to identify factors that may predispose towards postoperative hyperaemia. Within 6 h of endarterectomy, median MCAV in the operated hemisphere was 48 per cent (95 per cent confidence interval 37–60 per cent) above that on admission and remained 27 per cent (95 per cent confidence interval 19–37 per cent) higher at 72 h. There was a similar, but less marked, increase in MCAV in the contralateral middle cerebral artery during the same time period. There was no association between the postoperative increase in MCAV and clinical presentation, admission MCAV, the presence or absence of a residual neurological deficit or infarction on computed tomography before operation, carotid clamp time, shunt usage, internal carotid artery stump pressure or MCAV during clamping. The greatest increase in MCAV was observed in patients with internal carotid artery stenosis $\geqslant 50$ per cent and, more particularly, in those with preoperative evidence of impaired cerebrovascular reserve. In the latter patients, MCAV was 100 per cent above the admission level within 12 h of operation and was still 50 per cent raised at 72 h.

Immediately after carotid clamp release and restoration of blood flow, there is usually a surge in middle cerebral artery blood flow velocity (MCAV) that then decreases within 10 min of clamp release, although not back to the preoperative level[1]. Evidence suggests that this initial phenomenon represents a short-lived hyperaemic response to the effects of carotid clamping and may reflect the ability of the collateral circulation to maintain cerebral blood flow (CBF) during carotid occlusion[1].

After this initial surge, some patients progress to a secondary hyperaemic phase that may persist for up to 5 days after surgery[2]. The true incidence of this secondary hyperaemic phase is unknown, but it is much commoner than the associated clinical symptoms. Fewer than 1 per cent of patients will suffer a stroke, usually due to intracerebral haemorrhage[3], but a greater proportion will have headache or disorientation[2,4]. It is generally thought that this phenomenon results from transient impairment or failure of cerebral autoregulation[2,3,5], secondary to a chronic state of cerebral vasodilatation in an attempt to maintain blood flow. The clinical manifestations tend to become apparent 24–72 h after operation, although evidence suggests that the initial increase in CBF develops well before this, and CBF may even be falling by the time of onset of symptoms[2].

This prospective study used transcranial Doppler (TCD) ultrasonography to evaluate serially changes in MCAV in 37 consecutive patients during the first 72 h after carotid endarterectomy with the aim of identifying factors associated with this phenomenon.

Patients and methods

Assessment before operation

Twenty-three of the 37 patients presented with a transient ischaemic attack (TIA) or amaurosis fugax. Fourteen presented with a completed stroke, 11 of whom had a persisting neurological deficit at the time of operation. No operation was carried out on stroke patients within 3 months of onset of symptoms. All patients underwent carotid angiography, computed tomography (CT), TCD ultrasonography and assessment of cerebrovascular reserve (CVR) before operation.

The degree of stenosis of the internal carotid artery was determined as the maximal biplane diameter reduction expressed as a percentage of the normal internal carotid artery diameter above the stenosis[6]. Thirty of the 37 patients had internal carotid artery stenosis $\geqslant 50$ per cent, eight of whom had stenosis between 50 and 70 per cent. Seven patients had internal carotid artery stenosis < 50 per cent and had been randomized to surgery in the European Carotid Surgery Trial before publication of the interim results. Ten patients had a localized region of hypodensity on CT consistent with an area of old infarction. Five recordings of MCAV were measured in both the symptomatic and asymptomatic hemispheres in the manner described by Aaslid and colleagues[7] together with measurements of blood pressure and end-tidal carbon dioxide. End-tidal carbon dioxide was measured, using an infra-red capnograph, from continuous samples of air drawn from a tight-fitting face mask. The measurement was made because of the known dependency of MCAV on arterial partial pressure of carbon dioxide ($P_{a\text{CO}_2}$)[8].

CVR was evaluated to assess the haemodynamic state of the cerebral circulation before operation. Above a critical internal carotid artery stenosis, the brain attempts to maintain normal CBF by progressive pial vasodilatation, which increases the cerebral blood volume (CBV). Thus, while CBF may be maintained at near-normal levels, the progressive increase in CBV means that the cerebral arterioles have a reduced capacity to undergo further vasodilatation when stressed (the concept of impaired CVR). Conventionally, CVR is evaluated by measuring the increase in either blood flow or blood flow velocity in response to a vasodilatory stimulus, such as inhaling carbon dioxide[6,9]. Using positron emission tomography[10], it has been shown that the most sensitive indicator of CVR is the ratio of CBF to CBV. This ratio is an alternative expression for the reciprocal of mean cerebral transit time (MCTT), and Gibbs *et al.*[10] proposed that measurement of MCTT could provide a simpler method of evaluating CVR.

The present study used a novel technique for imaging regional changes in MCTT to evaluate CVR. The theory, experimental confirmation and validation have been detailed elsewhere[11,12]. In summary, a bolus of $^{99\text{m}}$Tc-sodium pertechnetate was injected rapidly into an antecubital vein, with the patient lying supine in a head-extended position with the skull vertex over a small field of view γ camera, equipped with a high-sensitivity collimator. Sequential frames were acquired using a 32×32 matrix at a rate of $3\,\text{s}^{-1}$ for 1 min, by which time the examination was complete. The method generates a colour parametric image of regional MCTT, while the computer calculates the mean transit time for each hemisphere. The normal range of hemispheric

0007-1323/93/121523–05 © 1993 Butterworth–Heinemann Ltd

MCTT (2·2–7·7 s) reflects the wide interindividual variability and the dependency of MCTT on end-tidal carbon dioxide[11]. Interhemispheric MCTT symmetry is, however, strictly maintained throughout the physiological range of end-tidal carbon dioxide[11,12] (median interhemispheric MCTT difference 0·2 (95 per cent confidence interval (c.i.) 0–0·6) s). In normal healthy volunteers an increase in end-tidal carbon dioxide causes a significant reduction in MCTT in both hemispheres (while maintaining interhemispheric MCTT symmetry) that correlates directly[12] with simultaneous increases in MCAV. Specifically, blood flow velocity changes[12] in direct proportion to the reciprocal of MCTT. Thus MCTT not only changes in the manner predicted through changes in MCAV, but also, because the reciprocal of MCTT is an alternative expression for CBF:CBV, the increase in MCAV (with increasing end-tidal carbon dioxide) measures changes in CBF:CBV, i.e. CVR.

In patients with haemodynamically significant extracranial internal carotid artery stenosis causing impaired CVR, the CBV increases to maintain CBF and there is a corresponding increase in MCTT. This, therefore, produces significant interhemispheric MCTT asymmetry, reflecting the change in CBF:CBV. Impaired CVR can thus be recognized by prolongation[11] of hemispheric MCTT beyond 7·7 s or by the development[11,12] of interhemispheric MCTT asymmetry $\geqslant 0{\cdot}7$ s. In this study, eight of the 37 patients had preoperative evidence of impaired CVR in the symptomatic hemisphere.

Surgical technique

Endarterectomy was performed under normotensive normocarbic general anaesthesia using systemic heparinization. All but one arteriotomy was closed with a vein patch and the nerve to the carotid sinus was not anaesthetized or divided in any patient. Systemic blood pressure and heart rate were measured continuously from a radial artery cannula and electrocardiogram respectively. A temporary indwelling shunt was employed in 19 patients using the criteria of slowing of the cerebral function monitor or internal carotid artery stump pressure < 50 mmHg. Systolic and mean ipsilateral MCAV were measured continuously throughout the operation[13].

Assessment after operation

On recovering from anaesthesia, two patients suffered a minor transient neurological deficit. One was thought to be embolic in origin and the other haemodynamic[13]. Both patients were confirmed to have a patent internal carotid artery using duplex ultrasonography. Serial measurements of MCAV, mean arterial blood pressure and end-tidal carbon dioxide were made every hour for the first 6 h and then again at 12, 24, 48 and 72 h in all patients. On each occasion, five measurements were taken from both the operated and non-operated middle cerebral artery, in addition to measurements of arterial blood pressure and end-tidal carbon dioxide. These values were then averaged and a mean calculated for each time period.

Statistical analysis

MCAV was not normally distributed (Filliben's test[14]) and so non-parametric analysis was used. Values in the text refer to the median (95 per cent c.i.). $P < 0{\cdot}05$ was taken as significant. Because of the normal range of interindividual variability[15] with regard to MCAV, data are presented as the percentage increase in systolic MCAV above the admission level, e.g. if the preoperative MCAV was 100 $\mathrm{cm\,s^{-1}}$ and rose to 120 $\mathrm{cm\,s^{-1}}$, this represents an increase of 20 per cent above baseline. This facilitates comparison between patients.

Results

Figure 1 illustrates a typical example of the two types of hyperaemic response after carotid endarterectomy. Note the initial surge in MCAV following release of the carotid clamps. This is followed by a transient decrease in MCAV, which then increases again to a peak of 210 $\mathrm{cm\,s^{-1}}$ 6 h after operation. In this example MCAV had returned to the preoperative level within 72 h. During this time, the patient suffered neither headache nor neurological morbidity.

Table 1 details the percentage increase in MCAV for the operated and non-operated hemispheres during the first 72 h after operation. *Table 2* shows the respective changes in mean arterial pressure and end-tidal carbon dioxide for each time period. Within 4–6 h of surgery, MCAV was 48 per cent (95 per cent c.i. 37–60 per cent) above the preoperative level in the operated hemisphere and 21 per cent (95 per cent c.i. 13–21 per cent) above baseline in the non-operated hemisphere. MCAV then gradually declined over the next 48 h but, at 72 h, remained 27 per cent (95 per cent c.i. 19–37 per cent) above the admission level in the operated hemisphere. This hyperaemic phase was not simply a consequence of concomitant changes in either mean arterial pressure or end-tidal carbon dioxide (*Table 2*) and could not be predicted from the preoperative MCAV value. Two patients recovered from anaesthesia with a transient minor neurological deficit. Both had an initial surge in MCAV on clamp release but neither developed a hyperaemic response over the ensuing 72 h.

Table 3 details the relationship between the percentage increase in MCAV and various parameters that might be associated with an increased likelihood of postoperative hyperaemia, if this were mediated by intraoperative ischaemic

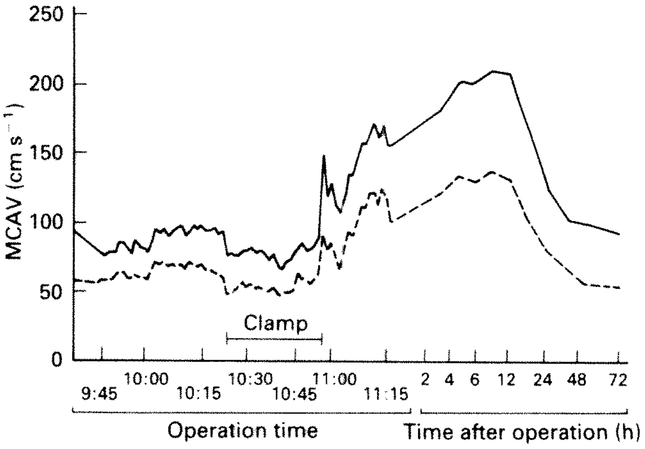

Figure 1 *Serial monitoring of systolic (——) and mean (– – –) middle cerebral artery blood flow velocity (MCAV) in the operated hemisphere during, and for 72 h after, carotid endarterectomy in a patient with preoperative evidence of impaired cerebrovascular reserve. Note the initial transient surge in MCAV immediately after carotid clamp release, followed by a more pronounced secondary hyperaemic phase over the next 24 h. At 12 h, MCAV was 100 per cent above the preoperative level*

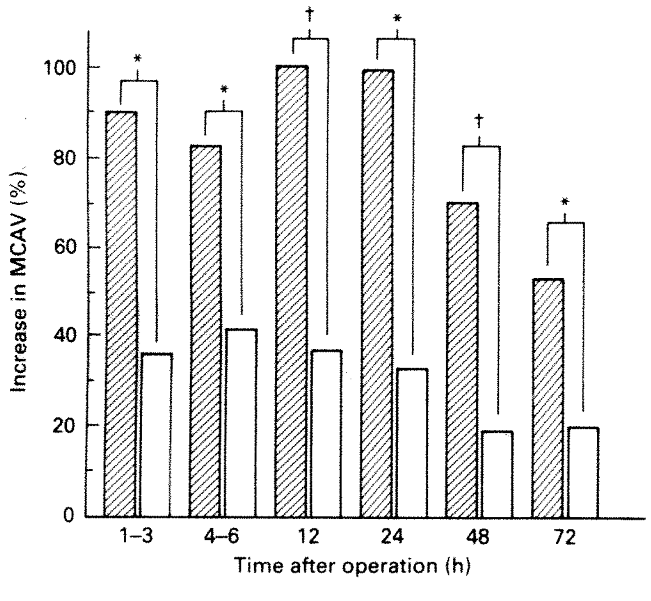

Figure 2 *Comparison of the median increase in middle cerebral artery blood flow velocity (MCAV) following carotid endarterectomy in patients with (▨) and without (☐) preoperative evidence of impaired cerebrovascular reserve.* *$P < 0{\cdot}05$, †$P < 0{\cdot}005$ *(Mann–Whitney U test)*

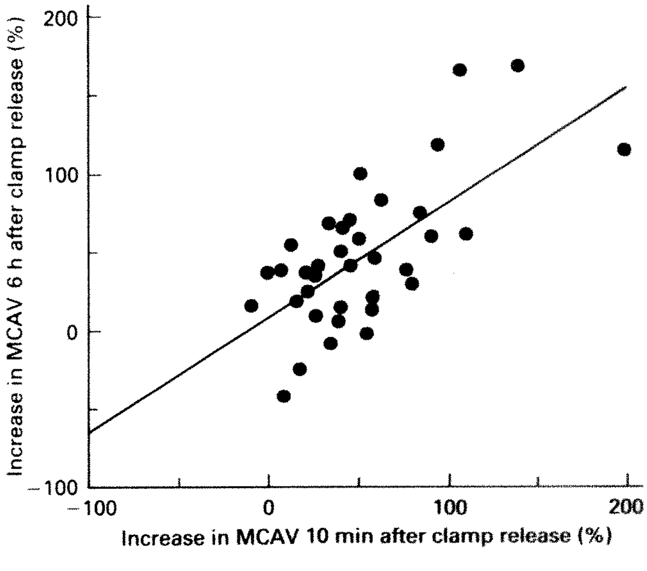

Figure 3 *Relationship between the increase in middle cerebral artery blood flow velocity (MCAV) (above the admission level) 6 h following surgery and the increase in MCAV measured 10 min after carotid clamp release and final restoration of flow.* $r_s = 0{\cdot}66$, $P < 0{\cdot}0001$

injury. There was no significant relationship between MCAV increase and mode of clinical presentation, or presence or absence of either a preoperative residual neurological deficit or CT infarct. Similarly, neither the duration of carotid clamping nor the use of a shunt appeared to influence the late hyperaemic response. There was, however, a significant trend for patients with extracranial internal carotid artery stenosis ⩾ 50 per cent to have a greater increase in MCAV than those with stenosis < 50 per cent. The strongest association was noted in patients with preoperative evidence of impaired CVR (*Figure 2*). Within 12 h of operation, MCAV had increased by 100 per cent (95 per cent c.i. 57–180 per cent) compared with only 37 per cent (95 per cent c.i. 27–47 per cent) ($P = 0.005$) in those with normal CVR. By 72 h, MCAV was still 53 per cent (95 per cent c.i. 39–106 per cent) above the admission level in patients with preoperative impairment of CVR as opposed to a 20 per cent (95 per cent c.i. 12–30 per cent) increase in MCAV in those with normal CVR ($P < 0.05$). None of these patients suffered any neurological morbidity although two described minor ipsilateral headache.

As can be seen in *Figure 1*, the secondary hyperaemic phase began almost immediately after the initial surge in MCAV following carotid clamp release; this was typical of the other patients in this series. There was no association between the secondary hyperaemic response and the initial surge in MCAV that immediately followed restoration of flow. There was, however, a clear association between the magnitude of MCAV increase at 6 h and the increase in MCAV 10 min after clamp release (*Figure 3*), suggesting that the secondary response was already gaining momentum at an early stage.

Discussion

The advent of TCD ultrasonography has enabled investigators to study non-invasively many of the physiological effects of carotid endarterectomy on cerebral haemodynamics. Principal advantages of the technique include the ability readily to perform intraoperative and postoperative bedside examinations with the minimum of inconvenience to the patient. One should, however, be aware that a measurement of MCAV cannot be directly converted into absolute volume flow, as velocity varies in proportion to the second power of the vessel radius, while volume flow changes in accordance with the fourth power. However, provided that P_{aCO_2} (which is one of the most powerful mediators of cerebrovascular tone) remains constant, it has become conventional[8] to assume that changes in MCAV provide an index of change in CBF.

This study has shown that, within 6 h of operation, MCAV was 48 per cent higher than before surgery in the operated hemisphere and was also 21 per cent higher in the non-operated hemisphere. This phenomenon was not mediated by concomitant changes in either mean arterial pressure or end-tidal carbon dioxide. These results are similar to those reported by Schroeder *et al.*[16] using the intravenous xenon technique, who noted a 37 per cent increase in CBF in the operated hemisphere within 24 h of surgery and a 33 per cent rise in the non-operated hemisphere. Quite why the hyperaemic response should be bilateral remains unclear.

As in the present study, Schroeder *et al.*[16] found no association between the magnitude of the postoperative hyperaemic reponse and preoperative clinical presentation, CT findings, internal carotid artery stump pressure or the use of an indwelling shunt, which suggests that the increase is probably not a reflection of intraoperative ischaemia. Although these authors did not evaluate CVR, they did measure an index of cerebral perfusion pressure by calculating the ratio of mean internal carotid artery to common carotid artery pressure. In patients with a ratio < 0.7, the increase[16] in CBF at 24 h was 60 per cent as opposed to only 24 per cent in those with a ratio > 0.7; this was the only factor predictive of significant hyperaemia in their series. A low internal carotid artery to common carotid artery pressure ratio reflects the fact that the perfusion pressure distal to severe internal carotid stenosis is reduced as a consequence of inadequate collateral circulation. In this situation, CBF is maintained by progressive cerebral arteriolar vasodilatation[10]. This situation is analogous to that in the patients in the present study with impaired CVR, who also exhibited the greatest increases in MCAV following operation. Like Schroeder *et al.*[16], the present authors observed that the hyperaemic phase was more prolonged in these patients and MCAV remained 50 per cent above the admission level at 72 h. These findings suggest a temporary impairment of cerebral autoregulation. Patients with preoperative impairment of CVR enter surgery with varying degrees of pial vasodilatation, and some may be approaching a state where the resistance vessels are maximally dilated[17]. After surgery there is a surge in blood flow through the dilated arteries which are unable to recover their normal vasomotor capacity for some days[17]. Clearly, the majority do not suffer any ill effects, but evidence suggests that those with coexistent episodes of hypertension may be more vulnerable to neurological morbidity[2], and blood pressure should be carefully controlled during this phase[15].

This study also suggests that the hyperaemic response starts almost immediately after carotid clamp release and final restoration of flow. The authors have previously shown that immediately after clamp release there is usually a transient surge in MCAV that appears to be a response to the effects of carotid occlusion and reflects the capacity of the collateral circulation to maintain flow during clamping[1]. No association was found between this primary hyperaemic response and the secondary phenomenon but, as *Figures 1* and *3* illustrate, there is a clear trend for the increase in MCAV to recur after the initial surge and then continue for many hours thereafter. Moreover, we agree with Schroeder *et al.*[16] that the later hyperaemic response is unlikely to result from intraoperative hypoperfusion injury during clamping, as there was no association between the subsequent MCAV increase and the level of MCAV during clamping, shunt usage or carotid clamp time.

In summary, this study has shown that there is a bilateral hemispheric hyperaemic response following carotid endarterectomy, especially in the operated side. The greatest and most prolonged increase in MCAV was observed in patients with preoperative evidence of impaired CVR. These findings support the observations of others that the phenomenon is probably due to transient postoperative impairment of vasomotor tone and cerebral autoregulation, which then normalizes over the first few days after operation.

Spontaneous staphylococcal peritonitis in an otherwise healthy young man

W. G. Manson, K. B. Hosie, R. Ackroyd and A. G. Johnson

Department of Surgery, Royal Hallamshire Hospital, Glossop Road, Sheffield S10 2JF, UK
Correspondence to: Mr K. B. Hosie

Spontaneous peritonitis caused by *Staphylococcus* species is rare, and has previously been reported only in immunocompromised patients or in association with continuous ambulatory peritoneal dialysis. An otherwise healthy patient with this condition is described.

Case report

A 28-year-old Caucasian man, who had previously been well, presented with a 12-h history of colicky abdominal pain and nausea. Some 2 weeks previously he had been treated empirically with antibiotics for a chest infection. On examination he had pyrexia (37·5°C) with generalized peritonitis. Abdominal radiography was normal. The haemoglobin level was 14·8 g/dl with a white cell count of $18 \cdot 8 \times 10^9$/l (83 per cent neutrophils). A diagnosis of appendicitis was made.

At laparotomy the peritoneal cavity was seen to have been totally replaced by thin adhesions and the small bowel was slightly distended with prominent vasculature and lymphatics. There were no localizing features of appendicitis or duodenal perforation. Biopsies of the adhesions were taken for histological and bacteriological assessment, and the abdomen was closed.

Histological examination showed fibrofatty tissue with fibrin and acute inflammation. *Staphylococcus aureus* was grown from the swab and biopsies of the adhesions taken during surgery, and the patient was treated with flucloxacillin and gentamicin. After operation he had prolonged ileus requiring 3 weeks of parenteral nutrition. At 5 weeks the man was tolerating a normal diet and was discharged home. He remains well at 6 months.

Discussion

Spontaneous ('primary') bacterial peritonitis is an infection of the peritoneum that occurs without perforation of an abdominal organ or penetration of the abdominal wall. It is most often associated with ascites, in which case the most common bacteria are Gram-negative bowel organisms. It is extremely rare in normal healthy adults[1].

The proposed routes of infection in spontaneous bacterial peritonitis are haematogenous, via internal female genital organs and by transmural migration. Animal experiments[2,3] have shown that inoculation of the blood or internal female genital organs with bacteria does not consistently produce bacterial peritonitis. Transmural migration has been suggested as the most likely pathogenesis in ascitic peritonitis. This condition is usually associated with an oedematous bowel wall in which, it is proposed, the usual barriers to bacteria are not effective.

The clinical picture in the present patient with fibrous adhesions may be due to the *Staphylococcus* being coagulase-positive and therefore tending to form adhesions. The only similar cases previously reported are sclerosing peritonitis as a reaction to practolol[4], which was not implicated in the present case, and the abdominal cocoon[5], which has previously been reported only in young women living in tropical or subtropical areas and is described as a dense fibrous capsule around the small bowel.

Similar patients have not been described in the literature and the prognosis is uncertain, but the man remains well at 6 months.

Randomized controlled trial of patch angioplasty for carotid endarterectomy

*A randomized controlled trial was performed to evaluate patch angioplasty for patients undergoing carotid endarterectomy. There were 213 patient episodes affecting 148 men and 65 women, with 109 allocated to patch angioplasty. Following surgery six patients suffered transient ischaemic attacks but these did not delay discharge from hospital. Six individuals (four patched operations, two not patched) required re-exploration for postoperative haemorrhage and eight (two patched procedures, six not) had potentially serious neurological problems after operation. Of these eight patients, four (none receiving patch angioplasty) underwent re-exploration and in each case a clot was removed and a patch inserted; three of the four made a good long-term recovery. The other four patients suffered completed strokes from which one died. Two further patients (one patched procedure, one not) died after operation from myocardial events, giving an overall 30-day stroke or mortality rate of 2·8 per cent. Objective follow-up assessment with duplex scanning at 1 year was completed by 94·8 per cent of patients; significantly more vessel restenoses and occlusions were observed in those not receiving patches (*P < 0·01*). Patch angioplasty reduces the number of immediate postoperative complications, and significantly lowers vessel restenosis and occlusion rates at 1 year after operation.*

Recent reports have confirmed the benefits of carotid endarterectomy for patients with high-grade carotid stenosis who have had associated cerebrovascular events[1,2]. Government policy[3] in the UK now includes commitment to a 40 per cent reduction in the number of strokes within the next 10 years.

The value of patch angioplasty after carotid endarterectomy has not yet been determined. Many feel that inclusion of a patch lengthens the clamp or shunt time, makes the procedure technically more demanding[4,5], may be unnecessary in some patients[6], and may put patients at risk of infection or aneurysm formation[7]. Others believe that use of a patch may reduce the number of both perioperative and later neurological complications and may prevent vessel stenosis at arterial closure and subsequently[8].

Many reports have been published on the subject of patching but several are essentially retrospective reviews of experience before and after introduction of the method[4,5,9]. Others, although prospective in design, are observational studies that failed to randomize patients[8,10–13]. Three prospective randomized studies have been reported[6,14,15] but in each of these a substantial proportion of cases (19 of 159, 30 of 152 and 46 of 164 respectively) was not randomized. Despite these problems all three suggested a benefit in favour of patch angioplasty over simple closure in terms of reduced restenosis rate; some also showed a reduction in the incidence of perioperative neurological events.

This paper reports results of a prospective randomized trial undertaken to examine the value of patch angioplasty for patients undergoing carotid endarterectomy; the surgical method was in strict accordance with randomization.

Patients and methods

A total of 199 patients undergoing 213 consecutive carotid endarterectomies at four participating centres (Belfast, Leicester, Portsmouth, Southampton) were recruited prospectively. Each was randomly assigned, using sealed envelopes, to receive either simple vessel closure or patch angioplasty. The age and sex distribution of the study cohort reflected the prevalence of carotid vessel disease in the general population, with similar groups being entered from each centre (*Table 1*).

Of 213 operations, 196 (92·0 per cent) were for symptomatic disease, 124 (58·2 per cent) for transient ischaemic attack, 42 (19·7 per cent) for amaurosis fugax and 30 (14·1 per cent) were carried out after a good functional recovery from stroke. The remaining 8·0 per cent of operations were for high-risk situations with high-grade asymptomatic stenosis affecting one carotid artery and with occlusion of the contralateral vessel. Whenever possible patients were treated with aspirin before surgery.

All patients were assessed before carotid endarterectomy by duplex scanning, the results of which could be supplemented with arteriography if necessary. An observed frequency shift of 3·8 kHz using a 4-MHz transducer was taken to indicate intermediate-grade stenosis of ≥50 per cent reduction in luminal cross-sectional diameter. A lesion creating high-grade stenosis of ≥75 per cent of the cross-sectional diameter had the same observed frequency shift using the same transducer, plus a positive compression test observed at the ipsilateral supraorbital artery. Eight symptomatic patients were operated on for low-grade (<50 per cent) stenosis. Some 84 operations were for intermediate-grade stenosis and the remainder for high-grade stenosis (*Table 1*).

At operation a shunt was used when technically possible, with full heparinization in all cases. The choice of patch material was made by the individual surgeon; two centres used autologous vein ($n = 53$) and two Dacron (Du Pont, Stevenage, UK) ($n = 56$). The duration of clamping was not recorded. At 3 and 12 months after operation each patient was re-examined with a duplex scanner for evidence of vessel restenosis or occlusion, using the same criteria for stenosis as were applied before endarterectomy.

Results

Patch angioplasty was used in 109 operations and simple non-patch arteriotomy closure in 104; there was no deviation from randomization. In the immediate postoperative period six patients (four undergoing patching, two not; *P* not significant) suffered haemorrhage or haematoma formation requiring a return to theatre.

After six operations (2·8 per cent; three patched, three not)

patients suffered a transient neurological event with no late sequelae. After eight other operations (3·8 per cent; two patched, six not) patients suffered serious neurological events, with effects lasting more than 24 h. After four of these operations (all unpatched) patients developed symptoms within 24 h of surgery. Each of these individuals underwent immediate re-exploration with thrombectomy and vessel closure using a patch; three made a full functional recovery with time. Each of these four episodes is counted as vessel occlusion within the original group in the subsequent analysis. However, where vessel patency was re-established by exploration and patching, each episode is counted in the patched group when considering outcome for restenosis at the 3-month and 1-year time points.

The remaining serious neurological events were completed strokes that developed later in the postoperative course; these were not treated by re-exploration. Two of these strokes (after patch operations) occurred despite there being a patent operated vessel on duplex examination, while cerebral infarction occurred in a patient receiving non-patched closure with an occluded operated vessel as revealed by post-mortem examination. Within 30 days of surgery two further patients died from myocardial infarction (one from each group).

At hospital discharge or by 30 days (whichever was the shorter), a total of six operated vessels had occluded, all without patches. During the subsequent year 14 further patients died (four patched operations, ten not; *P* not significant). Of these only one patient, who had undergone a non-patch operation, suffered a stroke and the operated vessel was shown to be occluded. Three patients suffered further symptoms, one patient receiving patch angioplasty in whom the vessel had occluded and two without patches.

At 3-month follow-up 94 of 107 (87·9 per cent) patched and 84 of 98 (86 per cent) non-patched vessels were re-examined (*Table 2*). Nine stenoses and one additional occlusion were detected in each group. At one year, five of the nine significant stenoses found in patients with patched closure at 3 months had regressed and no new lesion had developed. Only two stenoses regressed in the non-patched group and one new lesion developed (*Table 2*). Between 3 months and 1 year one further patched and two non-patched vessels asymptomatically occluded.

The results summarized in *Table 2* reveal that at all stages of follow-up significantly fewer vessels were occluded after patch angioplasty. Deaths and complications, other than neurological morbidity, did not vary significantly in incidence between the two groups, although more events occurred after simple closure (*Table 3*). No significant infections or aneurysms developed in either group. Analysis of the vein-patched and Dacron-patched subgroups did not show any difference with respect to the incidence of postoperative complication, neurological event, vessel occlusion or vessel restenosis.

Discussion

The present fully randomized study confirms the conclusions drawn by others[4–6,8–13,15]. First, there is an absence of early vessel occlusion after patch angioplasty. Second, there is a significant reduction in vessel occlusion and restenosis rates at 3 months and 1 year after surgery. Third, there is a trend towards lower mortality and morbidity rates after patch angioplasty.

Significant carotid artery restenosis of over 50 per cent occlusion may affect between 10 and 20 per cent of patients within 2–5 years of surgery[10,16,17]. Although vessel occlusion may occur at any stage, it most commonly develops in the immediate period after surgery; this occurs in about 2 per cent of cases[10,15], and morbidity and mortality rates become considerable if it is left untreated. In the longer term, between

1 and 2 per cent of all patients will have recurrence of symptoms from carotid restenosis[18,19].

Most restenoses develop in the early months after endarterectomy; Aldoori and Baird[20] have suggested that all recurrent lesions are detected within 6 months of operation. In the present study, therefore, with 95 per cent of patients being re-examined within 1 year, the vast majority of significant stenoses that are likely to develop will have been detected. The regression of stenosis detected by duplex scanning in the early months after endarterectomy is also well recognized[20]. This occurred in seven patients in the present study.

The benefits of patch angioplasty must be considered alongside its disadvantages. The use of a patch increases clamping time[4,5] by between 15 and 30 min. Suture-line disruption, leading to haemorrhage or false aneurysm formation, has been reported after both conventional and patched vessel closure. However, the incidence of these problems appears to be greater after patching, particularly if autologous vein is used and especially if this is harvested from the ankle saphenous or external jugular vein. Infection seems to be a much rarer cause for these complications[7]. In the present study no patient developed an infective or aneurysmal complication in the 1-year follow-up period. Six patients were returned to the operating theatre for haemorrhagic complications, four after patching and two after simple closure, but patch angioplasty did not seem to be associated with an excess of directly related complications.

Many reports have advocated a selective approach to the use of patch angioplasty for patients considered particularly at risk of restenosis or vessel occlusion, i.e. those with small vessels or those undergoing surgery for restenosis. The present results, however, do not allow identification of these subgroups specifically. It is concluded that patching is of benefit in the short and medium term; it may well be beneficial in reducing the long-term recurrent stenosis rate.

Popliteal aneurysm: morphology and management

Since January 1988, 32 patients have presented with 44 popliteal aneurysms (22 thrombosed, 22 non-thrombosed). Patients with thrombosed aneurysms were older (median age 72 versus *66 years), and more likely to have bilateral lesions* ($P < 0.02$) *and serious associated cardiovascular disease* ($P < 0.02$). *Nineteen aneurysms thrombosed acutely; 12 were treated with intra-arterial thrombolysis, which was at least partially successful in seven. All 12 were subsequently bypassed, as were the other seven which were associated with such severe ischaemia that they required urgent operation. One patient died and two others required major amputation. Other complications included foot-drop (two patients), renal failure (one) and wound infection (two). Two grafts thrombosed and required re-exploration. Elective bypass was carried out in 11 patients without acutely thrombosed aneurysms; there were no significant postoperative problems. Distortion within the aneurysm* ($P < 0.01$), *large size* ($P < 0.01$) *and distortion of the popliteal artery above or below the lesion* ($P < 0.02$) *were all associated with thrombosis. Stenosis within the aneurysm was more likely in patients with multiple lesions* ($P < 0.01$) *and distortion with larger aneurysms* ($P < 0.01$). *After correcting for distortion, none of the other variables was independently significant. The combination of distortion and diameter >3 cm was present in 13 of 15 thrombosed aneurysms. Morbidity is high following acute thrombosis of popliteal aneurysm. Distortion of the aneurysm appears to be a more sensitive predictor of thrombosis than size alone. The combination of distortion with a diameter >3 cm may help to define popliteal aneurysms that should be bypassed electively.*

There are two main controversies in the management of popliteal aneurysm. These concern the management of asymptomatic aneurysms and the treatment, once the run-off has been cleared, of aneurysms that have thrombosed. There are few data on the natural history of popliteal aneurysm. A recent review suggested an average annual thrombosis rate of 14 per cent in asymptomatic aneurysms, but with a wide range of 5–24 per cent per year[1]. This is almost certainly because popliteal aneurysms are a heterogeneous group of lesions; some are small and uncomplicated whereas others are larger, distorted, multiple or associated with stricture.

Early reports[2,3] highlighted the high amputation rate associated with acute thrombosis of popliteal aneurysm. It has therefore become accepted treatment to operate on the lesion once it has been diagnosed to prevent thrombosis occurring[4–6]. This view has recently been challenged for the following reasons. First, an asymptomatic patient is subjected to potential morbidity and mortality[7]. Second, with newer forms of treatment, particularly intra-arterial thrombolysis (IAT), the results of treating thrombosed aneurysms might be better than have previously been reported[8]. Finally, with the widespread use of duplex ultrasonography, minor degrees of popliteal dilatation are being identified; their relationship with clinical aneurysm is uncertain.

The aim of this paper is to review the authors' experience of popliteal aneurysm in an attempt to define those that are at risk of thrombosis. The management and outcome of thrombosed aneurysm is described.

Patients and methods

Data were collected prospectively as part of a continuing audit. All patients with asymptomatic aneurysms underwent arteriography and ultrasonography. For thrombosed aneurysms, IAT was regarded as the treatment of choice in the presence of a viable limb. The technique and results of IAT have been described previously[9–11]. The lytic agent was infused through a 5–7-Fr catheter placed in the ipsilateral femoral artery; streptokinase (5000 units/h) or tissue plasminogen activator (0·5 mg/h) were used. Even if thrombolysis was not successful in clearing the run-off, the aneurysm was often cleared sufficiently to allow a comparison of the radiological appearance of thrombosed and non-thrombosed lesions.

Popliteal aneurysm was defined[5] as a localized dilatation of the popliteal artery >2 cm in diameter or >150 per cent of the normal proximal arterial calibre[12].

Statistical analysis was carried out using the χ^2 test with Yates' correction, the Mann–Whitney *U* test or Student's *t* test as appropriate.

Results

During 5 years from January 1988, 32 patients presented with 44 popliteal aneurysms. Twenty patients presented with a thrombosed popliteal aneurysm; in two of these a contralateral aneurysm thrombosed within 6 weeks of initial presentation. Thus, there were 22 thrombosed aneurysms in this series, of which 19 thrombosed acutely. Eleven other patients had non-thrombosed aneurysms (one bilateral). Presenting features of non-thrombosed aneurysms included distal emboli in two and local discomfort in one. The remainder were asymptomatic. All of these aneurysms were atherosclerotic. One further patient presented with a mycotic aneurysm. He was excluded from the analysis. There was only one woman in the series.

Patients

The clinical details of patients with thrombosed and non-thrombosed popliteal aneurysms are shown in *Table 1*.

0007-1323/93/121531-03 © 1993 Butterworth-Heinemann Ltd

Patients with thrombosis were older and more likely to have serious associated cardiovascular disease than those with non-thrombosed lesions ($P < 0{\cdot}02$). Furthermore, there was a greater chance of an aneurysm being present on the contralateral side in patients presenting with thrombosis ($P < 0{\cdot}02$).

Aneurysms

Thrombosis of the aneurysm was significantly associated with distortion (*Figure 1*; *Table 2*), either within the aneurysm ($P < 0{\cdot}01$), or above or below it ($P < 0{\cdot}02$). There was no significant correlation between stenosis and thrombosis, although multiple aneurysms were more likely to have stenoses along their length ($P = 0{\cdot}009$). Thrombosed aneurysms were significantly larger than those that had not thrombosed; nevertheless, one of the thrombosed lesions was only 1·2 cm in diameter. Bilateral aneurysms were significantly bigger than unilateral lesions ($P = 0{\cdot}002$). The combination of distortion within the aneurysm and size >3 cm was associated with thrombosis in 13 of 15 cases. On the other hand, when neither of these features was present, only two of 19 aneurysms had thrombosed.

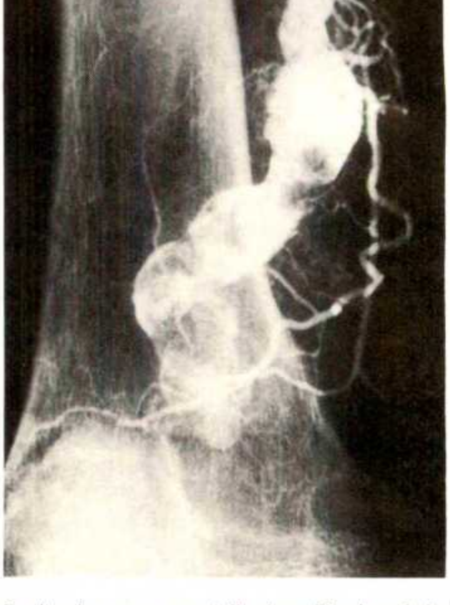

Figure 1 *Popliteal aneurysm partially cleared by thrombolysis, showing gross distortion within the lesion*

Management

The management of the 22 thrombosed aneurysms is shown in *Figure 2*. Of the three patients with chronic thrombosis, all were claudicants, but two were not incapacitated and so were treated conservatively. The remaining patient underwent ligation and bypass of the aneurysm. Of the 19 patients presenting with acute thrombosis, 12 were initially treated with IAT. This proved completely successful in clearing the run-off in six patients and partially so in one other. A further patient underwent partially successful thrombolysis for symptoms due to distal emboli from an aneurysm. In five patients the thrombolysis failed. In each, the procedure had to be terminated owing to complications: bleeding in three and significant worsening of the clinical condition of the limb in two. Seven patients underwent immediate operation as their legs showed signs of neurological impairment on admission. A total of 20 patients therefore underwent ligation and bypass of the aneurysm. Six fasciotomies were performed. Two limbs required amputation following attempts at revascularization. In retrospect, both of these were probably non-viable at the time of presentation, having presented after considerable delay. The complications sustained by these patients are shown in *Table 3*.

Eleven patients with non-thrombosed aneurysms were operated on. All three symptomatic patients had bypass of the aneurysm. All of the asymptomatic lesions operated on were large aneurysms associated with distortion. There were no postoperative complications. None of the aneurysms treated conservatively subsequently thrombosed (median follow-up 18 months).

Discussion

Over a 5-year period 32 patients presented with 44 popliteal aneurysms, a higher rate than is apparent in most other series. It may be that the prevalence of popliteal aneurysm is increasing but it is more likely that the condition is being diagnosed more efficiently. In other reports patients with chronic occlusion may have been treated for peripheral vascular disease without the recognition of an underlying aneurysm. Popliteal aneurysm may also have been underdiagnosed as a cause of acute ischaemia before the use of thrombolysis. The ratio of thrombosed to non-thrombosed aneurysms in the present series was 1:1, similar to that described by others[13]. The ratio of popliteal to abdominal aortic aneurysm (AAA) has been described[5] as approximately 1:15. During the 5-year period of the present study, about 300 patients with AAA presented, yielding a ratio of 1:8.

The association of popliteal aneurysm with other aneurysms, particularly AAA, is well documented and was confirmed in the present series. Patients with thrombosed lesions were more likely to have an aneurysm on the other side, and bilateral lesions were bigger than single ones. That patients with thrombosed aneurysms were older and had more serious cardiovascular disease may suggest that thrombosis represents a more advanced stage in the disease process. The rate of thrombosis varies from one series to another, but the present results suggest that some aneurysms are at greater risk of thrombosis than others. Although the aim of IAT is to clear run-off, it also allows detailed analysis of the morphology of the aneurysm. Distortion of the aneurysm and its size were the most important risk factors, and a combination of distortion and diameter >3 cm was present in 87 per cent of aneurysms that had thrombosed. Distortion probably represents the extent to which elongation and dilatation of the artery have occurred. The resulting tortuosity may be related to thrombosis due to kinking or turbulence.

Amputation rates of up to 30 per cent have been reported following thrombosis, with an average in the literature of 18 per cent[1]. The mortality rate is also high in these patients. Rates of mortality and limb loss are much reduced in asymptomatic patients. Long-term graft patency and limb salvage rates are also better in patients operated on before thrombosis of the aneurysm[1]. Nevertheless, serious complications may occur when operating on asymptomatic patients, such that some are made worse by a prophylactic operation. Clearly, identification of aneurysms at high risk of thrombosis would be useful in minimizing the number of patients undergoing elective operation.

If the limb is viable on presentation, IAT should be considered as the treatment of first choice in clearing the run-off. However, the technique itself is not without complications; reported rates of stroke and major bleeding are 1 and 5 per cent respectively[14]. Minor bleeding and catheter-related problems occur in up to 25 per cent of cases[10]. A further complication recently reported[15] is that of acute deterioration of the limb during IAT. This appears to be more common in thrombolysis of popliteal aneurysms and occluded grafts than in that of thrombosed atheromatous arteries. This complication occurred in two patients in the present series, at a time when thrombolysis appeared to be progressing satisfactorily. In both cases an urgent thrombectomy and bypass was carried out, with satisfactory results. This phenomenon is probably due to massive thrombus destabilization followed by distal embolization. Passing the perfusing catheter through the aneurysm to direct lysis at the run-off alone may be a better way of dealing with thrombosed aneurysms than attempting to lyse the aneurysm thrombus itself.

The present results suggest that there are significant morphological differences between thrombosed and non-thrombosed aneurysms. The presence of the abnormalities described in this paper might persuade the surgeon to consider elective operation in an otherwise asymptomatic aneurysm.

This prospective study of 335 patients with penetrating injuries of the neck examined the decision whether to operate or observe according to a protocol based mainly on physical examination. Emergency angiography was performed in only three patients. Sixty-six patients (20 per cent) were subjected to emergency operation because of signs and symptoms suggestive of significant injury (60 patients) or because of positive investigations (six). The remaining 269 patients (80 per cent) were selected for non-operative management. Two of these patients (0·7 per cent) required elective operation during the initial hospital stay. No deaths occurred in patients treated conservatively. Some 192 (72 per cent) of observed patients were available for early follow-up and 111 (42 per cent) for late follow-up. No significant complications were found. Physical examination is a reliable method for detecting significant injuries following penetrating neck trauma. Emergency angiography is rarely necessary.

Some trauma centres practise routine exploration of all neck injuries that penetrate the platysma, but most advocate some form of selective conservative management. Methods of patient selection vary widely. Many[1–3] believe that physical examination alone is unreliable and that significant injuries may be missed. An alternative to routine exploration is the liberal use of angiography and other investigations[1,2,4]. Others[5–7] believe that physical examination is reliable in detecting significant injuries. Most of the existing studies are retrospective and few include late follow-up of patients managed conservatively. A large prospective study was therefore undertaken to include late follow-up of observed patients to assess the reliability of physical examination.

Patients and methods

Patients with injuries violating the platysma and involving the anterior neck were recruited between 1989 and 1991. Those who died before admission to the trauma unit were excluded. The location of the injury was classified by zones: zone I included the base of the neck from the clavicles to the cricoid cartilage; zone II included the area between the cricoid cartilage and the inferior border of the mandible; and zone III comprised the area from the inferior border of the mandible to the base of the skull.

Patients with one or more of the following signs underwent emergency surgery: severe active bleeding, shock not responding to intravenous resuscitation, large expanding haematoma, absent or diminished peripheral pulse, air bubbling through the wound and major haemoptysis. Chest radiography was performed whenever there was suspicion of an associated chest injury and provided that the patient was stable.

In the absence of the above signs the patient was assessed whenever possible by careful digital exploration of the wound. This was to assess the direction of the injury track, i.e. towards or away from vital structures. No attempt was made to palpate adjacent major vessels, in case this precipitated bleeding. Some patients with subcutaneous emphysema were assessed by Gastrografin (Schering, Johannesburg, South Africa) swallow and endoscopy. If digital exploration or the entrance and exit sites of a bullet suggested that the direction of the wound track was away from the larynx, trachea and oesophagus, no further investigations were performed. Patients with painful swallowing or hoarseness were investigated by Gastrografin swallow or endoscopy. Doppler pressure measurements were obtained whenever it was difficult to palpate the pulses. Emergency angiography was performed only in haemodynamically stable patients with a widened mediastinum on erect chest radiography. Semielective angiography was performed whenever a bruit or abnormal peripheral pulse was detected after admission to the trauma unit. Patients with isolated brachial plexus injuries were operated on electively, within 24–72 h of injury.

Patients selected for non-operative management were admitted for observation for 24–48 h. They were discharged with instructions to return to the hospital if they experienced pain, discomfort or bleeding. Early and late outpatient assessment was carried out.

Results

Patients

The study group comprised 304 men and 31 women of mean age 28 (range 16–62) years. Of these, 283 (84 per cent) sustained a knife wound, 39 (12 per cent) a gunshot wound and 13 (4 per cent) injury by other sharp instruments. The left side of the neck was involved in 74 per cent of instances. Zone I was involved in 44 per cent of patients, zone II in 29 per cent and zone III in 27 per cent. Clinical findings on admission are shown in *Table 1*.

Investigations

Chest radiography was performed in 250 patients. The most common findings were: emphysema in the neck (56 patients),

haemopneumothorax (47) and a widened mediastinum (two). A Gastrografin swallow was performed in 18 patients with subcutaneous emphysema and a wound track towards the midline; this demonstrated oesophageal leakage in two patients. Endoscopic evaluation of the oesophagus and trachea was performed in five patients with subcutaneous emphysema or minor haemoptysis; tracheal injuries were found in two. Doppler pressures did not reveal any new information that was not detected clinically. Emergency angiography was performed in only three patients: in two because of a widened mediastinum on chest radiography and in one for a knife blade embedded at the base of the skull. One angiogram demonstrated a fistula between the aorta and the subclavian vein, and one a fistula between the innominate vessels. Both patients with an abnormal angiogram had a murmur on auscultation. Four later angiograms were carried out because of bruits detected after admission to the trauma unit. There was one fistula between the subclavian artery and the internal jugular vein, one intimal tear of the subclavian artery and two negative studies.

Management

Sixty-six patients (20 per cent) underwent emergency surgery on the basis of clinical signs (60 patients) or positive investigations (six). In ten of these operations no significant injuries were found. The remaining 269 patients (80 per cent) were selected for conservative management. Two of these patients required semielective surgery for vascular lesions, during the same hospitalization. In both a bruit was detected the day after admission and angiography demonstrated an arteriovenous fistula.

Table 2 demonstrates management according to the site of injury. The injured organs in the 58 patients with significant trauma are listed in *Table 3*. Of the nine patients with brachial plexus injury, only one was subjected to emergency operation because of an associated vascular lesion. The remaining eight patients were operated on electively for nerve repair.

Six (15 per cent) of patients with low-velocity bullet injuries required an operation compared with 57 (20 per cent) of those with knife wounds.

Morbidity and mortality rates and length of hospital stay

There were two deaths from massive bleeding in patients treated surgically. There were no deaths in the group of 269 patients initially selected for non-operative treatment. Of the conservatively treated group, 192 (72 per cent) returned for early follow-up within 1 month (mean 16 days) of discharge. Five patients had wound sepsis but neither aneurysm nor fistula. Of the rest, 111 (42 per cent) had a late follow-up, more than 1 month (mean 48 days) after discharge; no complications were found. Seventy-five patients (28 per cent) in the observed group were lost to follow-up; most of these patients had given false addresses. The mean hospital stay of patients treated conservatively was 2·6 days, that of patients subjected to non-therapeutic operation 3·5 days and that of those who underwent therapeutic surgery 7·7 days.

Discussion

The management of penetrating injuries of the neck remains controversial. Many[1–3] believe that physical examination is unreliable. Sclafani *et al.*[1] found that physical examination had a specificity of 80 per cent and a sensitivity of 61 per cent. Meyer *et al.*[8] in a prospective study found clinical examination to have an accuracy of only 68 per cent. Some[3,9,10], therefore, recommend exploration of all wounds that have violated the platysma. The incidence of unnecessary or negative explorations is high if this policy is followed, ranging from 46 to 89 per cent[2,8,11].

Triage criteria may vary considerably from clinical examination and observation alone to various invasive diagnostic tests. Many[2,4,11] recommend routine arteriography for all injuries in zones I and III, but only a few patients benefit. Meyer *et al.*[8] reported only nine positive angiograms in a series of 113 patients with zone II injuries who underwent routine angiography. Jurkovich *et al.*[2] found that only 9·4 per cent benefited from angiography. In the present series only 5 per cent of patients with zone I injuries and 13 per cent of those with zone III injuries had significant vascular lesions.

The reported incidence of false-positive and false-negative angiograms is 3 per cent each[2,8,12]. These figures are similar to the accuracy of physical examination in the present series. As angiography was not performed routinely, some arterial injuries may have been missed. This is, however, unlikely, because early and late follow-up of a significant number of observed patients did not show any vascular sequelae. Virtually all post-traumatic vascular lesions manifest within 3 months and the majority[13–15] within 1 month. Clinically occult angiographically detected vascular injuries have a good prognosis without surgery[12,16,17]. Many authors suggest that angiography in patients with zone I and III injuries may help in planning the incision, should operation become necessary. Depending on the operative findings, however, the exposure can be improved by adding a sternotomy or by anterior subluxation of the jaw. There is often poor correlation between angiographic reports and operative findings, and careful clinical examinations are reliable in detecting significant injuries. The accuracy of 97 per cent compares favourably with that of angiographic investigation. The reported low accuracy of physical examination may result from various factors: retrospective studies may not provide full details and trauma centres that practise mandatory exploration or rely on routine angiography may place too little emphasis on physical examination.

There is no argument that the presence of 'hard' signs is diagnostic of significant injury and emergency operation is needed. 'Soft' signs such as shock responding to resuscitation, minor active bleeding, haematoma, dyspnoea, subcutaneous emphysema, hoarseness, dysphagia or minor haematemesis are not an absolute indication for operation. These patients should be assessed individually, taking account of the direction of the injury track and the severity and type of 'soft' signs. Subcutaneous emphysema is considered by some[2,7] an indication for surgery but only 38 per cent of such patients in the present study needed an operation.

If the direction of the wound track is towards midline structures, contrast swallow studies and/or endoscopy are performed. Missed oesophageal or tracheal injuries may lead to adverse effects especially in the thoracic oesophagus but the cervical oesophagus may be more resilient. Ngakane *et al.*[18] showed that small oesophageal and tracheal injuries can be safely managed without operation. Some 80 per cent of patients with penetrating injuries of the neck can be safely managed conservatively. The decision whether to operate or observe can be made on the basis of careful initial and repeated clinical examinations. With this policy, only ten patients underwent unnecessary operation, only seven had an unnecessary arteriogram and there was no mortality or serious morbidity.

Timing of extubation after oesophagectomy

Ventilatory support for 24 h after surgery is standard practice in many units after oesophagectomy, especially for patients in whom respiratory problems are anticipated. Weaning difficulties may occur, however, and there is increasing evidence that mechanical ventilation is associated with alveolar trauma. A deliberate change in policy was instituted in the authors' unit in January 1990 to make early extubation mandatory in all patients undergoing elective oesophagectomy, apart from those in whom serious perioperative problems were encountered. The present study compared two sets of patients: group 1 ($\mathrm{n} = 36$*) underwent oesophagectomy in the year before the policy change and group 2 (*$\mathrm{n} = 45$*) oesophagectomy in the year after. The two groups were similar in age, sex and respiratory risk factors. Early extubation was carried out in 38 patients in group 2 compared with eight in group 1 (*$\mathrm{P} < 0{\cdot}001$*). Only two patients in group 2 required prolonged ventilation compared with ten in group 1 (*$\mathrm{P} < 0{\cdot}005$*). No patient in group 2 required reventilation compared with seven in group 1 (*$\mathrm{P} < 0{\cdot}005$*), and no patient in group 2 who had undergone early extubation required delayed ventilation. The mean ventilation time and length of stay in the intensive care unit were significantly reduced following the policy change. Early extubation after elective oesophagectomy is an attainable goal and results in a significant reduction in both the morbidity rate and cost of surgery.*

Respiratory complications are the main cause of morbidity after oesophagectomy[1–3]. Anaesthetic policy on ventilatory support after surgery varies considerably between units; it has become standard practice in many to ventilate patients overnight after operation on the assumption that this may minimize the number of respiratory complications[4,5]. Many of these patients experience weaning difficulties[6], and failed extubation is associated with high morbidity and mortality rates[7]. Pulmonary oedema has been attributed to alveolar barotrauma resulting from artificial ventilation[8]. Others[9,10] have attributed alveolar injury to overdistension with subsequent oedema.

An audit of oesophageal resection in the authors' unit revealed that respiratory complications may have been related to increasing use of overnight ventilation after oesophagectomy. A decision was made that all subsequent patients would be extubated in theatre immediately after oesophagectomy or shortly after admission to the intensive care unit. Patients were monitored closely to identify respiratory compromise or the need for repeated ventilatory support. This study examined the effect of this change in policy on morbidity and mortality rates, and intensive care and hospital stay in patients undergoing elective oesophagectomy.

Patients and methods

All patients undergoing oesophagectomy in the authors' unit have undergone a standardized preoperative investigation since 1987 and all details of their history, investigations, surgery, pathology and postoperative course have been collected prospectively and entered into a 128-field database (Reflex; Borland/Analytica, Scotts Valley, California, USA). Patients undergoing elective oesophagectomy during the period 1 January 1989 to 31 December 1989 were arbitrarily designated group 1.

A policy of early extubation after elective oesophagectomy was introduced in this unit in January 1990. After operation all patients, apart from the most seriously compromised, were required to be extubated in the theatre or on return to the intensive care unit. Patients undergoing elective oesophagectomy during the period 1 January 1990 to 31 December 1990 comprised group 2.

Patients who were not extubated by midnight on the day of operation but who underwent extubation the following day were defined as requiring overnight ventilation. Those who could not be extubated on the first day after surgery were considered as requiring prolonged ventilation. Patients who were extubated but required subsequent ventilatory support were classified as needing reventilation. Those who were not ventilated overnight but who subsequently required ventilation were deemed to have received delayed ventilation.

Statistical analysis

χ^2 analysis with Yates' correction, Fisher's exact test, the Wilcoxon rank sum test and Student's t test were used as appropriate.

Results

Forty-seven patients underwent oesophagectomy in 1989. Eleven undergoing pharyngolaryngo-oesophagectomy were excluded, leaving 36 for analysis in group 1. In 1990, 53 patients underwent oesophagectomy. Of these, three received emergency resection and five required pharyngolaryngo-oesophagectomy,

leaving 45 for analysis in group 2. The two groups were similar in age, sex and respiratory risk factors (*Table 1*). There was a difference in the type of operation performed (*Table 2*) in that more patients required thoracotomy in 1990 ($P < 0\cdot001$). Epidural analgesia was used routinely in the postoperative period in both years of the study.

After elective oesophagectomy, 28 of the 36 patients in group 1 received ventilation overnight compared with seven of the 45 in group 2 ($P < 0\cdot001$). The mean difference between the preoperative arterial oxygen tension and the first reading after extubation was similar in the two groups (0·35 *versus* −1·08 kPa, $P = 0\cdot18$). Two of the 45 patients in group 2 required prolonged ventilation compared with ten of the 36 in group 1 ($P < 0\cdot005$). No patient in group 2 required reventilation compared with seven in group 1 ($P < 0\cdot005$) (*Figure 1*). None of the 38 patients in group 2 who had undergone early extubation required delayed ventilation.

There was no increase in respiratory morbidity rate associated with the change in policy. In fact, cardiac complications were significantly fewer in group 2 (*Table 3*). The mean(s.e.m.) ventilation time was reduced from 4·6(1·3) to 1·1(0·7) days ($P < 0\cdot05$) and the mean(s.e.m.) length of intensive care fell from 9·8(1·6) to 5·9(0·8) days ($P < 0\cdot05$). The mean(s.e.m.) total postoperative stay was reduced from 22·1(2·6) to 18·5(2·0) days (P not significant) (*Figure 2*). The 90-day hospital mortality rate was also reduced from 17 per cent (six patients) in group 1 to 4 per cent (two) in group 2 ($P = 0\cdot07$).

Discussion

There is increasing evidence that mechanical ventilation is potentially harmful. Ventilator-induced pulmonary oedema is well recognized and produces pulmonary changes similar to those of adult respiratory distress syndrome[8,10–12]. Patients who are most likely to receive postoperative ventilation, i.e. those with poor respiratory reserve, may be at most risk of developing ventilator-related complications[13]. Some authors[8,13–15] have attributed these changes to trauma from high-pressure ventilatory support; others[9,11] have shown that similar changes may be produced by overexpansion. Dreyfuss and Saumon[16] recently advocated that the term volutrauma should be used in preference to barotrauma. The two mechanisms may have a synergistic role[17]. Thus, Hernandez *et al.*[10] showed that, in an animal model, chest wall restriction limited lung injury induced by high airway pressure.

Initial attempts at weaning may be unsuccessful in as many as 25 per cent of patients receiving short-term ventilation[18,19]. Those on prolonged ventilation are more likely to require many days for weaning and may take as long as a few months[20]. Respiratory muscle strength and maximum voluntary ventilation are reduced in undernourished patients[21]. Depletion of oxidative enzymes in the respiratory muscles, which are crucial to endurance in breathing, occurs within the first 3 days of complete mechanical ventilation[22]; the more prolonged the assistance the less likelihood of successful weaning. Demling *et al.*[7] found that failed extubation in surgical patients on the intensive care unit was associated with a morbidity rate of 50 per cent and a hospital mortality rate of 40 per cent.

Much work has centred on the investigation of parameters for successful weaning of patients receiving ventilation. Preoperative indices have not proved reliable predictors of weaning difficulty. Pulmonary function before surgery, age, sex and history of smoking were not associated with postoperative extubation outcome in patients undergoing cardiac surgery[23]. Many authors have looked at postoperative indices such as vital capacity, minute ventilation, maximal inspiratory pressure and maximum voluntary ventilation. The predictive power of such indices for successful weaning, however, has been poor[19,24,25]. Immediate postoperative extubation can be performed safely in most patients undergoing thoracotomy[26]. Quasha *et al.*[27] showed that early extubation after coronary artery bypass grafting was associated with a reduced cardiopulmonary morbidity rate. In the present authors' unit, a policy of early extubation was successfully introduced and was accompanied by a reduction in the number of cardiac complications. It appears that many of the problems of mechanical ventilation and weaning can be obviated by avoiding postoperative ventilation.

Patients who receive prolonged mechanical ventilation pose enormous clinical and ethical problems. Severe psychological stress is induced in such patients, their relatives and the intensive care nursing staff. In addition, these patients represent a heavy financial burden on hospital administrations[28]. In a recent audit of work in the authors' unit, it was calculated that the cost to the hospital of 1 patient-day in intensive care was IR£550 compared with IR£130 in a ward bed[29]. Using these figures, the observed reduction in the time in intensive care produced a mean saving per patient of IR£1638 for elective oesophagectomy in 1990.

Although there was no difference between the two groups in age, sex, tumour type and stage, or preoperative risk factors such as smoking, pulmonary function or cardiac history, there was a difference in the type of operation performed: more patients in group 2 had a thoracotomy. Transhiatal oesophagectomy has been advocated as the procedure of choice in high-risk patients because it was initially felt to be associated with fewer respiratory complications[30]. Shahian *et al.*[31] found higher morbidity rates associated with extrathoracic oesophagectomy than transthoracic resection. It is now felt that both operations have a place but that they result in similar morbidity and mortality rates[32–34]. The larger number of patients receiving a transthoracic approach in group 2 is unlikely to have influenced the outcome and, if anything, would probably have biased the results against these patients. The reduction in the number of transhiatal oesophagectomies in group 2 does not reflect a difference in patient selection (*Table 1*) but results from concern over one specific complication (chylothorax), which we have shown to be more frequent after transhiatal oesophagectomy[35] and which occurred in two of 13 patients in group 1. When the subgroup who underwent transhiatal oesophagectomy was excluded from the analysis, it was found that the difference between the two groups persisted.

In conclusion, early extubation after elective oesophagectomy does not result in increased respiratory morbidity rates. It is associated with a significant reduction in the number of cardiac complications, ventilation time and length of intensive care, and this has significant cost-saving implications. In the absence of reliable predictive indices of successful weaning, early extubation should be the goal in all patients. With adequate non-narcotic pain control, intensive preoperative patient counselling and perioperative physiotherapy, this can be successfully and safely achieved in the majority of cases.

Short myotomy for vigorous achalasia

P. Parrilla Paricio,

Professor P. Parrilla Paricio

Vigorous achalasia has been considered an indication for surgery, in which a thoracic approach is recommended for extending the myotomy along the whole of the oesophageal body to the point where manometry shows high-amplitude waves. Clinical results and postoperative manometric findings in 16 patients with vigorous achalasia undergoing abdominal surgery with myotomy limited to the lower oesophageal sphincter (LOS) were analysed to assess whether extended myotomy is necessary in surgery for this form of achalasia. The clinical results were excellent or good in all cases. Surgery induced a significant decrease ($P < 0.01$) in the diameter of the oesophagus as determined radiologically. The most significant postoperative manometric changes were a decrease in the resting pressure of the LOS and oesophageal body, a lowering of wave amplitude at all levels of the oesophagus, and a reduction in the proportion of repetitive waves. The results suggest that vigorous achalasia can be treated surgically in the same way as classical achalasia and question, at least from a therapeutic viewpoint, the use of the term vigorous achalasia.

The term vigorous achalasia was first coined by Olsen *et al.*[1] in 1957 to describe a variant of idiopathic achalasia characterized by the appearance of both simultaneous and high-amplitude contractions of the oesophageal body. Later, some investigators[2–6] defined vigorous achalasia by the additional criterion of repetitive contractions. However, the manometric criteria for defining the condition have been arbitrary[4,5,7]. Patients with vigorous achalasia have been reported to have less oesophageal dilatation and more chest pain than those with the classical type[2,5–7]. Nevertheless, there has been no direct comparison of manometric, radiographic and clinical findings in classical and vigorous achalasia, in spite of the introduction of modern manometric techniques. Some authors[8,9] consider that the distinction between these two types of achalasia has little clinical importance and that it might usefully be abandoned.

From a therapeutic viewpoint, vigorous achalasia has been thought to have a poorer response to dilatation than the classical variety[2,3]. For this reason, it has been considered an indication for surgical treatment in which a thoracic approach allows Heller's myotomy to be extended along the whole of the oesophageal body to the point where manometry shows pressure waves of above-normal amplitude[10–12]. However, some studies[13,14] have reported good results with dilatation, similar to those obtained in classical achalasia.

The aim of this study was to analyse the clinical results and postoperative manometric findings in 16 patients with vigorous achalasia who underwent abdominal surgery with myotomy of the lower oesophageal sphincter (LOS) not extended to the oesophageal body, to assess whether the term vigorous achalasia is useful in indicating myotomy involving a thoracotomy or whether there is no difference between treatment for this and the classical form.

Patients and methods

Patients

Of a total of 1298 patients admitted to the Digestive Motility Unit between January 1980 and January 1991, 102 showed clinical, radiological, endoscopic and manometric evidence of idiopathic achalasia. Of the 102 patients, 25 were considered to have vigorous achalasia because the mean amplitude of contractile waves was above normal (values considered normal in the authors' laboratory are shown in *Table 1*) and/or pressure waves were normal but more than 50 per cent were repetitive (three or more pressure peaks). Patients who had an associated longitudinal myotomy of the oesophagus via a thoracotomy (five patients) and those who refused to undergo postoperative manometry (four) were excluded. Of the 16 subjects studied, 11 were men; the median age was 50 (range 20–65) years. The mean duration of symptoms was 1·7 years (range 3 months to 10 years). Symptoms were, in order of frequency, dysphagia and substernal pain (100 per cent), regurgitation (81 per cent) and weight loss (25 per cent). Radiological examination showed a pointed distal oesophagus in all cases and a median oesophageal diameter of 4 (range 2·5–5) cm. All patients underwent endoscopy to exclude organic pathology. Dilatation was not attempted in any patient.

Surgical technique

The abdominal oesophagus and cardia were isolated via a supra-umbilical median laparotomy. Traction was applied to the oesophagus with a ribbon, and an 8–10-cm myotomy performed on the anterior distal oesophagus, extending for 1 cm on to the gastric wall. The gastric fundus was then mobilized behind the abdominal oesophagus, creating a posterior partial fundoplication of approximately 270° with suture of the stomach to each of the edges of the myotomy[15].

Postoperative evaluation

All patients underwent clinical, radiological, endoscopic, manometric and pHmetric evaluation. Clinical assessment was carried out annually by personal interview, and the results were considered excellent, good, fair or bad, as described by Vantrappen and Hellemans[13]. The median follow-up was 4 (range 1–14) years. A gastro-oesophageal barium

Table 1 *Manometric results in normal subjects in the authors' laboratory*

Lower oesophageal sphincter

study and manometric evaluation were performed 1–2 years after operation. The results were compared with preoperative values. Endoscopy was also performed every 2 years after surgery, and 24-h pH monitoring between 1 and 6 years after operation.

Manometry

Oesophageal manometry was performed using a probe with three microtransducers (Gaeltec, Dunvegan, UK) located at the distal end 120° radially to one another and spaced 5 cm apart and a 7754B System polygraph (Hewlett–Packard, Palo Alto, California, USA)[15]. Mid-respiratory LOS pressure relative to the gastric baseline was measured by the slow pull-through technique. Total length was calculated as the length of the sphincter between the initial rise above the gastric baseline and the return of the tracing to the oesophageal baseline. Intra-abdominal length was calculated as the length of the sphincter between the initial rise above the gastric baseline and the respiratory inversion point. The LOS pressure, as well as the value of its total and intra-abdominal length, represents a mean of values from the three transducers. The oesophageal body was divided into thirds and in each the following parameters were studied: mean amplitude of contractile waves, mean duration of contractile waves, mean percentage of tertiary waves and mean percentage of repetitive waves (three peaks or more). Mean basal pressure in the lower third of the oesophageal body was also calculated.

pHmetry

Continuous 24-h intra-oesophageal pH monitoring was performed using a PHM62 Standard Digital Precision pHmeter (Radiometer, Copenhagen, Denmark), a GK2801C combined glass-reference pH electrode (Radiometer) and a Hewlett–Packard polygraph, which has a continuous-current amplifier (Medium Gain DC Pre-Amplifier 8802A) for recording pH on heat-sensitive paper. The method has been described elsewhere[15]. Following the criteria of Johnson and DeMeester[16], reflux was considered pathological when the proportion of total time at pH < 4 was more than 4·5 per cent.

Table 2 *Manometric results in the lower oesophageal sphincter before and after surgery for vigorous achalasia in 16 patients*

	Before operation	After operation	*P**
Mean resting pressure (mmHg)	20·1 (12·0–52·5)	10·5 (6·7–31·4)	<0·05
Total length (cm)	3·5 (2–4)	3·7 (2–4·5)	n.s.
Intra-abdominal length (cm)	2·2 (1·0–3·5)	3·0 (1·8–4·5)	n.s.
Percentage relaxation	44 (0–61)	10 (0–70)	n.s.

Values are median (range). *Wilcoxon rank sum test for paired data; n.s., not significant

Statistical analysis

The Wilcoxon rank sum test for paired data was used for statistical comparison.

Results

Clinical

Clinical results were excellent in 12 patients and good in four. Classification of the four patients as 'good' was due to the presence of occasional mild thoracic pain, associated with occasional dysphagia in one. Only one patient showed symptoms of gastro-oesophageal reflux, which were alleviated with attention to diet and posture, and the use of antacids.

Radiology

Postoperative radiology showed that the narrowing of the oesophagogastric junction had disappeared in all patients, and that the median oesophageal diameter had been reduced from 4 (range 2·5–5) to 2·5 (range 2–3·5) cm (*P* < 0·01).

Endoscopy

Endoscopy findings were normal in all but one patient, in whom grade I oesophagitis was observed according to the Savary–Miller classification.

pHmetry

Continuous 24-h pH monitoring disclosed pathological gastro-oesophageal acid reflux in only one patient (the proportion of time at pH < 4 was 17·6 per cent).

Manometry

As shown in *Table 2*, surgery did not involve any significant changes at the LOS, except in mean resting pressure, which dropped significantly. *Table 3* shows a significant decrease in mean resting pressure in the oesophageal body after surgery. There was a significant postoperative decrease in the mean amplitude of waves and in the mean percentage of repetitive waves at all levels of the oesophagus. In addition, postoperative peristaltic waves appeared in the upper and middle thirds (*Table 3*).

Discussion

Olsen *et al.*[1] introduced the term vigorous achalasia in 1957 to designate a variant of idiopathic oesophageal achalasia that, from a manometric viewpoint, presented the characteristics of achalasia and idiopathic diffuse oesophageal spasm. In the absence of oesophageal peristalsis (achalasia) there were

Table 3 *Manometric results in the oesophageal body before and after surgery for vigorous achalasia in 16 patients*

Values are median (range). *Wilcoxon rank sum test for paired data; n.s., not significant pressure waves of normal or above-normal amplitude, which were often repetitive. Some 10 years later, Sanderson *et al.*[2], using manometric criteria, selected a group of patients and established that, apart from dysphagia and regurgitation, thoracic pain was an important symptom and was associated with a marked pattern of abnormal contractility and reduced oesophageal dilatation. Since then, the definition of this variety of achalasia, based fundamentally on manometric findings, has varied with different authors[3-5,7]. This has recently led to some[8,9] questioning the validity of vigorous achalasia as a clinical syndrome distinct from the idiopathic form. Todorczuk *et al.*[9] established three subgroups of patients with achalasia based on amplitude of deglutition waves. They found no significant clinical differences in these groups. Likewise, Goldenberg *et al.*[8], who classified patients into two subgroups (typical and vigorous achalasia) using the same criteria as Todorczuk *et al.*[9], found that clinical and radiological data and certain manometric results (proportion of repetitive waves) were very similar in both forms of achalasia, and concluded that the distinction of 'vigorous' and 'non-vigorous' subsets based on mean amplitude alone is arbitrary, of little clinical importance and should possibly be abandoned.

From a therapeutic viewpoint, some authors have reported that vigorous achalasia has a poorer response to dilatation than the typical form[2,3] and have recommended surgical treatment. A thoracic approach allows the myotomy to be extended, if so desired, further on to the body of the oesophagus to the point where there are excess pressure and/or repetitive waves[10-12]. However, the therapeutic response to dilatation has recently been reported to be good and similar to that obtained in typical achalasia[13,14]. The present results show that Heller's myotomy, not extended to the oesophageal body and performed via an abdominal approach, achieves good or excellent clinical results in 100 per cent of patients with vigorous achalasia, similar to results obtained in typical achalasia. Likewise, postoperative manometry showed that suppression of the 'barrier' effect at the LOS causes a significant decrease in the amplitude of tertiary waves in the oesophageal body, together with the almost total disappearance of repetitive waves.

The present results suggest that in vigorous achalasia the motor alterations of the oesophageal body may be partly connected with the barrier effect produced at the LOS. The authors, like others[8,9], question the use of the term vigorous achalasia, not only from a clinical and radiological viewpoint but also from a therapeutic perspective.

The effect of granulocyte–macrophage colony-stimulating factor (GM–CSF) on murine antitumour responses was examined. Sixty mice received Lewis lung carcinoma implants and were then randomized to receive GM–CSF 1 μg/day, GM–CSF 0·5 μg/day or saline for 10 days and studied with regard to tumour volume, carcass weight and food intake. Macrophage antitumour mechanisms including oxygen free radical production and nitric oxide release were studied in peritoneal macrophages after co-culture with GM–CSF in vitro *and* in vivo. *GM–CSF 1 μg/day decreased tumour growth after 5 days (mean(s.e.m.) 0·62(0·14)* versus *1·24(0·19) cm*^{3}, $P = 0·017$*). GM–CSF upregulated macrophage antitumour mechanisms by enhancing the* in vivo *production of superoxide radicals (mean(s.e.m.) 0·69(0·06)* versus *0·45(0·10) nmol,* $P < 0·05$*) and nitric oxide (mean(s.e.m.) 48(3)* versus *24(4) μmol,* $P < 0·01$*). GM–CSF functions through the enhancement of macrophage tumoricidal activity, suggesting a therapeutic potential for this cytokine in the tumour-bearing host.*

The immune system plays a pivotal role in the host response to disease and recent anticancer therapy has been directed at modulation of components of this system. Cytokine immunotherapy regulates antitumour defence mechanisms and may be beneficial as a form of immunotherapy. The cytokine granulocyte–macrophage colony-stimulating factor (GM–CSF) is a glycoprotein of molecular mass 14 kDa secreted by activated T cells, endothelial cells, fibroblasts and macrophages[1].

GM–CSF supports proliferation of bone marrow-derived progenitors of granulocytes and macrophages, and regulates the development of these early haematopoietic progenitor cells. Phase I and II clinical trials currently under way indicate that GM–CSF may be effective in accelerating the recovery of patients with leukaemia after autologous bone marrow transplantation[2]. GM–CSF is also of benefit to patients with myelodysplastic syndrome[3]. Neutropenic patients with acquired immune deficiency syndrome receiving daily doses of GM–CSF for 14 days exhibited marked leucocytosis[4], and patients with inoperable metastatic sarcoma receiving doxorubicin, ifosfamide and dacarbazine experienced a reduction in the duration and degree of neutropenia when treated with this cytokine[5].

Although GM–CSF has an established myelopoietic activity, its role as an antineoplastic agent awaits further evaluation. An important pathway in antitumour defence may be provided by GM–CSF as it induces macrophage tumoricidal activity *in vitro*[6] and is capable of stimulating antibody-dependent cytolysis of tumour cells by mature human neutrophils and eosinophils[7]. The present study evaluated the *in vitro* and *in vivo* antineoplastic effects of GM–CSF in a murine carcinoma model.

Materials and methods

Reagents

Endotoxin (lipopolysaccharide (LPS) from *Escherichia coli* serotype 055:B5), superoxide dismutase and cytochrome *c* type III were obtained from Sigma Chemicals, Poole, UK. Cytochrome *c* was stored at −20°C in Krebs–Ringer phosphate dextrose (KRPD). Dulbecco's modified Eagles medium (DMEM) and all chemicals used for making KRPD and phosphate-buffered saline (PBS) were purchased from Life Technologies, Paisley, UK. Purified recombinant murine GM–CSF with a specific activity in excess of 1×10^5 units/mg was a gift from Dr Stephen Gillis, Immunex, Seattle, Washington, USA. All solutions were free from detectable LPS as tested by *Limulus* amoebocyte assay (E-toxate; Sigma).

In vivo *tumour studies*

Female C57/Bl6j mice (H_2D) (6–8 weeks old; $n = 60$ – Charles River Laboratories, Margate, UK) were studied. Animals were fed standard rodent chow, and after a 7-day acclimatization period were weighed and administered 10^6 Lewis lung carcinoma cells (LL/2, CRL, 1642; ATCC, Rockville, Maryland, USA) subcutaneously in the right flank. All mice developed palpable tumours 7–10 days after inoculation. At 14 days after inoculation, when the mean tumour volume was 0·4 cm^3, mice were randomized to receive intraperitoneal injections of either GM–CSF for 10 days at a dose of 1 μg/day ($n = 22$) or 0·5 μg/day ($n = 24$), or saline vehicle control ($n = 14$). These doses were based on pilot studies assessing dose-related toxicity. All mice were killed 21 days after the start of treatment.

In vivo *cytotoxicity studies*

Female CD-1 mice (6–8 weeks old; $n = 16$) (Charles River Laboratories) were randomized to receive intraperitoneally either GM–CSF 0·5 μg/day ($n = 7$) or saline vehicle control ($n = 9$) for 5 consecutive days. Animals were then killed and peritoneal cells harvested for assessment of antitumour activity.

In vitro *cytotoxicity studies*

Peritoneal macrophages from normal 6–8-week-old female CD-1 mice ($n = 30$) were co-cultured in DMEM with or without GM–CSF 50 ng/ml for 24 h (superoxide radical) or 72 h (nitric oxide) before *in vitro* cytotoxicity assays.

Assessment of tumour volume, carcass weight and food intake

Tumour volume (V) was assessed according to the equation:

$$V = (\pi/6) \times L \times S^2$$

where L is the longest dimension and S the shortest. Measurements were made immediately before treatment and at 5, 10, 15 and 20 days afterwards. All measurements were carried out using callipers by an observer who was unaware of the treatment group.

Carcass weight was calculated by subtracting tumour weight from total body-weight. Food intake was measured each day.

Presented to the Surgical Research Society in London, UK, January 1992 and published in abstract form as Br J Surg *1992;* **79***: 459*

Isolation of peritoneal cells

Peritoneal macrophages were harvested by peritoneal lavage with 7–10 ml LPS-free PBS as previously described[8]. Macrophages were plated at a concentration of 1×10^6 cells/ml and allowed to adhere for 2 h before study.

Assay of superoxide radical generation

Superoxide anion generation was measured as the superoxide dismutase-inhibitable reduction of ferricytochrome *c*, using phorbol myristate acetate (PMA; 1 μg/ml) as a stimulus[8]. Results are expressed as nmoles of oxygen free radical per 2×10^5 cells plated per 90 min.

Assay of nitric oxide release

Nitric oxide was determined by measuring the stable end-product nitrite[9] after 72 h incubation of macrophages with LPS (1 μg/ml) and GM-CSF (50 ng/ml for *in vitro* studies).

Macrophage phagocytosis of tumour cells

Peritoneal macrophages from CD-1 mice ($n = 8$) were plated (2×10^5 cells/well) in Labtek tissue culture slides (Nunc, Naperville, Illinois, USA). After 2 h adherence, macrophages were cultured in DMEM for a further 24 h with or without GM-CSF 50 ng/ml. Macrophage phagocytosis of Lewis lung carcinoma cells was determined by co-culturing tumour cells with macrophages (tumour cell:macrophage ratio 4:1) for 1 or 3 h. After incubation, wells were washed twice with PBS to remove non-phagocytosed tumour cells. Macrophage phagocytosis of tumour cells was assessed by counting the number of macrophages that had completely phagocytosed one or more tumour cells after 1 or 3 h. Data are expressed as the percentage of macrophages ingesting one or more tumour cells; at least 200 macrophages were counted per slide. All experiments were performed a minimum of three and some up to five times. The Lewis lung cell line was maintained in an albumin-enriched DMEM culture medium; cell culture flasks were split twice weekly. The immunogenicity of the tumour did not vary throughout the study.

Effect of GM-CSF on different cell populations

Peritoneal cell harvests were obtained from mice treated *in vivo* with GM-CSF 0·5 μg/day or saline vehicle control for 5 days, and assessed for cell yield and percentage of resident peritoneal macrophages and neutrophils, using a Romanofsky stain.

Direct effect of GM-CSF on tumour cell proliferation

Lewis lung carcinoma cells (1×10^6/ml) were cultured in 5 ml DMEM with or without GM-CSF 50 ng/ml. After 24 h, the tumour cells were removed from the culture flasks using trypsin-ethylene diamine tetra-acetic acid and counted with a haemocytometer. The direct effect of GM-CSF on tumour cell proliferation was assessed by comparing the number of tumour cells that were co-cultured with GM-CSF with those that were cultured in medium alone.

Tumour histology

Tumour specimens were fixed in formalin and stained with haematoxylin and eosin. Specimens were examined for the presence of inflammatory cells from both control and GM-CSF-treated animals killed on days 6, 9 and 12.

Statistical analysis

Assays were performed on pooled peritoneal macrophages using three to five mice for each assay. Data are presented as mean(s.e.m.). Statistical analysis was performed using Student's unpaired *t* test for comparison of two groups and analysis of variance for more than two groups. Significance was determined at $P < 0{\cdot}05$.

Results

Tumour volume, carcass weight and food intake

As shown in *Figure 1*, administration of GM-CSF 1 μg/day was associated with a significant ($P = 0{\cdot}017$) decrease in tumour volume at day 5 and throughout the 20-day study period. At a dose of 0·5 μg/day the reduction in tumour volume became significant ($P = 0{\cdot}038$) only at 19 days.

There was a mean(s.e.m.) 14·6(3·7) per cent reduction in carcass weight in the control group at day 10; this was significant compared with treated mice. The percentage changes in carcass weight did not remain significant at day 20 (*Figure 2*).

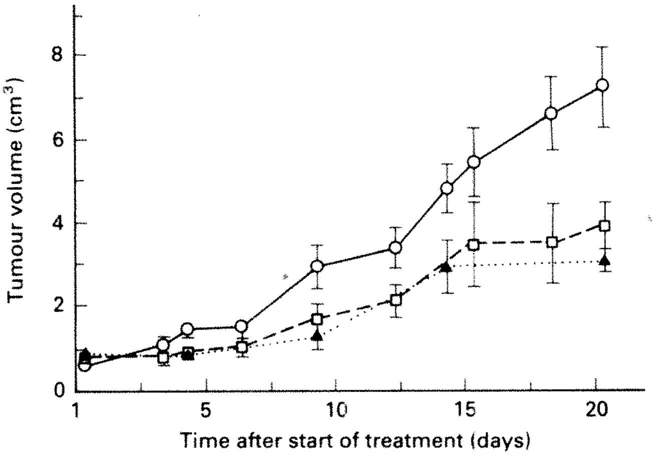

Figure 1 *Effect of granulocyte–macrophage colony-stimulating factor (GM-CSF) on tumour volume. Values are mean(s.e.m.).* ○, *Controls;* □, *GM-CSF 0·5 μg/day;* ▲, *GM-CSF 1 μg/day*

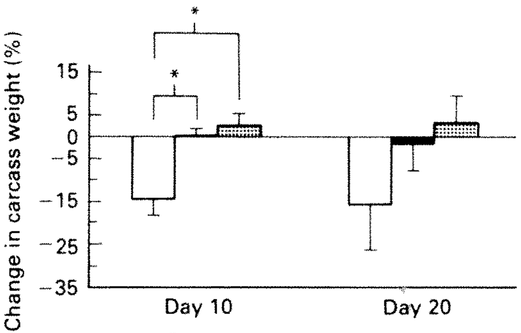

Figure 2 *Effect of granulocyte–macrophage colony-stimulating factor (GM-CSF) on carcass weight. Values are mean(s.e.m.).* □, *Controls;* ■, *GM-CSF 1 μg/day;* ▨, *GM-CSF 0·5 μg/day.* **P < 0·05 (Student's t test)*

There was no significant alteration in food intake during the study period in any group (data not shown).

Macrophage antitumour mechanisms – superoxide radical production

PMA-stimulated superoxide anion production was significantly ($P < 0{\cdot}01$) increased compared with controls in peritoneal macrophages from CD-1 mice co-cultured *in vitro* with GM-CSF (*Figure 3a*).

In vivo administration of GM-CSF upregulated PMA-stimulated superoxide radical release from peritoneal macrophages harvested from CD-1 mice after 5 days (*Figure 3b*).

Macrophage antitumour mechanisms – nitric oxide release

Nitric oxide, the tumoristatic product of L-arginine metabolism, was released from peritoneal macrophages in significantly ($P < 0{\cdot}01$) higher amounts after co-culture with GM-CSF (*Figure 4a*).

In vivo administration of GM-CSF also caused a significant ($P < 0{\cdot}01$) upregulation in generation of nitric oxide when peritoneal macrophages were co-cultured with LPS 1 μg/ml for 72 h (*Figure 4b*).

Peritoneal cell response to GM-CSF

In vivo administration of GM-CSF 20 μg per kg body-weight for 5 days was associated with a significant increase in mean(s.e.m.) peritoneal cell yield ($10{\cdot}3(1{\cdot}0) \times 10^6$ for controls *versus* $17{\cdot}9(0{\cdot}1) \times 10^6$ for GM-CSF, $P < 0{\cdot}02$) and a significant influx of neutrophils into the peritoneal cavity (8·5(0·5) *versus* 17·5(1·0) per cent, $P < 0{\cdot}02$). There was no

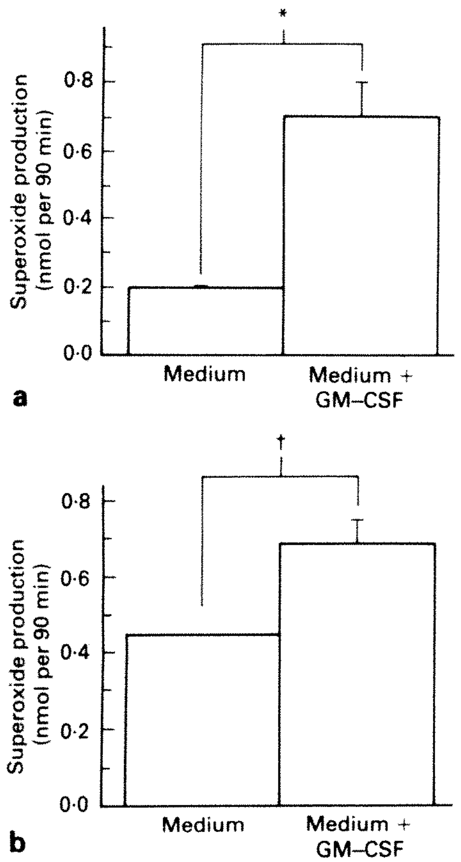

Figure 3 *Effect of granulocyte–macrophage colony-stimulating factor (GM–CSF) on superoxide radical production* **a** in vitro *and* **b** in vivo. *Values are mean(s.e.m.).* *P < 0·01, †P < 0·05 (*Student's* t *test*)

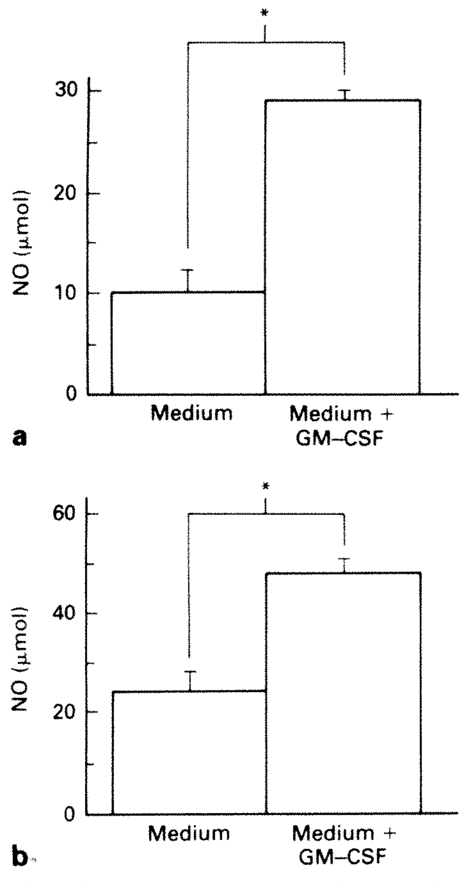

Figure 4 *Effect of granulocyte–macrophage colony-stimulating factor (GM–CSF) on nitric oxide (NO) release* **a** in vitro *and* **b** in vivo. *Values are mean(s.e.m.).* *P < 0·01 (*Student's* t *test*)

significant difference in the proportion of peritoneal macrophages in the GM–CSF-treated group (45(1) per cent for controls *versus* 47(2) per cent for GM–CSF).

Macrophage phagocytosis of tumour cells

Co-culture of macrophages and tumour cells in medium alone and in medium with GM–CSF 50 ng/ml for either 1 or 3 h revealed no evidence of direct ingestion of tumour cells by macrophages.

Direct effect of GM–CSF on tumour cell proliferation

GM–CSF caused no direct enhancement of tumour cell proliferation. After 24 h culture in 5 ml DMEM, 1×10^6 tumour cells increased in number to $3{\cdot}85 \times 10^6$, whereas 24 h of culture in 5 ml DMEM with GM–CSF 50 ng/ml increased the tumour cell count to $3{\cdot}87 \times 10^6$ (*P* not significant).

Percentage cell influx into tumours

No significant influx of inflammatory cells was revealed in either the control or GM–CSF-treated tumour specimens by standard haematoxylin and eosin staining. Areas of necrosis within the tumour specimen showed an influx of inflammatory cells.

Discussion

Cytokines implicated for use in cancer therapy include the interleukins, the interferons, tumour necrosis factor[10,11] and the colony-stimulating factors[12]. Cytokines are capable of producing significant and sustained responses against a number of tumours. Clinically, the highest response rates to cytokine immunotherapy have been seen in patients with melanoma and renal cell cancer[13].

In the present study, GM–CSF at 1 and 0·5 μg/day was associated with a significant reduction in tumour volume. The reduction in carcass weight was significantly greater after 10 days in control mice than in those that had received GM–CSF, suggesting that this cytokine may be important in regulating metabolic processes such as the cachectic response in tumour-bearing animals. No significant alteration in food intake was noted between the groups.

GM–CSF caused an increase in the release of the tumoricidal superoxide anion from peritoneal macrophages both *in vitro* and *in vivo*. To date, interferon (IFN) γ is the only cytokine that fulfils the criteria of a macrophage-activating factor[14]; however, the present experiments indicate that GM–CSF has potent macrophage-activating properties. IFN-γ and GM–CSF may function through similar pathways.

Nitric oxide production has been identified in a large number of mammalian cells[15]. Activation of the deiminase pathway has been implicated in macrophage-mediated tumoristatic[9] and microbicidal[16,17] mechanisms and may also play a role in regulating macrophage activation[18]. Release of nitric oxide, the tumoristatic product of L-arginine metabolism, was significantly upregulated by GM–CSF *in vitro* and *in vivo*. This is another mechanism through which GM–CSF may enhance macrophage cytotoxicity against tumour cells.

The mechanism of inhibition of tumour growth by GM–CSF remains unclear. The cytokine appears to have no direct action on tumour cell proliferation as no significant effect on proliferation was caused by co-culturing tumour cells with GM–CSF. Although macrophage-mediated mechanisms appear important in reducing tumour growth, no evidence of direct ingestion of tumour cells by macrophages was demonstrated.

No histological evidence was found of increased macrophage infiltration in GM–CSF-treated mice. Peritoneal cell harvests from animals treated with GM–CSF *in vivo* revealed no increase in the proportion of macrophages. These data support the theory that inhibition of tumour growth by GM–CSF results from activation of tumour-associated macrophages by this cytokine with enhanced release of superoxide anion and nitric oxide, rather than from an increase in macrophage infiltration of the tumour.

Announcement

Frontiers and Perspectives of Surgical Oncology

A tripartite meeting of the European Society of Surgical Oncology, British Association of Surgical Oncology and the Oncology Section of the German Society of Surgery will take place on 8-11 June 1994 in Heidelberg, Germany. The meeting, Frontiers and Perspectives of Surgical Oncology, is the idea of leading surgical oncologists from the European Society of Surgical Oncology and will provide a unique opportunity for exchange of ideas and information between members of national and European societies. The scientific programme reflects the clinical relevance and increasing importance of surgical oncology. This will be the largest convention of surgical oncologists ever to have met in Europe. The official language of the meeting is English. For further details contact: Dr Thomas Lehnert, Department of Surgery, University of Heidelberg, Im Neuenheimer Feld 110, D-69120 Heidelberg, Germany. Telephone: +49 6221 566207. Facsimile: +49 565450.

Role of surgery and chemotherapy for peripheral lymph node tuberculosis

M. Subrahmanyam

Department of Surgery,
Dr Vaishampayan Memorial Medical College, Solapur 413 003,
Maharashtra, India
Correspondence to:
Professor M. Subrahmanyam

A total of 105 patients with peripheral lymph node tuberculosis were treated by either surgical excision and chemotherapy or chemotherapy alone. The cervical nodes were affected in 98 patients, axillary nodes in four and inguinal nodes in three. Biopsy of the lymph nodes confirmed the diagnosis in all cases. Thirty-five patients who had sinus, ulcer or abscess underwent excision of the lymph nodes with drainage of the abscess, or resection of the sinus or ulcer. The remaining 70 patients received only chemotherapy. Chemotherapy in all patients consisted of isoniazid and ethambutol for 18 months. Of the 35 patients treated with surgery and chemotherapy, two had gaping wounds, one infection and one cellulitis of the face and neck. After 3 months, one patient had recurrence of the lymph node mass and one recurrence of a sinus; these were excised. Of the 70 patients treated only with chemotherapy, 13 were lost to follow-up. Four had non-healing wounds at the biopsy site, six wound infection and two sinus formation. Five of these patients had persistent lymph node masses, which were excised after 3 months. The remaining 52 patients had no recurrence.

The diagnosis and management of peripheral lymph node tuberculosis remain major problems in most countries of Asia and Africa. The disease frequently involves the lymph nodes draining the head and neck[1]. There are many types of management, each having its own advocates. Surgery with chemotherapy and chemotherapy alone have been tried with varying results[2–7].

On the basis of specific indications, patients in the present study were treated by either surgery with chemotherapy or chemotherapy alone. The results are reported.

Patients and methods

A total of 105 patients with peripheral lymph node tuberculosis treated between January 1988 and July 1989 formed the study group. All patients underwent biopsy of a peripheral lymph node for histological analysis. A diagnosis of lymph node tuberculosis was based on the following histopathological findings: caseating type, consisting of central caseation necrosis, surrounded by epithelioid cells, lymphocytes and Langhans' giant cells; and lymphadenoid type, without caseation necrosis and consisting of reticuloendothelial hyperplasia, with sheets of epithelioid cells and irregular arrangements of Langhans' giant cells. The nodes were not subjected to microbiological examination. Other investigations included estimation of the erythrocyte sedimentation rate (ESR) and chest radiography.

Patients were divided into two groups: those with complications such as ulcer, abscess or sinus ($n = 35$) and those without complications ($n = 70$). Patients with complications were treated by surgery, i.e. lymph node excision with resection of an ulcer or sinus, or drainage of an abscess, and chemotherapy. All 105 patients were treated with oral isoniazid 15 mg per kg body-weight and ethambutol 25 mg/kg as a single daily dose for 18 months. Patients without complications were given chemotherapy alone.

The size of the lymph nodes was measured at the beginning of treatment and patients were followed at intervals of 3 months. Those who did not respond to drugs underwent excision of the nodes after 3 months. A node was considered to have disappeared when its diameter was <5 mm. Patients were encouraged to continue drug treatment and followed to 18 months to assess progress, as evidenced by improvement of general symptoms, weight gain, regression of lymph nodes and a decreasing ESR.

Results

Of the 105 patients, the youngest was 1·5 and the oldest 68 years of age; 78 patients were between 11 and 30 years old. The male:female ratio was 1:1·3 (*Table 1*). Cervical lymph nodes were affected in 98 patients, axillary nodes in four and inguinal node involvement was present in three. Of the 98 patients with cervical lymph node tuberculosis, the jugulodigastric ($n = 32$), posterior triangle ($n = 28$), submandibular ($n = 19$), submental ($n = 7$), supraclavicular ($n = 10$), preauricular ($n = 1$) and postauricular ($n = 1$) nodes were involved. Clinical evidence of matting of nodes was found in 71 patients (68 per cent) and in 34 patients (32 per cent) the nodes were discrete. The mean node diameter was 19 (range 17–28) mm. Weight loss was noted in 78 per cent of patients, fever in 45 per cent and night sweats in 35 per cent. Pulmonary tuberculosis was detected on chest radiography in 17 patients. One had diabetes mellitus. Six had a positive history of a family member suffering from pulmonary or extrapulmonary tuberculosis. The diagnosis was confirmed by histopathological analysis. The ESR was increased in all patients and ranged from 21 to 60 mm/h.

Thirty-five patients had complications: 16 had abscesses, 11

Table 1 *Age and sex of 105 patients with peripheral lymph node tuberculosis*

Table 2 *Results of treatment in 105 patients with peripheral lymph node tuberculosis*

Patients treated with surgery and chemotherapy ($n = 35$)	
Cosmetically acceptable scars, good response	33
Recurrence of sinus (re-excision performed)	1
Recurrence of lymph nodes (re-excision performed)	1
Complications	
Non-healing wound	2
Wound infection	1
Cellulitis of face and neck	1
Patients treated only with chemotherapy ($n = 70$)	
Lost to follow-up	13
Good response	52
Persistent lymph node masses (excision performed)	5
Complications	
Non-healing wound	4
Wound infection	6
Sinus formation	2

The two groups were not significantly different (χ^2 test)

sinuses and eight ulcers. The other group ($n = 70$) had palpable lymph nodes only. After the diagnosis was confirmed, patients with complications underwent excision of lymph nodes, drainage of abscesses, and resection of sinuses or ulcers as appropriate. Those without complications were managed only with chemotherapy.

Response to treatment in both groups and the rate of complications are given in *Table 2*. Non-healing of wounds, wound infections and cellulitis of the face followed node biopsy. In patients of both groups, non-healing wounds and other complications responded well to chemotherapy. In the group undergoing surgery, wounds healed well with cosmetically acceptable scars. One patient had recurrence of a sinus after 3 months and one palpable nodes 15 mm in diameter; these were excised. In the group treated only with chemotherapy, 13 patients were lost to follow-up; of the remaining 57, five had persistent lymph node masses (mean diameter 14 mm), which were excised at the end of 3 months. Nodes disappeared in 52 patients.

Results were analysed using the χ^2 test; the two groups did not differ significantly. The difference in the rate of complications was also found not to be significantly different in both groups. Patients with a good response had weight gain, were symptom-free and had a decreasing ESR.

Discussion

Tuberculosis is one of the commonest diseases affecting peripheral lymph nodes. Cervical nodes are most frequently involved[4,5,7]; in the present study these nodes were involved in over 90 per cent of cases. Histopathological findings, whether indicating caseating or lymphadenoid type, are unrelated to treatment, and biopsy is always undertaken to confirm the diagnosis of tuberculosis in the Indian subcontinent[2].

Associated pulmonary lesions were found in 16 per cent of the present cases and a family history of tuberculosis in 6 per cent, suggesting that the incidence of tuberculosis has not significantly decreased in the general population.

Many treatments have been tried in the management of peripheral node tuberculosis. Surgical excision with chemotherapy, chemotherapy first and then surgery, or chemotherapy alone with antitubercular drugs for varying durations have been used[4,6,7]. Reports of the efficacy of these methods have usually been based on retrospective studies with uncontrolled data for patient selection[6,7]. The results of such studies suggest that surgery and chemotherapy, or chemotherapy alone, yield similar results[2,4,6], but in patients with sinuses and ulcers excision with chemotherapy helps to obtain a cosmetically acceptable scar[8].

In the present study both the group with complicated disease and that without achieved similar results. Surgery may be recommended for ulcers, sinuses or abscess with a view to obtaining a cosmetically acceptable scar. Although various drug regimens are available, in the present study ethambutol and isoniazid were used for 18 months as recommended by the government of India and Maharashtra[9], with good results.

Prognostic value of DNA ploidy in primary gastric leiomyosarcoma

H. Suzuki and
N. Sugihira

Second Department of Surgery, Mie University School of Medicine, 2-174 Edobashi, Tsu City, 514 Japan
Correspondence to:
Professor H. Suzuki

The prognostic value of DNA ploidy was evaluated in 25 patients with primary gastric leiomyosarcoma, using paraffin-embedded archival specimens analysed by DNA flow cytometry. Ploidy patterns were diploid in ten tumours and non-diploid in 15. They did not correlate with clinicopathological features of the lesions such as tumour size and grade or mitotic index. A non-diploid pattern was associated with a significantly reduced patient survival rate ($P < 0.05$)*, as was higher tumour grade* ($P < 0.01$)*. Neither tumour size nor mitotic index correlated with patient survival.*

The prognosis of patients with primary gastric leiomyosarcoma has traditionally been predicted by morphological features of the lesion such as tumour size and grade, cellularity and mitotic index[1,2]. Recently, DNA ploidy patterns of tumour cells determined by flow cytometry have become accepted as indices for predicting the survival of patients with various malignant tumours[3–6].

In the present study, the ploidy of 25 primary gastric leiomyosarcomas was determined using flow cytometric techniques, in an aim to assess the prognostic value of ploidy for malignant smooth muscle tumours of the stomach.

Patients and methods

Patients

Twenty-five patients who had undergone apparently curative resection of primary gastric leiomyosarcoma between October 1975 and July 1991 were studied. The patients comprised 15 men and ten women of mean(s.d.) age 58(15) (range 20–77) years. Tumour size was defined as the largest dimension of each lesion, as obtained from medical records; it ranged from 15 to 200 mm and was greater than 50 mm in 14 tumours.

The mitotic index was determined by counting mitotic figures from the most cellular area of tumour tissue in ten consecutive high-power fields (×40 objective lens), which corresponded to 1·94 mm^2 in a section[7]. The index ranged from 0 to 80 mm^{-2} and was greater than 5·0 mm^{-2} in 16 tumours. The tumour grade, determined histopathologically according to a clinicopathological staging system for soft tissue sarcoma[8], was grade I in seven tumours, grade II in 11 and grade III in seven.

Follow-up was complete until December 1992 or death of the patient. Eighteen patients are alive and free from recurrent disease and seven have died from malignancy.

DNA flow cytometry

Two or three 50-μm sections were cut from paraffin-embedded tumour tissue. The technique of Schutte *et al.*[9] was employed for the preparation of single dissociated nuclei. The method of Vindeløv *et al.*[10] was used for staining nucleic acids with propidium iodide. The nuclear content of 20 000 cells was measured using a flow cytometer (FACScan; Becton–Dickinson, Mountain View, California, USA) and DNA histograms generated using a computer attached to the system. Stromal cells contained in tumour tissue were used as an internal standard for 2C (i.e. diploid) DNA content. The DNA index was defined as the ratio of the G0/G1 peak modal chamber number for tumour cells to the G0/G1 peak modal chamber number for diploid stromal cells. The DNA histogram was defined as diploid when tumour cells generated a single G0/G1 peak in the diploid region (DNA index 1·0), as shown in *Figure 1*. Other DNA histograms were defined as non-diploid (*Figure 2*). Samples with G0/G1 peaks with a coefficient of variation greater than 8 per cent were excluded.

Statistical analysis

χ^2 test with Yates' correction was used for determining the significance of correlation between each variable. Cumulative survival rates were obtained using the Kaplan–Meier method. The significance of the difference in survival rates between each group of patients was determined by the log rank test. $P < 0.05$ was considered significant.

Results

The mean(s.d.) coefficient of variation of the G0/G1 peaks of 25 tumour tissue samples was 4·9(2·0) per cent. Non-diploid DNA patterns were detected in 15 of 25 tumours. The DNA index ranged from 0·59 to 2·01. There was no significant correlation between DNA ploidy and clinicopathological features of primary gastric leiomyosarcoma (*Table 1*).

The non-diploid DNA patterns of tumour cells were associated with a significantly reduced patient survival rate ($P < 0.05$; *Figure 3*), as was higher tumour grade ($P < 0.01$; *Figure 4*). On the other hand, there were no significant effects

of larger tumour size (greater than 50 mm; $P = 0{\cdot}16$) or higher mitotic index (greater than 5·0 mm^{-2}; $P = 0{\cdot}07$) on survival.

Discussion

Morphological features such as tumour size and grade, cellularity[11] and mitotic index[12] have been recognized as markers indicating the biological behaviour of malignant smooth muscle tumours. However, these conventional pathological variables have often been defined arbitrarily and determined subjectively. Recently, DNA patterns of tumour cells, determined by flow cytometric techniques, have been recognized as accurate, objective and easily reproducible markers for predicting the prognosis of patients with a malignant tumour[3–6].

DNA flow cytometric analysis of primary gastric leiomyosarcoma has been reported by others[13,14]. In the present study, non-diploid patterns were found in 15 of 25 primary gastric leiomyosarcomas, in accord with previous reports that 50–60 per cent of such tumours had non-diploid DNA patterns[13,14].

Tsushima *et al.*[13] reported that there was a close correlation between DNA ploidy and tumour grade, but such an association was not found in the present study. The different results may reflect differences in the grading system employed: Tsushima *et al.*[13] did not describe the system they used for grading gastric leiomyosarcoma. The present study showed no significant correlation between DNA ploidy and morphological features of the tumour such as size and grade or mitotic index. This suggests that the DNA ploidy pattern of tumour cells may be useful as an independent prognostic variable for malignant smooth muscle tumours of the stomach.

The present study has confirmed previous reports[13,14] that non-diploid patterns of tumour cells are associated with a significantly reduced patient survival rate.

In conclusion, DNA ploidy, together with tumour grade, is significantly correlated with the survival of patients with this relatively rare malignant lesion. However, further studies on a larger patient population are necessary to determine whether the ploidy pattern of tumour cells may be used as a prognostic marker for primary gastric sarcoma, independent from conventional prognostic variables.

Paper accepted 25 February 1993

Short note

Br. J. Surg. 1993, Vol. 80, December, 1551

Raised serum CA125 level in leiomyoma and leiomyosarcoma of gastrointestinal origin

M. S. Whiteley and J. Marshall

Department of Surgery, St Mary's Hospital, Portsmouth, UK
Correspondence to: Mr M. S. Whiteley, Department of Surgery, Royal United Hospital, Combe Park, Bath BA1 3NG, UK

CA125 is a serum antigen used as a marker for epithelial ovarian carcinoma. Its level is raised in some other gynaecological conditions and a few gastrointestinal carcinomas. Leiomyoma and leiomyosarcoma are stromal tumours. When they originate from the gastrointestinal tract, these tumours exhibit a wide variability in clinical behaviour. Once the tumour has been resected, subsequent follow-up relies on outpatient examination, endoscopy and imaging techniques. A serum marker for such tumours could simplify the follow-up of these patients.

Case reports

Patient 1

A previously well 61-year-old woman was admitted with a 1-week history of abdominal pain. Examination revealed a smooth firm mass arising out of the pelvis. Ultrasonography demonstrated a mainly solid mass, probably of ovarian origin. The serum CA125 level was raised at 194 units/ml (normal below 35 units/ml).

At laparotomy, a solid mass with cystic areas was found within the ileal mesentery, close to the bowel wall. The mass was resected and no other abnormalities were found.

The patient made an uneventful recovery and 4 months after operation, with no detectable recurrence, the serum CA125 level had dropped to 9 units/ml. Histological examination showed a leiomyoma without mitoses. Immunohistochemical analysis performed 6 months after resection showed no CA125 antigen expressed on the cells of the tumour.

Patient 2

A 60-year-old woman, previously fit, was admitted with a 12-h history of epigastric pain and vomiting. Physical examination revealed generalized peritonitis; urgent laparotomy was arranged.

Free intraperitoneal pus was found and a perforated tumour in the upper jejunum identified. Two solid masses were palpable in the right lobe of the liver. The tumour was resected; histological analysis showed a low-grade leiomyosarcoma.

Postoperative ultrasonography confirmed multiple hepatic metastases. Some 11 days after operation the serum CA125 level was raised at 107 units/ml.

Discussion

CA125 is the antigenic determinant identified by a murine monoclonal antibody raised specifically against epithelial ovarian carcinoma. The radioimmunoassay for serum CA125 has a high specificity in these patients[1], hence its widespread use as a serum tumour marker.

A raised serum CA125 level has been found in patients with advanced endometriosis[2], pancreatic carcinoma, cancer of the biliary tree and hepatocellular carcinoma[3]. These pathologies are of epithelial origin, although CA125 has also been demonstrated in patients with uterine leiomyosarcoma[4]. In addition, a few healthy women under 49 years of age have raised levels, as do those in early pregnancy[5]. There have been no previous reports linking a raised serum CA125 level with stromal tumours of gastrointestinal origin.

Leiomyoma and leiomyosarcoma of gastrointestinal origin are well known for their wide variability in clinical behaviour. Leiomyoma and leiomyosarcoma are the commonest stromal tumours of the stomach, although the division between the two histological entities is not clear cut. Both tumours occur less commonly elsewhere in the gastrointestinal tract. At present, surgical removal is the treatment of choice, but is not always technically possible. Follow-up of these patients consists of regular clinical review and repeated imaging investigations.

Immunohistochemical analysis was performed on tissue taken from patient 1 and there was no evidence of the CA125 antigen on the tumour cells. Thus the site of production of the serum-borne CA125 antigen is unknown and it may be produced from some distant site, stimulated by factors released by the leiomyoma. Further work is required to investigate the association between serum CA125 levels and stromal tumours of gastrointestinal origin. If this marker reflects the course of tumour growth and treatment, serum CA125 levels may prove useful in follow-up of these patients.

Laparoscopic repair of peptic ulcer disease complicated by anterior duodenal perforation could offer a number of advantages over laparotomy[1]. Endoscopic suturing, whether extracorporeal or intracorporeal, is usually tedious and time consuming for most surgeons who perform laparoscopic procedures. Undoubtedly, this problem deters surgeons from repairing perforated duodenal ulcers in this manner. Use of an automated endoscopic stapling device (Multifire Endo-Hernia; Auto Suture, Ascot, UK) in two patients with perforated duodenal ulcer is described.

Surgical technique

Two men, aged 24 and 49 years, were admitted to hospital on an emergency basis with classical features of perforated peptic ulcer and radiological evidence of free air under the right hemidiaphragm. After initial resuscitation, laparoscopy was undertaken under general anaesthesia with full muscle relaxation. Each patient was placed in a supine position with legs apart. The surgeon stood between the legs of the patient, the first assistant on the patient's left side and the second on the right. Pneumoperitoneum was established using carbon dioxide and intraperitoneal pressure maintained at or below 15 mmHg. A 12-mm cannula was inserted at the umbilicus and used to introduce a forward-viewing laparoscope and later the endo-stapler. Under direct vision, the remaining abdominal ports were established (*Figure 1*). A 10-mm cannula in the left upper quadrant at the anterior axillary line was used to introduce an atraumatic Babcock clamp. This clamp was employed to retract the gastric antrum downwards and to the left to expose the first part of the duodenum. A 10-mm cannula to the left of the umbilical port at the mid-clavicular line enabled the introduction of the forward-viewing laparoscope. A 5-mm cannula to the right of the umbilicus allowed insertion of the grasping forceps and an optional 5-mm port was used for liver retraction.

The abdominal cavity was first explored with the laparoscope to determine the degree of peritoneal soiling and the site of perforation. Abdominal fluid was obtained for bacterial culture and sensitivity testing. The peritoneal cavity was irrigated copiously with 3 litres warm saline, ensuring that peritoneal contamination was minimized. Healthy omentum was pulled upwards towards the perforation. The endo-stapler was introduced through the 12-mm umbilical cannula and the omentum stapled to the gastric antrum, duodenum and falciform ligament (*Figure 2*). Six staples were used in each case; no attempt was made to close the perforation with the stapler. The pneumoperitoneum was desufflated and the abdominal punctures closed. The mean operating time was 18 min.

A nasogastric tube was left in place for 24 h, and both patients were discharged on day 4 after surgery.

Discussion

In the authors' initial experience with six patients undergoing sutured repair of duodenal perforation[1], a technique of laparoscopic suturing and either intracorporeal or extracorporeal knot tying was adopted; this proved tedious, the mean operating time being 175 min. Use of the endo-stapler in laparoscopic repair of perforated duodenal ulcer has several advantages. First, the head of the stapler articulates enabling stapling of the omentum on to the anterior wall of the stomach; second, it greatly reduces the operating time.

With regard to the safety of the device, the staples bite only the serosa of the stomach wall rather than its full thickness. No staples are visible at endoscopy 6 weeks after operation. We believe that this preliminary study demonstrates a rapid and simple technique of laparoscopic omental patch repair of uncomplicated perforated duodenal ulcer.

Reliability of clinical judgement in evaluation of the nutritional status of surgical patients

The ability of surgeons to make a reproducible and reliable evaluation of the nutritional status of patients was assessed. Three independent observers assigned 64 patients to one of four nutritional states – normal nourishment, and mild, moderate and severe malnutrition – using a questionnaire and clinical examination. Interobserver variability was analysed using the κ *statistic and reliability by assessing the correlation between the assigned class and total serum protein, haemoglobin, albumin, transferrin and cholesterol levels, weight loss and the results of immunological skin tests. Concordance was observed in 49 of the 64 judgements (77 per cent) and partial agreement in the remainder* ($\kappa = 0{\cdot}74$, $P < 0{\cdot}001$)*. Clinical judgement correlated significantly with albumin, transferrin and cholesterol levels and weight loss* ($R^2 = 0{\cdot}73$, $P < 0{\cdot}001$)*. Surgeons are able to assess nutritional status using clinical judgement.*

Poorly nourished patients are more prone to develop postoperative complications and have a higher risk of mortality[1–4]. Several studies have attempted to define nutritional status in terms of anthropometric variables, laboratory assays of circulating proteins, cholesterol levels and immunological factors[5–10]. It may be assessed before surgery using mathematical formulae that contain various combinations of these measurements[10–15].

No universally accepted definition of malnutrition exists and therefore there is no 'gold standard'. The clinical judgement of the surgeon, taking into account the history, food intake, physical activity and some simple observations of muscle mass and fat deposits, might be an equally valid method.

This prospective study evaluated the reproducibility of clinical judgement in assessing nutritional status. This was compared with accepted objective tests for malnutrition. The clinical features with the greatest influence on the clinical judgement of surgeons were assessed.

Patients and methods

Patients

In total, 64 patients (33 men, 31 women; median age 62 (range 18–79) years) admitted for elective surgery entered the study. They were chosen randomly and prospectively, and constituted 20 per cent of all such patients admitted over a 3-month period. Selection was on the basis of the clinical record number; only numbers ending in 0 or 5 were chosen.

Characteristics of the study group

Table 1 shows the distribution of the patients according to age and diagnosis, compared with the total population over the same period. There were no significant differences between the two groups and the study sample can therefore be considered representative of the general population.

Objective tests

The weight of each patient was recorded at admission and compared with that measured 3 months earlier. Blood samples taken at admission were analysed for levels of albumin, haemoglobin, transferrin, total protein and cholesterol. A lymphocyte count was performed and a skin test with seven common anamnestic antigens (Multitest; Merieux, Lyon, France) carried out.

Clinical judgement

Three surgeons (one consultant, two registrars) examined each patient independently and without knowledge of the diagnosis, planned operation or results of the objective tests. They were asked to assign each patient to one of four classes: normal nourishment, and mild, moderate or severe malnutrition. These were not defined by any preset criteria. As part of the examination protocol, the observers scored specific variables shown in *Table 2* according to methods previously described[16]. No criteria were set for this scoring. The surgeons also scored their own observational assessments of the patient's adipose mass, muscle mass and conjunctival pallor on similar scales, without preset criteria.

Statistical analysis

Reproducibility of clinical judgement, assessed by the degree of interobserver variation, was analysed by the κ statistic[17,18]. The value of κ varies from 0 to 1; a value of 0·4 or less indicates that chance alone can account for the observed agreement and a value of 1 perfect concordance. The statistical significance of κ and its 95 per cent confidence interval were calculated.

For correlational analysis, the nutritional status was assigned a numerical value ranging from 1 (normally nourished) to 4 (severely malnourished). For assessment of reliability, this value was taken as the dependent variable in multiple stepwise regression, with the objective assay results taken as independent variables[19]. Similarly, the eight clinical scores were taken as independent variables when assessing the contribution of each to the clinical judgement.

Differences in the distributions of the values for albumin, transferrin, cholesterol and objective weight loss among the four nutritional classes were tested by analysis of variance (ANOVA). Categorical data were analysed by the χ^2 test.

Results

Interobserver agreement

Reproducibility of clinical judgement was excellent (*Table 3*). Complete agreement was achieved in severely malnourished patients with good concordance in the normally nourished group. The greatest discordance occurred in assigning patients to mild or moderate malnutrition. Discordant results are shown in *Table 4*; in each case the disagreement was by one class.

Correlation with objective test results

No difference between the nutritional classes was present

Table 3 *Distribution of patients by level of surgeon agreement and assigned nutritional class*

	Nutritional class				
Level of agreement	Normal nutrition	Mild malnutrition	Moderate malnutrition	Severe malnutrition	Total
3 of 3	28	9	7	5	49
2 of 3	7	5	3	0	15
None	0	0	0	0	0
Total	35	14	10	5	64

$\kappa = 0{\cdot}74$ (95 per cent confidence interval 0·63–0·85) ($P < 0{\cdot}001$)

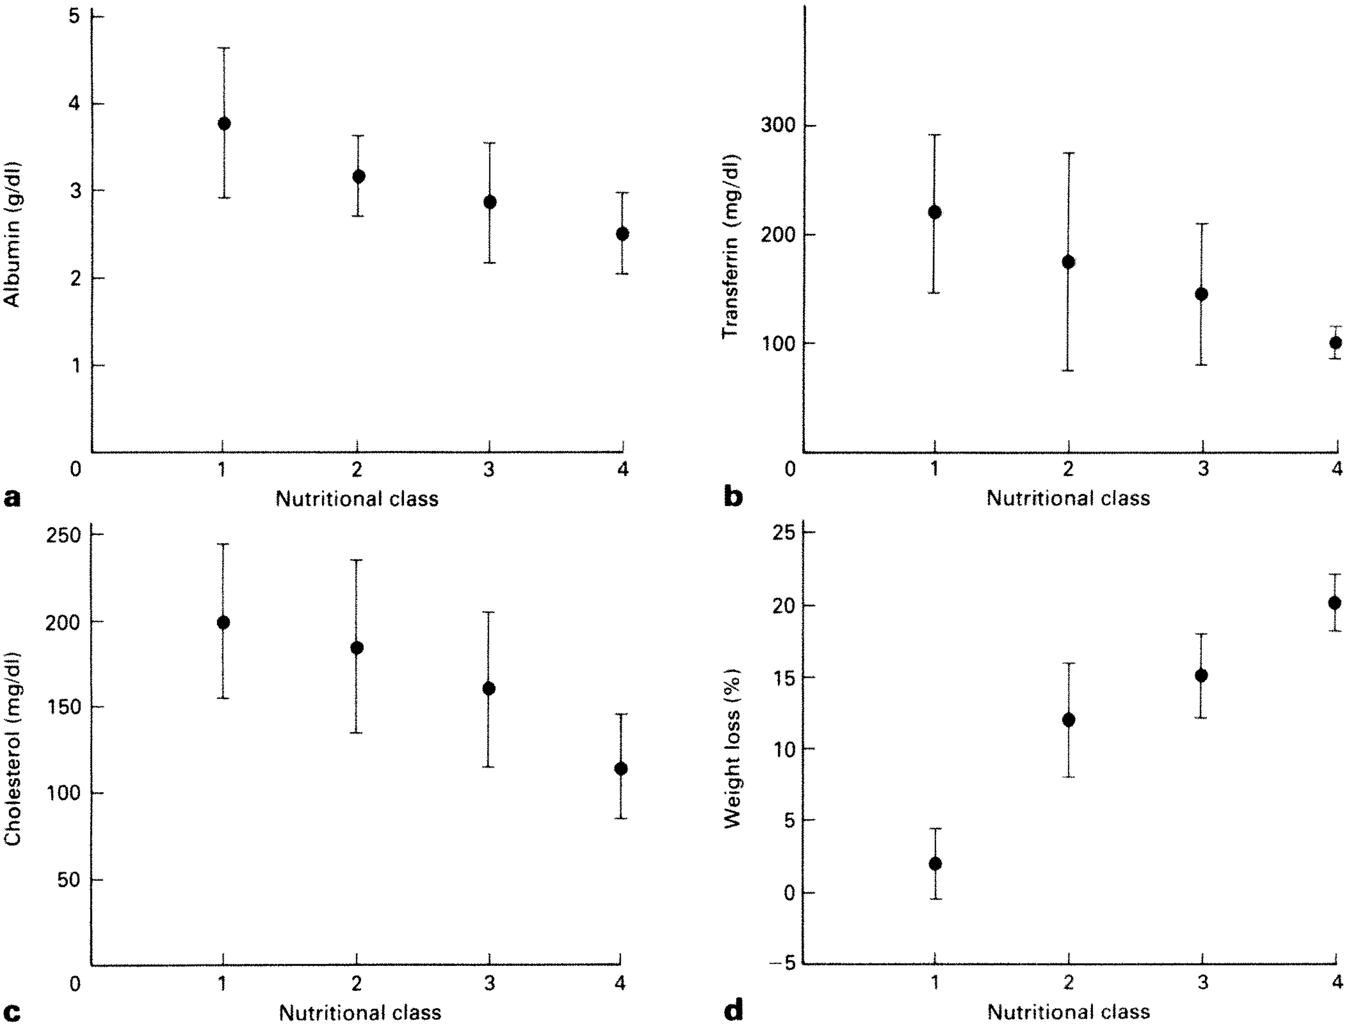

Figure 1 *Results of the four objective tests according to assigned nutritional class.* **a** *Serum albumin;* **b** *serum transferrin;* **c** *serum total cholesterol;* **d** *weight loss over a 3-month period (expressed as a percentage of initial weight). Values are mean(s.e.m.). Nutritional classes were assigned as in* Table 3

Table 4 *Distribution and quality of disagreement of the three surgeons*

	Surgeon no.			
	1	2	3	Total
No. of disagreements	3	6	6	15
Overestimation	1	3	2	6
Underestimation	2	3	4	9

regarding age distribution, or benign or malignant disease. ANOVA revealed significantly different distributions of values for objective weight loss, and albumin, transferrin and cholesterol levels between the four nutritional groups (*Figure 1*). The correlation between these variables could be expressed in the form:

$$\begin{aligned}\text{Nutritional status} = {} & 1{\cdot}78 + 1{\cdot}41 \times \text{weight loss (\%)}\\ & + 0{\cdot}019 \times \text{cholesterol (mg/dl)}\\ & - 0{\cdot}53 \times \text{albumin (g/dl)}\\ & - 0{\cdot}016 \times \text{transferrin (mg/dl)}\end{aligned}$$

This multiple regression had an R^2 value of 0·73 ($P < 0{\cdot}001$). Adding more variables did not significantly improve the correlation. Clinical judgement, therefore, correlates well with four commonly used objective parameters in the assignment of nutritional status.

Positivity to the skin tests was different in the four nutritional classes, but in the mathematical model neither this variable nor levels of serum protein and haemoglobin or lymphocyte count were found to be significant.

Clinical factors contributing to the clinical judgement

Four of the eight clinical variables were found to be strong determining factors in forming a clinical judgement. Two of these involved the patient's own assessment of well-being and weight loss, and two were observational (the observer's assessment of muscle and adipose mass). They could be fitted to an equation of the form:

$$\begin{aligned}\text{Nutritional status} = {} & 6{\cdot}109 - 5{\cdot}39 \times \text{muscle mass}\\ & - 3{\cdot}44 \times \text{adipose mass} - 0{\cdot}06 \times \text{well-being}\\ & - 0{\cdot}037 \times \text{weight loss}\end{aligned}$$

where all these variables were measured on an arbitrary scale of 0–10. The regression line had an R^2 value of 0·82 ($P < 0{\cdot}001$).

Discussion

Malnutrition has an important influence on outcome in surgical patients. There is evidence that only the severely malnourished benefit from nutritional support[20]; it is therefore important to identify these patients accurately.

Nutritional assessment is now dependent largely on the measurement of biological variables and the use of models predicting the risk of septic complications[13–15]. This approach is limited by two factors: the wide biological variability introduced by different clinical conditions such as heart, liver and renal disease, for which these measurements are unreliable, and the improper use of epidemiological models for individual estimation[21]. Shizgal[22] found that the confidence intervals of the variables usually considered are too wide to be of much value in any given patient. Measurements of total exchangeable potassium concentration[23] and neutron activation analysis[24] are not readily amenable to clinical practice. Distinctions should be drawn between methods suitable for research and those for routine clinical use, between methods for epidemiological estimation and those for evaluation of a single patient, and between techniques for group prognosis and those for recognition of malnutrition[25].

Hill[26] emphasized that 'it is time for some clinical common sense'. A valid bedside method must be simple to apply, reproducible under every condition, generally acceptable and cost–effective.

The present study shows that simple clinical examination is capable of recognizing malnutrition with a high degree of reliability and confirms the work of Baker, Detsky and colleagues[21,27]. Such judgements, although subjective and independent, are highly reproducible. No global disagreement between observers was registered. Considering that, unlike the Baker study, no training was given before the trial, no criteria were set up for the assignment of the patients to different classes and the diagnosis was deliberately withheld before formulation of the judgement, this result assumes even greater significance.

Concordance was best in the assignment of patients to the two extreme nutritional states and less complete in the two intermediate classes. Total agreement in the recognition of severely malnourished individuals is most important because these patients benefit from perioperative nutritional support[28].

Distributions of the levels of albumin, transferrin and cholesterol correlated well with clinical nutritional status but were overlapping; this makes them unsuitable for the assignment of individual patients.

Weight loss, calculated from measurements at two defined times, correlated well with clinical nutritional status and could be used to assign individuals to the correct class. This method, while practicable, is unlikely to be accurate in routine clinical practice, since the time interval between weight measurements usually varies.

The lack of correlation between nutritional classes and the skin test results can be ascribed to the multifactorial determinants of this variable. Internal analysis of data has shown that results of skin tests correlate with the presence and stage of cancer, the age of the patient and the level of serum albumin, in accordance with the findings of Twomey *et al.*[29].

The four most significant clinical variables in the formulation of clinical judgement were derived from questioning and observation of the patient. Both aspects of examination are crucial in this formulation.

This study did not consider the relationship between nutritional status and surgical outcome since variables such as type of disease, extent of surgery, technical factors, preoperative and postoperative care, and individual response to treatment were not considered[30].

Clinical evaluation of nutritional status deserves a more important role and wider use in clinical practice since it is inexpensive and easy to apply.

Repeat hepatectomy for cancer

In a series of 279 hepatectomies performed for cancer between June 1984 and March 1992, 46 were repeat operations, for metastases in 41 patients. The primary tumour was in the colon and rectum (28 patients), APUDoma (five) and miscellaneous (eight). Repeat hepatectomies were performed in 26 per cent of patients who had recurrence after the first liver resection and in 40 per cent of those who had liver recurrence. An unsuspected extrahepatic recurrence was discovered and resected in eight instances and in two other cases a known extrahepatic recurrence was resected during the second hepatectomy. The hospital mortality rate was 2 per cent (one patient); the death was from nosocomial pneumonia. The total morbidity rate including minor complications was 32 per cent, with a higher frequency of haemorrhagic problems after secondary liver resection (12 per cent) than after primary hepatectomy (5 per cent). The rate of postoperative complications after repeat hepatectomy was related significantly to operative blood loss greater than 1500 ml (P = 0·04). The technical problems of repeat hepatectomy were: (1) re-exposure of the liver, considered to be difficult in 67 per cent of second liver resections and 80 per cent of third procedures; (2) the liver parenchyma, which often had histological modifications between first and second resections and was more difficult to 'work' as shown by the mean duration of clamping of the hepatic pedicle (54 min for secondary versus *36 min for primary liver resection); and (3) modification of the intraparenchymal vasculobiliary anatomy following liver regeneration after major hepatectomy. Intraoperative ultrasonography was of great benefit. Rates of crude and recurrence-free survival were relatively encouraging at 47 and 33 per cent 3 years after the second liver resection for the whole group. These values were lower for colorectal cancer (37 and 21 per cent 3 years after the second hepatectomy). These figures do not, however, convey the complete picture of the outcome for these patients. During the same follow-up period, 143 recurrences were detected and a mean of 2·9 resections per patient were performed. The indications for repeat hepatectomy are still to be clarified, although the surgical technique is safe.*

Dr D. Elias

The resection of hepatic metastases of colorectal origin, when possible, is still the only treatment that enables a 5-year survival rate of 33 per cent[1–3]. The resection of hepatic metastases of origin other than colorectal or hepatocellular carcinoma (HCC) gives similar results[4,5]. After hepatectomy, 40–60 per cent of patients will have recurrence only in the liver, whether the primary tumour is in the colorectum[6,7] or elsewhere[8,9]. Until now, there have been seven reported series of at least ten cases of repeat hepatectomy for tumour resection of malignant recurrence in the liver[10–16], of which the largest comprised 34 repeat hepatectomies carried out on 28 patients[10]. Although the published results are good, little is reported on the feasibility of repeat hepatectomy and the long-term outcome. To evaluate feasibility and survival, a prospective study was conducted on 41 patients who underwent 46 repeat hepatectomies in this institute.

Patients and methods

Between June 1984 and March 1992, 41 patients underwent repeat hepatectomy for recurrent malignant disease (five patients had a third hepatectomy). All but two patients had metastasis from colorectal, neuroendocrine or miscellaneous primary sites. Two patients underwent repeat hepatectomy for recurrent HCC. The 46 resections represented 16 per cent of 279 hepatectomies carried out for malignancy in this department during the study period. Sixteen patients had their first hepatectomy in another hospital. The 25 patients who had their first and second hepatectomies in this department represented 12 per cent of 217 patients who had a first hepatectomy for cancer in this institute. Ninety-five (44 per cent) of these patients had recurrence after a mean(s.d.) interval of 14(8) months; 65 per cent of recurrences were in the liver. A second liver resection was performed in 26 per cent of patients who had recurrence and in 40 per cent of those who had hepatic recurrence after the first liver resection. Selection criteria for repeat hepatectomy were: patient in good health, with recurrence only in the liver after a complete investigation, and recurrence that was technically resectable whatever the extent. The mean age of the 41 patients, 25 women and 16 men, was 54·7 (range 22–73) years. They were classified into groups 1–3 according to the site of the primary tumour (*Table 1*). One woman had malignancy of both colon and breast. Her first hepatectomy was for metastases of the colonic cancer and the second proved to be for metastases of the breast malignancy. Of the five patients who underwent a third hepatectomy, four were in group 1 and one in group 2.

The intervals between resection of the primary tumour and the hepatectomies are shown in *Table 1*. Synchronous resection of the primary lesion and metastases was carried out in 11 cases. One patient had 12 metastases of a carcinoid tumour that were completely resected in two successive hepatectomies. A 3-month interval was allowed for compensatory hypertrophy of the remaining liver parenchyma to occur between the two hepatic resections.

After primary liver resection, 12 patients in group 1 received

0007-1323/93/121557-06 © 1993 Butterworth-Heinemann Ltd

systemic chemotherapy (5-fluorouracil (5-FU) and folinic acid) for 6 months. In group 2, three patients received systemic chemotherapy (5-FU and streptozotocin) for 6 or 8 months before primary hepatectomy; after this resection two received intra-arterial hepatic chemotherapy with the same drugs for 1 year. In group 3, all patients received systemic chemotherapy before and after the first hepatectomy and, in five cases, second-line chemotherapy after the second liver resection. The extent of hepatectomy at the first and second liver resections is shown in *Table 2*. Twenty patients had primary hepatectomies that were major (i.e. excision of at least three segments according to Couinaud's classification, or four metastases in the case of multiple wedge resections). Of these 20, eight underwent another major hepatectomy (i.e. excision of at least one-third of the remaining liver). Of the 21 minor hepatectomies at the first resection, nine were followed by major hepatectomy at the second procedure. Operations included one right hepatectomy extended to segment IV and one central hepatectomy; in three cases segment I was resected. For the four patients in group 1 the third liver resections were one right hepatectomy (after two consecutive wedge resections), excision of segment I (after removal of segment IV followed by a wedge resection), a segmentectomy IV (after a bisegmentectomy V–VI followed by a bisegmentectomy II–III) and a wedge resection (after a segmentectomy VIII followed by three wedge resections). The patient in group 2 underwent four wedge resections (after a bisegmentectomy II–III, followed by right hepatectomy).

Complete abdominal exploration was always undertaken before hepatectomy. Except in cases of primary liver malignancy, the previous midline laparotomy was extended by a right transverse incision after the exploration. On exploration in group 1 there were eight unsuspected extrahepatic recurrences. Intraoperative ultrasonography was performed routinely during all hepatectomies. Hepatic resection was usually carried out under intermittent pedicle clamping[17]. Continuous clamping[18] was used when total vascular exclusion of the liver was necessary (in five cases at first and in two at second hepatectomy). The

*According to Couinaud's classification. †Two haemorrhage and two subphrenic abscess; ‡five haemorrhage and one subphrenic abscess approach to the portal pedicles was mainly transparenchymal; early dissection of the porta hepatis was necessary only for centrohepatic tumours and for left hepatectomy extended to segments V and VIII[19].

The difficulty of surgery was estimated by the length of operation, duration of hepatic pedicle clamping, blood loss, consistency of the non-malignant hepatic parenchyma and difficulty of the liver exposure. The difficulty of exposure was classified into four levels: low (no abnormal adhesions), moderate (normal postoperative adhesions), difficult (the exposure took more than 2 h or there was blood loss above 1 litre), and very difficult (necessity to pass under the liver capsule or through the diaphragm). In two cases in group 1 preoperative hypertrophy of the potential remaining left lobe was induced by complete embolization of the right portal branch 4 weeks before resection, once before primary hepatectomy and once before secondary liver resection[20,21].

In ten cases in group 1 resection of extrahepatic tumour was performed at the same time as repeat hepatectomy (colon, two; abdominal wall, two; mesocolic lymph nodes, two; adrenal gland, two; ovary, one; small bowel, one). Each resected specimen was cut into 1-cm slices including tumour and liver parenchyma, fixed in Bouin's fluid, embedded in paraffin and cut to 4 μm in thickness. The routine stains included haematoxylin–eosin–saffron, chromotrope aniline blue for fibrous tissue, Turnbull's stain for iron and silver impregnation for reticulin fibres.

The data were collected prospectively. Survival curves were calculated according to the Kaplan–Meier method; no patients were lost to follow-up.

Results

Operation

The main difficulties encountered in repeat hepatectomy were re-exposure of the liver and dissection of the porta hepatis and inferior vena cava, especially if they had been dissected before. The approach to the liver was difficult or very difficult in 67 per cent of cases at the second liver resection and in 80 per cent at the third, while it was difficult in 29 per cent of primary hepatectomies (*Table 2*). For primary liver resection these difficulties occurred mainly if a previous surgical procedure had been carried out on the liver, gallbladder or hepatic artery. It was necessary to pass under the hepatic capsule to free the liver in six cases and the pleura was breached in five. In four cases it took 4 h to expose the whole liver and its vascular structures.

The mean duration of hepatic resection, as reflected by the clamping time of the pedicle, was 54 min for secondary hepatectomy and 36 min for primary resection (*Table 2*). As there was little difference between the extent of hepatic resection at the first and second operations, this suggests that the second resections were more difficult to perform than the first. It is interesting to note that in two cases the intermittent clamping time was more than 140 min without producing postoperative liver cell failure[17].

The median operative blood loss was 1·4 litres (*Table 2*), including resection of extrahepatic recurrence performed at the same time as hepatectomy. Resection of extrahepatic recurrence

HCC, hepatocellular carcinoma

(only in group 1) was twice as frequent at the secondary (24 per cent) as at the primary (10 per cent) hepatectomy.

Mortality and morbidity

Only one postoperative death (2 per cent) occurred before discharge from hospital, caused by acute bilateral nosocomial pneumonia that started during operation and did not respond to aggressive postoperative treatment. Although general complications (including pulmonary, urinary tract and abdominal wall infection, and pleural effusion) were no more numerous following primary than secondary liver resection (*Table 2*), local complications, especially haemorrhage, were more frequent after repeat hepatectomy and necessitated surgical intervention five times after the second liver resection but only twice after primary procedures. Complications were significantly more frequent when blood loss was greater than 1500 ml (70 per cent *versus* 16 per cent for loss under 1500 ml, $P=0{\cdot}04$).

Pathological characteristics

In 52 of the 87 hepatectomies (41 first, 41 second, five third), non-tumour liver tissue was examined histologically (*Table 3*). A relative increase in the extent of pathological liver tissue, especially fibrosis following chemotherapy, was observed at repeat hepatectomy. There was no significant difference between primary and secondary liver resection in the maximum tumour dimension, the number of tumours resected (a maximum of seven lesions in the first and eight in the second resection) and the mean minimum resection margin.

Outcome

Table 4 shows the current clinical status of the patients. Overall and disease-free survival after the second liver resection are shown in *Figure 1*. The 1-, 2- and 3-year overall survival rates after second hepatectomy were 84, 60 and 47 per cent, while 71, 46 and 33 per cent of patients were disease-free after the same intervals. Of the 28 patients who underwent secondary hepatectomy for colorectal metastasis, 21 per cent were alive and disease-free 3 years after the second liver resection (*Figure 2*). The prognosis of patients with tumours of neuroendocrine origin was significantly better than that of those with other primaries (*Figure 3*). Unfortunately, repeat hepatectomy was not the only treatment required by these selected patients during the course of the disease. The 41 patients developed 143 different recurrences (*Table 5*) during this period of limited survival (i.e. a mean of 3·5 recurrences per patient). A third recurrence occurred in 32 and a fourth in 22; seven patients developed a fifth recurrence at different sites. Two-thirds of the patients received complementary chemotherapy and/or radiotherapy.

Discussion

This series of patients who underwent repeat hepatectomy, which is believed to be the largest reported to date, indicates that this procedure is more difficult than primary liver resection but that it may be achieved with low morbidity and mortality; the role of repeat hepatectomy in the management of patients with recurrent metastatic malignancy after hepatic resection remains controversial.

Repeat hepatectomy is more difficult than primary resection for three reasons. First, re-exposure of the liver is difficult, especially where the previously resected edge adheres intimately to nearby organs. This is particularly likely after right hepatectomy or bisegmentectomy VI–VII, where the liver has turned through 90° and the resected edge adheres to the diaphragm. It is not unusual for the dissection to be subcapsular or inside the diaphragmatic muscle to allow mobilization of the liver. The same problem occurs when the hepatic pedicle and the inferior vena cava have been explored previously. In the present series this re-exposure was difficult or very difficult in 67 per cent of second and 80 per cent of third liver resections (*Table 2*).

Second, the liver parenchyma is more friable, and so more difficult to deal with, after hepatic regeneration and/or intensive chemotherapy (*Table 3*). After a relatively extensive first hepatectomy and compensatory hypertrophy, the liver parenchyma undergoes fatty infiltration[22] and so is more friable than in the normal state. This friability is also found in conditions of fibrosis following chemotherapy[23], and complicates haemostasis and biliostasis of the resected edge.

Third, after hepatic regeneration (especially when extensive) the vasculobiliary intraparenchymal anatomy is completely altered. This change is infinitely variable and depends both on the type of previous hepatectomy and on individual variations. Thus, leaving a margin of 5–10 mm of liver parenchyma along the right border of the median hepatic vein at right hepatectomy results, after regeneration, in a new right hepatic lobe, 3–4 cm thick, in which atypical vasculobiliary elements develop or hypertrophy. After extended right hepatectomy to segment IV, the anatomy of the remaining hypertrophied left liver is also modified, especially its three-dimensional orientation, and classical anatomical landmarks on the liver surface disappear. This 'neoanatomy' is not troublesome if carefully studied by intraoperative ultrasonography, which we believe to be essential if repeat hepatectomy is to be undertaken with safety.

Such operative difficulties explain the long time taken to perform these procedures (4–5 h) and the amount of blood lost (1·5–2 litres) in this series (*Table 2*).

This study and earlier reports in the literature (*Table 6*) all show low mortality and morbidity rates after repeat hepatectomy similar to those observed after primary liver resection. However, in both the cohort of Borgonovo *et al.*[15] and the present series the risk of bleeding seems higher than at primary resection. On the other hand, the risk of hepatic failure does not seem to be modified, mainly because the liver returns nearly to its original volume after primary resection. The indications for repeat hepatectomy should be the same as for primary resection with respect to patient characteristics (general condition, age, liver function) and tumour parameters (number, size, site, predicted resection margin). The same operative techniques can be used. From the technical point of view, repeat hepatectomy has been shown to be feasible and safe.

It is still difficult to state with confidence that survival times are improving. Until now, no large series of repeat hepatectomy has been published. Only three series[10,13,15] have included more than 15 patients and only two of these[10,13] give survival results, with respectively 25 and 36 per cent of patients disease-free and alive a mean of 20 months after the second liver resection. In the present series of 41 patients an overall survival rate of 48 per cent and disease-free survival rate of 33 per cent were observed 3 years after secondary hepatectomy. However, follow-up is limited and the number of long-term survivors small. Only eight patients survived more than 3 years, of whom two had recurrence at 42 and 54 months (*Figure 1*).

These results are encouraging and for the moment this therapeutic approach seems justified, but this optimism should be tempered by the frequency of recurrence at various sites (*Table 5*). Although this is a selected population by virtue of being suitable for liver resection, five patients had recurrence outside the liver and were treated curatively before presenting again with one or more liver metastases, ten patients had extrahepatic recurrence at the time of second hepatectomy and 32 had recurrence later. Twenty-two of these last patients were brought once again into complete remission. The 41 patients underwent a mean of 3 operations after resection of the primary tumour and two-thirds of them received chemotherapy and/or radiotherapy. There was an increase in the incidence of extrahepatic lesions after repeat hepatectomy: 10 per cent at the first, 24 per cent at the second hepatectomy and 40 per cent at the third operation. Although survival may be encouraging, it is at the cost of major and repeated interventions. It cannot yet be seen whether these patients can be cured in the long term, as no plateau appears on the survival curves. The same observation has been made with repeated treatment of local recurrence of colorectal cancer[24]. Only a longer period of follow-up with larger numbers can answer this question.

Analysis of the 28 patients who underwent second liver resection for a colorectal primary (*Figure 2*) is less encouraging, even with three patients exceeding 3 years' disease-free survival after this resection: only one of five patients is free from recurrence at 36 months. The selection criteria for repeat hepatectomy were the technical feasibility of performing complete resection of liver tumours and the exclusion of patients who had early and/or non-isolated liver recurrence. It seems that more restricted selection criteria may be appropriate. In metastases from neuroendocrine tumours, survival after the second liver resection is obviously superior to that observed for other primaries (*Figure 3*) as only one of the five patients died and the mean survival time is high (*Table 4*). This justifies a surgical approach of doing everything possible for patients with these tumours[25] even when complete long-term cure is not expected[26].

Are there any other curative procedures available for this population of selected patients with isolated hepatic recurrence after primary liver resection? Percutaneous ethanol injection gives good results when it is technically possible (small-sized tumours, not more than three in number and suitably placed)[27]. This technique is useful for patients in poor general condition. Liver transplantation has as yet no place in the treatment of hepatic metastases except perhaps for those of neuroendocrine origin, for which it is currently being evaluated. The role of transplantation for recurrence of HCC in the cirrhotic liver is also currently under evaluation.

A third hepatectomy is possible in very few selected cases, bearing in mind that it is a far more difficult procedure than a second resection. It is not yet possible to evaluate its benefit for survival.

In conclusion, it is clear that the technical problems of repeat hepatectomy have been solved as proven by the low operative mortality rate of this series. However, the length of remission that can be achieved by these extensive surgical procedures is not yet known. The indications for and results of repeat hepatectomy are independent variables that are still to be defined. This is difficult, as indications for the first hepatectomy for liver metastases are still not clear[3,28].

The argon beam coagulator is a new device for haemostasis during and after surgery on parenchymatous organs. No data are available on its efficacy and tissue effect following hepatic resection. Blood loss, the time needed to achieve adequate haemostasis and histological findings after liver resection were assessed in 12 pigs using argon beam coagulation or suture ligation only, the mattress suture technique and tissue glue application. The treatment was randomly assigned to each of the four liver lobes in each pig. Median blood loss following argon beam coagulation was 13 (range 2–47) ml and after simple suture ligation 55 (range 2–260) ml ($P < 0{\cdot}02$)*. The median time needed for adequate haemostasis following argon beam coagulation was 3 (range 2–7) min* versus *14 (range 2–48) min in the control group* ($P < 0{\cdot}005$)*. There was no difference between argon beam coagulation and tissue glue, which were both superior to the use of mattress sutures. Argon beam coagulation resulted in less tissue damage than tissue glue or mattress suturing. The argon beam coagulator is an efficient device for achieving haemostasis following partial hepatectomy in the pig. It causes only a moderate tissue reaction.*

Since the beginning of liver surgery, surgeons have tried to control haemorrhage during operation on this highly vascularized organ. One of the problems encountered during liver surgery is the continuous oozing of blood from vessels that are too small to be ligated individually. Several techniques for controlling this kind of haemorrhage are currently available. A recent development is the use of argon beam coagulation. This is performed using a monopolar coagulator, which conducts radiofrequency current to the tissue using a jet of inert and non-flammable argon gas. The motion of current through the gas beam ionizes the argon, giving it a blue colour. It is the arcing of current into tissue, rather than any action of the argon gas, that leads to coagulation[1].

Although some reports have been published on argon beam coagulation in gynaecological[1], head and neck[2] and urological[3] surgery, few data are available on this haemostatic technique in procedures on the liver.

This study was designed to compare the efficacy of argon beam coagulation with that of three standard techniques in partial hepatectomy.

Materials and methods

Twelve pigs of Yorkshire–Danish Landrace crossbreed and bodyweight 22–30 kg were used. Part of each of the four lobes of the liver (left lateral, left medial, right medial and right lateral lobes) was resected using the blunt dissection method[4]. Because porcine liver lobes differ in size, care was taken to create resection surfaces of equal area. This was achieved by encircling the lobe with a 15-cm long tape to delineate the line of resection. Major vessels were ligated and other bleeding points sutured. The relative weights of each resected part of liver lobe in the 12 pigs, expressed as the mean(s.e.m.) proportion of total liver weight were: left lateral lobe 2·2(0·2) per cent; left medial lobe 3·5(0·3) per cent; right medial lobe 1·3(0·1) per cent; and right lateral lobe 2·4(0·2) per cent. The total amount of liver tissue resected in the 12 pigs, expressed as the mean(s.e.m.) proportion of total liver weight, was 9·4(0·4) per cent. The order in which the different lobes were operated on was randomly established.

After resection, the lobe was randomly assigned to one of four coagulation treatments: (1) control group ($n = 12$) in which no additional measures were taken; (2) suture group ($n = 12$) where 3/0 polydioxanone (PDS; Ethicon, Norderstedt, Germany) mattress sutures were inserted 0·5 cm from the resection edge, compressing the resected surface[5]; (3) tissue glue group ($n = 12$) in which Tissucol (Immuno, Vienna, Austria) was applied by jet spray in several layers[6], using a total of 1·0 ml per lobe; and (4) argon beam group ($n = 12$) in which an argon beam coagulator (Beamer One; Beacon Laboratories, Broomfield, Colorado, USA) was applied to the cut surface, 'painting' the whole area, at a setting of spray 1, level 3.

Before operation penicillin 600 000 units and streptomycin 600 mg were administered intramuscularly. All animals received 500 ml 35 per cent polydextran (Haemaccel; Behringwerke, Marburg, Germany) and 500 ml 0·9 per cent saline solution during operation to compensate for any blood loss.

Blood loss was estimated by weighing the swabs placed around each lobe after applying the coagulation treatment to the resected surface. Some 10 min after each technique was applied, the remaining bleeding points were sutured or coagulated with the conventional electrocoagulator. The time needed to achieve adequate haemostasis following coagulation was recorded. One pig was killed 3 h after operation and biopsy specimens of the freshly coagulated liver lobes

Table 1 *Blood loss and time to achieve adequate haemostasis with each coagulation technique in 12 areas of liver resection*

taken. The other pigs were killed 1 week after operation and specimens of the resected area taken. The specimens were fixed in formalin, sectioned and stained with haematoxylin, azophloxin and saffron for light microscopy. A Videoplan-assisted microscope (Kontron, Munich, Germany) was used to assess the depth of scar formation and fibrosis.

Results are given as median (range). Statistical analysis was carried out using the Kruskal–Wallis test. Statistical significance was assumed at $P < 0.05$. The study was approved by the Animal Experiments Committee of Erasmus University Rotterdam.

Results

There were significant differences between the techniques tested for blood loss, time to achieve haemostasis and depth of fibrosis on histological examination (Kruskal–Wallis test).

Blood loss

The blood loss in the 12 pigs with each coagulation technique is shown in *Table 1*. The smallest loss was seen with argon beam coagulation, the largest with mattress suturing. There was no difference in blood loss between the argon beam and tissue glue techniques, or between mattress suture and control methods. However, blood loss with argon beam and tissue glue haemostasis was considerably less than that with the mattress suture and control techniques. When all four methods were considered together, there were no differences in blood loss between the different liver lobes and the amount of loss was not linked to the order of resection (first, second, third or fourth lobe).

Time to achieve adequate haemostasis

With argon beam coagulation, haemostasis was quickly achieved, while the control technique took the longest (*Table 1*). There was no significant difference between argon beam coagulation and the tissue glue technique. Again, both the argon beam and tissue glue methods were superior to the other two.

Table 2 *Depth of fibrosis 1 week after operation*

	Median (range) depth of fibrosis (mm)
Argon	1·7 (1·2–4·5)
Tissue glue	2·6 (1·2–2·9)*
Mattress sutures	2·2 (1·0–5·3)
Control	1·5 (1·1–3·7)

*$P < 0{\cdot}01$ (tissue glue *versus* control, Kruskal–Wallis test)

Number of additional sutures and coagulations

The smallest number of additional sutures and conventional electrocoagulations was needed following partial lobectomy using argon beam haemostasis (*Table 1*). The largest number of additional sutures was required following the control technique. The largest number of additional electrocoagulations was needed after mattress suturing. The largest number of additional sutures plus additional electrocoagulations had to be used following the mattress suture technique.

Autopsy findings

Autopsy 1 week after resection showed a large number of adhesions between the resected liver lobes and surrounding organs. There was no correlation between the technique used and the number or severity of adhesions. Nearly all pigs had some ascites in the abdomen; this was not haemorrhagic.

Histology

Histological examination of the liver lobes 3 h after operation showed that following argon beam coagulation there was a thin layer (about one lobule in thickness) of coagulation necrosis (*Figure 1*). The lobe treated with tissue glue demonstrated a layer of fibrin on top of largely viable liver parenchyma, with a small area of regressive and haemorrhagic abnormalities. In the lobe treated with mattress sutures, a layer with ischaemia and necrosis of moderate thickness was seen (*Figure 1*). The lobe treated using the control technique showed some necrosis, sharply confined to a very thin layer of tissue. There were no abnormalities in the remainder of the liver parenchyma after coagulation with the different techniques.

By 1 week after resection and coagulation, the lobes treated using argon beam coagulation showed, from the top downward, a small layer with fibrin deposition, a broad layer of necrotic parenchyma containing many neutrophil granulocytes, and a layer showing an acute inflammatory reaction with active fibroplasia. In the lobes treated with tissue glue, a very active proliferative inflammatory reaction with coagulation necrosis in some areas and a foreign body reaction in others could be seen around the necrotic parenchyma (*Figure 2*). The lobes treated with mattress sutures demonstrated a broad and irregular fringe of fibrosis and an active proliferative inflammatory reaction. There was a distinct foreign body reaction around the sutures. In the lobes treated using the control technique, a mild proliferative inflammatory reaction with a small fringe of fibrosis was noted (*Figure 2*). The remainder of the liver parenchyma demonstrated no abnormality following haemostasis with the different techniques.

The depth of fibrosis in the liver was significantly different between the groups ($P < 0{\cdot}01$, Kruskal–Wallis test). After tissue glue haemostasis, the median area of fibrosis was deeper (2·6 (range 1·2–2·9) mm) than that after the control technique (1·5 (range 1·1–3·7) mm) ($P < 0{\cdot}01$). The depth of fibrosis after the other techniques was between these two extremes (*Table 2*).

Discussion

These results demonstrate the superiority of argon beam coagulation and tissue glue over mattress suture and control techniques used for haemostasis following partial hepatectomy. This was the case both for the severity of blood loss and the time needed to achieve adequate haemostasis. The pig was chosen as an experimental animal because of similarities between porcine and human liver parenchyma. Because the pig has four liver lobes it was possible to use four different coagulation techniques in each animal.

Blood pressure was not measured during operation because previous investigators[4] have shown there to be no relationship between blood pressure and the amount of blood lost during partial hepatectomy in pigs. The present study has confirmed that there is no relationship between the individual porcine liver lobe and the amount of blood loss during resection[4]. There was no influence of the order of resection on the amount of blood loss per lobe.

As expected, the control technique gave the least disruption of liver parenchyma and the least fibrosis. Argon beam coagulation was second best in this respect. The mattress suture technique caused considerable ischaemia and thus necrosis. There was also an impressive foreign body reaction to the sutures.

Depth of fibrosis, after 1 week of healing, was used as a parameter for the loss of liver parenchyma. It was smallest with the control technique and largest with tissue glue. The fact that tissue glue produces the greatest fibrosis is probably due to the stimulating effect on fibroblast growth of fibrin and factor XIII, which form the major constituents of Tissucol once the components of the glue (fibrinogen, thrombin, factor XIII, calcium chloride and aprotinin) have reacted with each other[6]. This may therefore represent increased fibrosis on the liver surface, and may not necessarily reflect tissue destruction.

Argon beam coagulation has several advantages over conventional electrocoagulation. The depth and horizontal extent of coagulation are relatively fixed, which is not the case with the conventional procedure. The argon beam blows blood away from the tissue, thereby giving better cauterization and visualization[2]. Furthermore, the argon gas jet reduces the availability of oxygen at the desiccation site, resulting in less smoke[3]. Another difference is that the argon beam coagulator functions in a non-contact manner[2], thereby allowing the bleeding surface to be 'painted'.

In conclusion, the argon beam coagulator is a useful device and a promising addition to the surgical armamentarium for liver resection.

Prolonged normothermic ischaemia of human cirrhotic liver during hepatectomy: a preliminary report

To evaluate the tolerance of the cirrhotic liver to extended warm ischaemia, 47 patients with cirrhosis who underwent liver resection over a 4-year period were studied retrospectively. Three groups of patients were identified. In group 1 (14 patients) liver resection was performed under conditions of portal triad occlusion ranging from 50 to 75 (mean 57·1) min. Group 2 (12 patients) was treated with portal occlusion for a period ranging from 30 to 42 (mean 33·1) min. Group 3 comprised 21 patients who underwent hepatectomy using conventional techniques. Mean blood loss was significantly reduced by portal triad occlusion (819 ml in group 1, 523 ml in group 2) compared with the conventional technique (1652 ml in group 3) ($P < 0.05$, group 1 versus *group 3;* $P < 0.01$, *group 2* versus *group 3). Hospital death occurred in three of the 21 patients in group 3 but in no patient who underwent portal triad occlusion. The morbidity rate was lower in the two occlusion groups (four of 26 patients) than in group 3 (six of 21). Bilirubin metabolism was substantially better after surgery in the occlusion groups* ($P < 0.05$, *groups 1 and 2* versus *group 3 at day 14). Although the serum levels of transaminases were significantly raised until day 3 in patients undergoing long-term occlusion, the cirrhotic liver withstood the ischaemia–reperfusion insult, as assessed by changes in hepatic microcirculation, lipid peroxidation and the morphology of hepatic sinusoids. It is concluded that prolonged ischaemia during liver resection can be sustained in patients with cirrhosis and without high-risk factors.*

The liver can withstand inflow occlusion[1–3] for up to 1 h. It remains to be clarified whether this applies when the hepatic parenchyma is abnormal. Other workers have found that the cirrhotic liver tolerates warm ischaemia for longer than the 'accepted' limit[4,5] of 15–20 min. Reduction of blood loss has resulted in fewer complications after hepatic resection[2,6,7] and the present authors introduced this practice from August 1987. Massive bleeding during hepatectomy often results in serious consequences, particularly in patients with cirrhosis who have metabolic and coagulation disorders, and a hyperdynamic circulation[8,9].

The clinical course of 26 patients with liver cirrhosis in whom normothermic ischaemia of >30 min duration had been induced was evaluated retrospectively. These patients were compared with those with cirrhosis who had undergone partial liver resection using conventional techniques.

Patients and methods

Between August 1987 and July 1990, 26 patients with cirrhosis underwent liver resection (segmental or subsegmental) with prolonged occlusion of the portal triad. To effect the occlusion, a tape was placed around the portal triad. Parenchymal transection was facilitated with an ultrasonic dissector (CUSA; Cavitron, Stanford, Connecticut, USA). A local haemostatic agent (microfibrillar collagen Hemo-stat; Alcon, Humacao, Puerto Rico) was applied to the raw surface of the transected liver to control oozing. Anaesthesia was maintained by use of enflurane supplemented with nitrous oxide. A cephalosporin (1·0 g cefotiam or cephazolin) was administered intravenously to all patients during resection. The mean(s.d.) central venous pressure during occlusion was 8·0(2·5) cmH_2O.

The 26 patients were divided into two groups according to the period of occlusion. Patients in group 1 ($n = 14$) underwent long-term inflow occlusion ranging from 50 to 75 min. In group 2 ($n = 12$) portal triad occlusion of medium-term duration (30–42 min) was performed during hepatectomy. Group 3 consisted of 21 patients with cirrhosis in whom liver resection was carried out by conventional methods using manual parenchymal compression, liver clamping, temporary inflow occlusion for < 10 min or a combination of these. All but three patients in group 3 underwent surgery between September 1986 and May 1988.

Liver cirrhosis and carcinoma were diagnosed histologically in all 47 patients. There were 41 men and six women with a mean age of 60·2 (range 37–80) years. The estimated blood loss, coagulation profile, serum biochemistry, postoperative complications and mortality were compared. To evaluate ischaemia–reperfusion injury to the liver, tissue blood flow, lipid peroxidation and histology were studied during operation in the last 11 patients subjected to long-term ischaemia. Flow was measured using a laser Doppler flowmeter (BPM403; TSI, St Paul, Minnesota, USA)[10]. The Doppler probe was placed randomly on the liver until a stable flow value was obtained. The mean of at least three determinations was taken as the representative value. The degree of lipid peroxidation was estimated by measuring the stable end-product of the reaction, liver tissue malondialdehyde (MDA), by a colorimetric reaction with thiobarbituric acid as described by Ohkawa *et al.*[11].

All values are expressed as mean(s.d.), although standard error of the mean is shown in figures to reduce overlap. Statistical analysis was performed using analysis of variance by Scheffé's method and Student's t test or the χ^2 test (High-quality Analysis Libraries for Business and Academic Users; G. Sugakusha, Tokyo, Japan). $P < 0.05$ was considered significant.

Results

Patient profiles

Clinical details of the patients are shown in *Table 1*. There were no significant differences between the groups with respect to clinical data. No more than 50 min occlusion was allowed for patients with Child's grade C disease. The majority of patients underwent subsegmentectomy. Four patients in group 3

underwent segmentectomy (right posterior segment, one patient; left lateral segment, three). There were five patients in groups 1 and 2 in whom hepatic segments or similar amounts of tissue had to be resected (right posterior segment, one patient; left lateral segment, three; resection of Couinaud segments V and VII, one). In two patients a second hepatectomy with portal triad occlusion was performed.

Blood loss and plasma replacement

The mean(s.d.) estimated blood loss during surgery was significantly lower ($P < 0{\cdot}05$ and $P < 0{\cdot}01$) in the occlusion groups (group 1, 819(572) ml; group 2, 523(457) ml) than in group 3 (1652(1240) ml). The mean(s.d.) plasma requirement up to day 7 after operation was 3351(1079) ml in group 1, 2433(1308) ml in group 2 and 4208(1792) ml in group 3. There were no intraoperative adverse effects of portal triad occlusion on systemic haemodynamics.

Postoperative morbidity and mortality

As shown in *Table 2* there were three hospital deaths in group 3, all a result of liver failure. Postoperative mortality was nil in the 26 patients treated by portal triad occlusion. Six patients in group 3 had one or more postoperative complications, including fatal ones. The three who died had a combination of liver failure, coagulopathy, adult respiratory distress syndrome and pleural effusion. In the other three patients subphrenic abscess occurred in two and massive pleural effusion in one. There was no morbidity in patients in group 2. In group 1 four patients had complications: pleural effusion, two; abscess, two; and coagulation disorder, one. The overall morbidity rate of patients treated with portal triad occlusion was 15 per cent.

Liver function tests and coagulation profiles

Serum transaminase levels reached a peak on day 1 after surgery in all groups (*Figure 1*). There were no significant differences between groups 2 and 3. However, in group 1 long-term occlusion induced a significant rise in transaminase activity compared with levels in groups 2 and 3. There were no significant differences in total bilirubin level between the groups up to day 7 after operation (*Figure 2*). Bilirubin levels in the

control patients remained high thereafter, while values in the occlusion groups decreased. There was a significant difference between the three groups on day 14. Prothrombin time in group 1 remained higher than that in group 3 (*Figure 2*).

Liver tissue blood flow and determination of malondialdehyde concentration

Figure 3a shows liver tissue blood flow in group 3. The mean(s.d.) preclamping value of 32·0(10·6) ml per 100 g tissue per min fell during occlusion to 6·3(4·1) ml per 100 g per min. This finding confirmed the efficacy of the method used to occlude hepatic inflow. The flow recovered to preoperative levels 60 min after hepatic recirculation. There were no differences in MDA levels before, during or 60 min after warm ischaemia (*Figure 3b*).

Histology

As shown in *Figure 4* there was no evidence of ischaemia–reperfusion injury to the liver after 55 min of portal triad occlusion. Even after 75 min of hepatic inflow occlusion, the hepatic sinusoidal structure was well preserved in patients with early cirrhosis; however, eosinophilic changes in the hepatocytes were evident (*Figure 5*).

Discussion

Huguet *et al.*[1] reported that the human liver can tolerate warm ischaemia for > 60 min. This has been confirmed by other researchers[2,3]. Pigs and dogs can also tolerate hepatic inflow occlusion for longer than expected, if venous stagnation of the abdominal viscera is avoided by portosystemic shunting[12–14]. In the early 1900s, it was thought[15] that cirrhotic human livers could not withstand porta hepatis occlusion > 15 min, but this has recently been shown not to be the case. Nagasue *et al.*[4,5] found that the cirrhotic liver can tolerate up to 47 min of warm ischaemia, and Elias and colleagues[16] reported satisfactory tolerance of abnormal hepatic parenchyma to intermittent prolonged ischaemia lasting > 90 min. Yamaoka *et al.*[17] recently reported that cirrhotic human liver can tolerate 60 min of total vascular exclusion.

In the present study cirrhotic human liver withstood continuous occlusion for up to 75 min. There was no mortality and the overall morbidity rate was 15 per cent. Long-term portal occlusion (> 50 min) caused some parenchymal hepatocyte injury, with a substantial rise in serum transaminase activity, while medium-term ischaemia decreased serum enzyme levels compared with conventional procedures. Despite significant hepatocyte injury, the cirrhotic liver tolerated the ischaemia. There is evidence that in ischaemia–reperfusion injury liver integrity is affected mainly by the condition of non-parenchymal sinusoidal lining cells[18–20].

To evaluate damage to the cirrhotic liver, the production of tissue MDA, a biochemical marker of oxidative stress, was determined[11]. The MDA levels of liver subjected to long-term inflow clamping remained steady during ischaemia and for 60 min after reperfusion. This indicates that the lipid peroxidation reaction, mediated by oxygen radicals in the cirrhotic liver, was not clinically significant, although the technique employed may not be sufficiently accurate to detect minor changes unless high-performance liquid chromatography is used to measure thiobarbituric acid.

Histologically, satisfactory preservation of the hepatic endothelium during ischaemia–reperfusion was found, despite degenerative changes in hepatocytes. To evaluate further the integrity of the sinusoidal lining system, liver tissue blood flow was measured. Coincident with morphological and biochemical data, the hepatic microcirculation was well maintained following ischaemia. Thus, the cirrhotic liver can withstand continuous inflow occlusion if the sinusoidal lining system is intact. With regard to parenchymal hepatocyte injury, about 50 min is the limit beyond which hepatocytes are substantially damaged.

The present data show that flow in the liver tissue after portal triad occlusion was maintained at approximately 20 per cent of the level before ischaemia although the liver became pale immediately after tape occlusion. These observations can be explained by retrograde flow of blood from the vena cava into the hepatic veins. Active bleeding from the hepatic veins was sometimes encountered during parenchymal dissection under the control of hepatic inflow, as was found by Nagasue *et al.*[5]. We speculate that this back flow contributes to the maintenance of liver function.

Portal triad occlusion enables sufficient time to be gained to complete the resection, and to identify and ligate vascular and biliary structures in a bloodless field. Indeed, continuous occlusion in the present patients resulted in substantial reduction of intraoperative bleeding and less plasma had to be administered after surgery. The reduced blood loss was associated with fewer perioperative complications, in agreement with results from other studies[2,6,7]. The procedure is simpler than other techniques, such as selective control of hepatic inflow[21].

Because the cirrhotic liver is more vulnerable to ischaemia than the healthy organ, the possible risks of occlusion, particularly hepatic insufficiency, should be borne in mind. Although the advisability of the routine use of this procedure may be debatable, the present data show that some cirrhotic livers tolerate continuous warm ischaemia of about 50 min, a time sufficient to complete resection safely. The authors' working policy is that, under conditions of portal triad occlusion, local resection of a lesion located in the superior portion or deep within the central part of the liver is feasible if the cirrhotic changes are moderate, for instance in patients with Child's grade A or, perhaps, grade B disease. A patient with liver cirrhosis but with no high-risk factors can tolerate prolonged ischaemia during hepatectomy.

Dr M. A. Cuesta

Despite the advances made since the introduction of ultrasonography, computed tomography and magnetic resonance imaging, a wide discrepancy may occur between preoperative and peroperative staging of gastrointestinal malignancy with liver and peritoneal metastases. Diagnostic laparoscopy performed immediately before a planned laparotomy can provide valuable information for the accurate assessment and appropriate management of some forms of gastrointestinal malignancy, especially that of the liver and pancreas. For evaluation of small liver and retroperitoneal malignancies, intraoperative ultrasonography performed by laparotomy is of proven value. It is now technically possible to perform ultrasonography through a laparoscopic cannula using high-resolution ultrasonographic transducers. This combination of laparoscopy and ultrasonography was studied in 25 patients with established liver lesions, carcinoma of the gallbladder or pancreatic cancer. Additional information leading to a change in surgical approach was obtained in 20 patients. Laparoscopic ultrasonography, although still in a preliminary phase of development, is a simple and reliable technique that will contribute to more accurate staging of intra-abdominal malignancy.

Imaging of abdominal organs, especially the liver and pancreas, has greatly improved with the introduction of ultrasonography, computed tomography (CT) and magnetic resonance imaging (MRI)[1,2]. Although these techniques afford considerable advantages, the surgeon dealing with gastrointestinal malignancy is often faced with a discrepancy between preoperative and peroperative staging, due mainly to the presence of liver and peritoneal metastases. In cancer of the oesophagus, gastric cardia, liver and pancreas, more accurate staging before operation is desirable because surgery may not be the best palliative treatment when metastases are present[3–5]. Laparoscopy performed immediately before a planned laparotomy will enable visualization of these metastases and prevent unnecessary operation.

Laparoscopy is limited in the assessment of less obvious hepatic and retroperitoneal malignancies, but ultrasonography performed during laparotomy has proven its value for these lesions. For hepatic tumours and liver metastases from colorectal cancer, this technique gives significant additional information, leading to a change in surgical approach in 30 per cent of patients[6,7]. The exact diagnosis of hepatic lesions, and knowledge of their number and precise localization, are essential when considering liver resection or adjuvant therapy.

It is now possible to perform laparoscopic ultrasonography of the liver and pancreas by introduction of an ultrasonographic transducer through a cannula[8]. This technique, combining inspection and ultrasonography, has been used in the preoperative assessment of 25 patients with established liver lesions, carcinoma of the gallbladder or pancreatic cancer. Preoperative assessment was by ultrasonography, CT and MRI. Special attention was paid to the additional information provided by laparoscopic ultrasonography, particularly when it led to a change in surgical approach.

Patients and methods

Between October 1990 and February 1992, 25 patients underwent laparoscopic ultrasonography immediately before a planned surgical intervention for hepatobiliary–pancreatic lesions. Ultrasonography, CT and MRI were used before operation. Hepatic lesions were found in 19 patients during the investigation of abdominal pain (two patients), breast cancer (three), colorectal cancer (two), primary liver cancer (three) and oesophageal cancer (one), and follow-up of colorectal cancer (six), ovarian cancer (one) and carcinoid syndrome (one). Five patients had potentially curable pancreatic cancer and another carcinoma of the gallbladder. In all 25 patients, a surgical procedure was indicated, but no certainty of resectability was offered by the preoperative investigation.

Selection criteria for laparoscopic ultrasonography

The selection criteria for laparoscopic ultrasonography were: (1) the presence of hepatic lesions with no certainty regarding diagnosis (i.e. lesions found during investigation for abdominal pain); (2) hepatic lesions found during staging of tumours other than gastrointestinal cancer (e.g. breast cancer) and where the correct diagnosis is decisive for further treatment; (3) the need to ascertain resectability of hepatic metastases (from colorectal cancer) when doubt existed before operation regarding the number of tumours; (4) evaluation of metastases in primary liver cancer and determination of its resectability in relationship to hepatic vascular structures; and (5) preoperative assessment of the operability of gallbladder and pancreatic cancer.

Criteria for resectability on laparoscopic ultrasonography

The criterion for resectability of patients with liver metastases from colorectal cancer was the presence of fewer than four metastases in the whole liver parenchyma.

For primary liver carcinoma, the only criterion was the possibility of performing radical resection, up to extended right or left hemihepatectomy. Extension of the cancer outside the liver indicated unsuitability for resection.

For gallbladder carcinoma, spread of the tumour outside the gallbladder and its hepatic bed, such as metastases in the liver, obstruction of the confluence of the bile duct and peritoneal metastases, implied irresectability.

For pancreatic cancer, the criteria for irresectability were: (1) the presence of liver or peritoneal metastases; (2) visualization of the tumour in the hepatoduodenal ligament or outside the duodenum (indicating that radical resection was not possible); (3) the presence of portal hypertension; and (4) encasement or thrombosis of the portal vein (seen on ultrasonography).

Technique

Laparoscopic ultrasonography was performed under general anaesthesia. After the induction of pneumoperitoneum, the laparoscope was introduced in the lower aspect of the umbilicus or through the lateral aspect of the rectus muscle. A 5-mm cannula was introduced in the anterior axillary line under the costal margin to retract the liver. After inspection of the peritoneal cavity, the liver was examined for lesions on the superior and inferior surfaces of both lobes. A 20-mm sheath was introduced below the right costal margin in the mid-clavicular line (*Figure 1*), under direct vision to prevent injury. This wide cannula permitted introduction of a 16-mm linear-array cylindrical 5-MHz transducer (Aloka, Tokyo, Japan) (*Figure 2*). The transducer was placed under direct vision on the right superior surface of the liver, which was then examined in the same way as during laparotomy. In patients with pancreatic cancer, the probe was placed on the hepatoduodenal ligament and pancreatic area to localize the tumour and its relation to the portal vein and superior mesenteric artery.

Confirmation of the diagnosis by laparoscopic ultrasonography

First, lesions were identified by inspection and ultrasonography and, in all cases where inoperability was determined by laparoscopic ultrasonography, biopsies were taken to confirm the diagnosis, either with a biopsy forceps or a biopsy needle guided ultrasonographically.

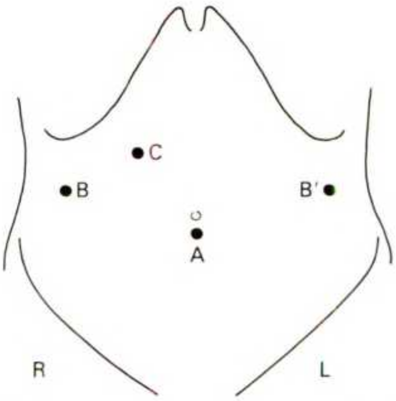

Figure 1 *Positions for cannula placement during laparoscopic ultrasonography. A, 10 mm (for laparoscope); B, 5 mm (for retraction and palpation); B', alternative site to B; C, 20 mm (for ultrasonographic transducer)*

Results

A total of 25 patients (eight men, 17 women) met the criteria for preoperative assessment by laparoscopic ultrasonography. Patient age ranged from 26 to 72 (mean 56) years. Diagnoses made by laparoscopic ultrasonography were compared with those made before operation (*Tables 1* and *2*).

In the evaluation of hepatic lesions found during investigation for abdominal pain, haemangiomas were found by laparoscopic ultrasonography in one patient and carcinoid metastases in the other.

Of the three patients with breast carcinoma, one had haemangiomas, another had several metastases, while the third had a paraganglioma of adrenal origin adjacent to the liver. In the two patients without metastases, laparoscopy was followed by mastectomy.

Carcinoid syndrome	1	–	Multiple metastases	1

*Values in parentheses are numbers of patients

Hepatic metastases were found during the staging of disease in two patients with colorectal carcinoma, one with a small sigmoid cancer and the other with a rectal tumour. The initial treatment considered for the first patient was resection (fewer than four metastases) and for the second local chemotherapy. During laparoscopic ultrasonography, multiple metastases were found in both patients, with extrahepatic disease in the second. This finding resulted in a change in strategy (no resectional therapy in the first patient and only local palliative treatment of rectal cancer in the second).

In the evaluation of three patients with primary liver cancer, ultrasonography made it possible to determine that the tumour did not involve the left hepatic vein in one. Extended right hepatectomy was subsequently performed. In the other two patients, the tumours were not resectable because of intrahepatic metastases in one and diaphragmatic metastases in the other.

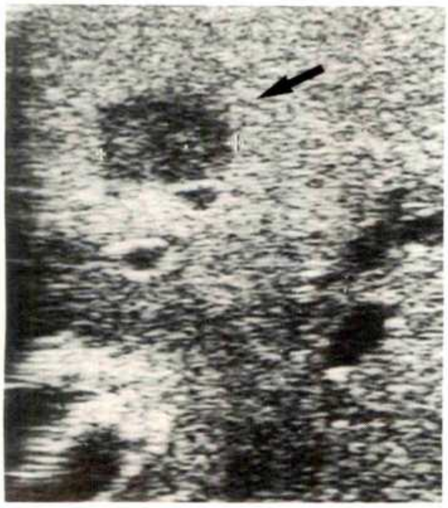

Figure 3 *A 1·5-cm metastasis (arrow) in segment IV, localized using ultrasonography*

Of the six patients in whom liver lesions were found during follow-up for colorectal cancer, multiple haemangiomas were detected in one, multiple cysts in another and multiple liver metastases in the remaining four (peritoneal metastases in two). Because of the large number of metastases, resection was not considered.

In 17 of the 25 patients, biopsy of the lesions (17 liver and two peritoneal biopsies) was performed (*Tables 1* and *2*). Frozen-section studies confirmed the diagnosis in each case.

In the other patients, diagnosis was based on the appearance of the lesion by visualization and ultrasonography (cysts and haemangiomas). The imaging quality of the liver and lesions was very high and the 5-MHz transducer provided a quality equivalent to that obtained by open operative ultrasonography (*Figure 3*).

Of the 19 patients with hepatic lesions, additional information leading to a change in surgical approach was obtained in 16 (*Table 3*). Based on this information laparotomy was avoided in 11 patients and the necessity for resectional therapy confirmed in another four. Of the 16 patients, this additional information was provided in nine by the combination of findings obtained by laparoscopy and ultrasonography, in a further two by laparoscopic visualization of the metastases, and in the remaining five by the information given only by ultrasonography of less obvious lesions.

Three of the five patients with pancreatic cancer had small liver metastases, all of which were visualized by laparoscopy. Ultrasonography of the pancreatic and hepatoduodenal areas was difficult. Although it was possible to ascertain the

size of the tumour, no reliable information could be obtained concerning the relation of the tumour to the portal vein and the presence of lymph nodes.

There were no complications related to the procedure and the 12 patients who did not undergo surgical treatment following laparoscopic ultrasonography were discharged the following day. In the eight patients in whom diagnosis was based on the appearance of the lesion, clinical outcome and radiological follow-up have confirmed, so far, the diagnosis made by laparoscopic ultrasonography.

Discussion

Imaging of abdominal organs, especially the liver and retroperitoneum, has improved greatly with the introduction of ultrasonography, CT and MRI. However, these techniques have a sensitivity less than 80 per cent, which is inadequate when very precise information is required for resectional therapy[2,7]. This information may include exact localization and number of liver metastases from colorectal carcinoma or involvement of the portal vein in pancreatic cancer. Furthermore, these techniques are not adequate for the assessment of peritoneal or small liver metastases or lymph nodes, and the surgeon is often faced with a wide discrepancy in diagnoses obtained before and during operation.

The importance of laparoscopic assessment of proximal gastrointestinal malignancies such as those of the oesophagus and gastric cardia, liver and pancreas before a planned laparotomy has been stressed by several authors, who point out[5] that, if these tumours have metastasized, surgery is neither the only nor always the best form of palliative treatment. In the assessment of cancer of the oesophagus and cardia, laparoscopy was found to be more sensitive and accurate than either preoperative ultrasonography or CT with regard to hepatic status (88 *versus* 48 and 56 per cent respectively)[3]. Neither ultrasonography nor CT detected any peritoneal metastases, while laparoscopy detected them in eight of nine cases. The authors concluded that laparoscopy may obviate the need for surgery in some patients with malignant dysphagia. Cuschieri[9] and Warshaw *et al.*[4] have repeatedly shown the value of laparoscopy for staging disease in patients with pancreatic cancer, by obtaining information about small liver and peritoneal metastases. Warshaw *et al.* found this type of metastasis in 22 of 88 patients, metastases that were not found by CT or MRI.

The limitation of laparoscopy lies in the evaluation of less obvious hepatic and retroperitoneal malignancy. Intraoperative ultrasonography was developed to overcome this problem. Rifkin *et al.*[6] found additional information leading to a change in surgical approach in no fewer than 31 per cent of patients with liver tumours. The present authors have obtained similar results[7] using this technique in screening for liver metastases from colorectal cancer. Determining the exact diagnosis of hepatic lesions, their number and precise localization is imperative when considering liver resection or adjuvant therapy. The demonstration of resectability of pancreatic and extrahepatic biliary cancer by intraoperative ultrasonography remains difficult, especially by reason of the encasement and occlusion of the coeliac artery and superior mesenteric and portal veins[10].

A combination of laparoscopy and ultrasonography, using a high-resolution ultrasonographic transducer, is now possible. The use of laparoscopy for inspection of the liver, abdominal cavity and lesser sac, and ultrasonography for the liver and retroperitoneum, can therefore offer significant advantages for the preoperative assessment of these gastrointestinal malignancies. Furthermore, this combination will permit cytological examination and guided biopsies of lesions, and it is even possible to 'palpate' the liver with the laparoscopic instruments.

Yamakawa and Wagai[11] introduced laparoscopic ultrasonography in the evaluation of gallbladder cancer in 1963. Since then, other authors have described similar examinations for the diagnosis of hepatic and pancreatic lesions using linear-array[8,12–14] and sector[15] scanners.

Using a laparoscopic linear-array scanner in the present study, additional information was obtained leading to a change in surgical approach in 16 of 19 patients with liver lesions. In nine of these the information was provided by a combination of data obtained by laparoscopy and ultrasonography, while in a further five with less visible tumours the information was obtained primarily by ultrasonography. Recently, Miles *et al.*[14], using a similar technique with a 5-MHz linear transducer, also found unexpected intrahepatic disease in six of seven patients with hepatic malignancy.

No advantages were derived from the use of the laparoscopic ultrasonography in patients with pancreatic cancer, the additional information for selection of patients for resection being obtained solely by laparoscopic findings. Identification of local resectability in this area will improve with the introduction of 10-mm flexible sector probes with frequencies of 5 and 7·5 MHz and with better understanding and resolution of the ultrasonographic anatomy in this particular area.

Future applications of laparoscopic ultrasonography will include the detection of common bile duct stones during laparoscopic cholecystectomy, liver assessment during laparoscopic resection of colonic cancer, and the precise delineation of renal tumours before laparoscopic resection[16].

Laparoscopic ultrasonography is currently in a preliminary phase of development. It is a simple and reliable technique that will contribute to more accurate preoperative staging of liver and retroperitoneal malignancy.

Dr Molewaterplein 40, 3015-GD Rotterdam, The Netherlands

A retrospective study of 310 patients with carcinoma of the head of the pancreas or periampullary region was performed. Preoperative bile drainage by placement of a stent reduced the number of postoperative complications, especially bleeding ($P = 0{\cdot}03$)*. The operative mortality rate was nil in patients with periampullary cancer aged under 70 years and 23 per cent in those over 70 years of age* ($P < 0{\cdot}001$)*. In the last 2 years of the study, the mortality rate following resection decreased to 2 per cent. Tumour-containing resection margins did not influence survival after resection* ($P = 0{\cdot}48$)*. Tumour dimension of pancreatic and periampullary cancer and the presence of tumour in locoregional lymph nodes* (N_{1a}) *resected with the primary tumour in cancer of the head of the pancreas were of no prognostic value. Following palliative resection of carcinoma of the pancreatic head, median survival was significantly better than when no resection was performed (10·1* versus *3·9 months,* $P < 0{\cdot}001$)*. In conclusion, even palliative resection may benefit some patients. Preoperative bile drainage is indicated in those with jaundice. Resection should be performed, irrespective of tumour size, provided that the unit's operative mortality rate is sufficiently low.*

In patients with cancer of the head of the pancreas, pancreatoduodenectomy (Whipple's procedure) is the treatment of choice in most centres. However, the tumour proves to be irresectable in many cases and 90 per cent of all patients admitted to hospital with pancreatic cancer die within 1 year. The only chance of prolonged survival lies in radical tumour resection. After surgical treatment with curative intent, a 5-year survival rate of only 0–15 per cent has been found and about 80 per cent of patients die within 2 years of resection. Efforts[1–4] to improve survival by extending the resection to total pancreatectomy or regional extended pancreatectomy as described by Fortner[5] have not met with great success.

The question therefore arises as to whether surgical resection is the best treatment for pancreatic cancer. The operative mortality and morbidity rates are high, and operative risks should be weighed against any expected gain in survival. The operative mortality rate over the years 1981–1986 reported in a recent review of 2398 pancreatic resections from different centres was 16 per cent. Nevertheless, improvement has been made in recent years and even a 0 per cent mortality rate has been reported[6,7].

Operation for cancer of the pancreas can be potentially radical if the malignant process is still confined to the resected area. Before operation an attempt should be made to select patients who have a limited tumour mass without distant metastases or lymph node involvement outside the resection area. At present, no techniques are available to identify such patients accurately. In a previous study[8,9], one general risk factor for operative mortality was identified: patients aged over 70 years had an operative mortality rate of 27 per cent compared with 3 per cent in those less than 70 years of age.

In this study, the results of treatment in 310 patients admitted in the period 1977–1988 were analysed retrospectively to determine the influence of preoperative symptoms, preoperative biliary drainage, tumour size, tumour-containing resection margins and lymph node involvement on the outcome of surgical resection in cancer of the head of the pancreas and periampullary region.

Patients and methods

Between 1977 and 1988, 310 patients were admitted to the Department of Surgery of the University Hospital Dijkzigt, Rotterdam, for cancer of the head of the pancreas or periampullary region. Standard preoperative investigation included ultrasonography, computed tomography (CT), endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC) and optional angiography of the coeliac and superior mesenteric arteries.

The mean age of the patients was 62·6 (range 26–89) years. There were 180 men and 130 women. Cancer of the head of the pancreas was diagnosed in 226 patients. No operation was performed in 59 of these patients (26 per cent) because of distant metastases or a bad World Health Organization performance rating. Clinical history, preoperative diagnostic procedures, intraoperative and pathological findings, and follow-up data were analysed using the log rank test, the Cox regression model and Kaplan–Meier life-tables.

The standard operation for resectable cancer was Whipple's procedure. A jejunal loop was used for reconstruction, with end-to-side or end-to-end pancreatojejunostomy with a one-layer inverting running suture. An end-to-side choledochojejunostomy was constructed on the same jejunal loop, also with a one-layer running suture. Stents were not used for the pancreatic duct and in only a few cases for the bile duct. In the case of positive frozen-section examination of the pancreatic resection margin, subtotal or total pancreatectomy was carried out. Pancreatic resection was performed by a limited number of surgeons. Operative mortality was defined as death within 30 days of operation or during the first admission to hospital. Tumour node metastasis (TNM) staging after operation was as defined in the Union Internacional Contra la Cancrum 1987 system, with a modification for the N stage, stage N_{1a} indicating positive lymph nodes within the resection specimen and N_{1b} positive nodes outside the specimen.

Results

Of a total of 242 operations for carcinoma of the head of the pancreas ($n = 167$) or periampullary region ($n = 75$), a radical resection with curative intent could be performed in 106 patients (34 per cent): 50 with cancer of the head of the pancreas (30 per cent resection rate) and 56 with periampullary cancer (75 per cent resection rate). In 19 patients (6 per cent) a

0007-1323/93/121575-04 © 1993 Butterworth-Heinemann Ltd

palliative, i.e. non-radical, resection was performed. Non-radicality was shown after operation by pathological examination: stage T_3 pancreatic cancer (seven patients) and T_4 periampullary cancer (three), N_{1b} (eight) and M_1 (one). Stage T_4 periampullary carcinoma resembles stage T_3 pancreatic cancer, with tumour extending directly to any of the stomach, spleen, colon or adjacent large vessels. In 34 patients with infiltration of tumour into vital organs or distant metastasis to lymph nodes or liver, the operation was limited to an exploratory laparotomy. To treat or prevent biliary or gastric outlet obstruction, a drainage procedure, i.e. choledochojejunostomy and/or gastrojejunostomy, was performed in 83 patients.

Preoperative stent drainage was established by means of PTC or ERCP in 88 patients (39 per cent) with cancer of the head of the pancreas. In 16 patients (7 per cent) stenting was undertaken during operation as a palliative procedure when none had been placed before surgery and no resection was possible. In patients with cancer of the periampullary region, a stent was placed before operation in 28 (33 per cent) and during operation in six (7 per cent). In total, 138 patients (45 per cent) received an endoprosthesis. In 38 patients no treatment other than stenting was possible.

In 40 per cent of all patients (125 of 310) malignancy was cytologically or histologically confirmed before operation.

Patient details

Cancer of the head of the pancreas. Presenting symptoms in 226 patients with carcinoma of the pancreatic head are listed in *Table 1*. Pain, weight loss, jaundice and increased levels of alkaline phosphatase and γ-glutamyl transferase were the main signs. Of patients with pain, distant metastases were found in 97 (62 per cent) during preoperative investigation and, as a consequence, no operation or surgical drainage procedure was performed. Coagulation disorders were all the result of vitamin K deficiency. In 54 patients (24 per cent), tumour size was estimated before surgery by ultrasonography, CT and ERCP; in 15 the tumour was less than 3 cm in diameter.

The surgical procedures performed are shown in *Table 2*. Tumour in the resection margin was found in 20 patients with cancer of the head of the pancreas (11 after palliative Whipple's resection, nine after curative resection).

Cancer of the periampullary region. Eighty-four patients were admitted for carcinoma of the periampullary region, defined as a tumour in the ampulla of Vater (59 patients), distal common bile duct (CBD) (13) or duodenum (12). Weight loss, jaundice and raised levels of alkaline phosphatase and γ-glutamyl transferase were the main presenting features in this group (*Table 1*). Surgical procedures are listed in *Table 2*. Six patients with periampullary cancer had tumour growth in the resection margin (two after palliative, four after curative resection).

Postoperative complications

Cancer of the head of the pancreas. After resection, 14 re-explorations (22 per cent of patients) were needed, ten for intra-abdominal bleeding, one for leakage of the pancreatojejunostomy and three for various reasons. Two wound abscesses were drained on the ward and one intra-abdominal abscess treated conservatively, as were 12 other minor complications. Non-surgical complications (cardiac, respiratory and urinary tract) occurred in 45 patients (27 per cent).

Cancer of the periampullary region. In this group, 14 re-explorations (19 per cent of patients) were carried out, four for intra-abdominal bleeding, two for intra-abdominal abscess, three for leakage of the pancreatojejunostomy and five for other reasons. In one patient, leakage of the pancreatojejunostomy was treated conservatively, as were eight other minor complications. Non-surgical complications occurred in 23 patients (31 per cent).

Preoperative drainage. No preoperative drainage for jaundice was performed in 170 patients; 116 had an endoprosthesis inserted for preoperative biliary drainage. Postoperative laparotomy for bleeding occurred in two patients who underwent stenting before operation and in 14 with no stent ($\chi^2 = 4{\cdot}60$, 1 d.f., $P = 0{\cdot}03$), probably due to disturbance of coagulation as a result of impaired liver function.

Operative mortality

The hospital mortality rate after all surgical interventions was 11 per cent. Patients aged over 70 years had a higher operative risk (*Table 3*). However, this was significant only in overall mortality after all surgical interventions for patients with cancer of the pancreatic head; following resection the difference was not significant. During the last 2 years of study the operative mortality rate after curative resection has fallen to 2 per cent (one patient) in the last 40 procedures.

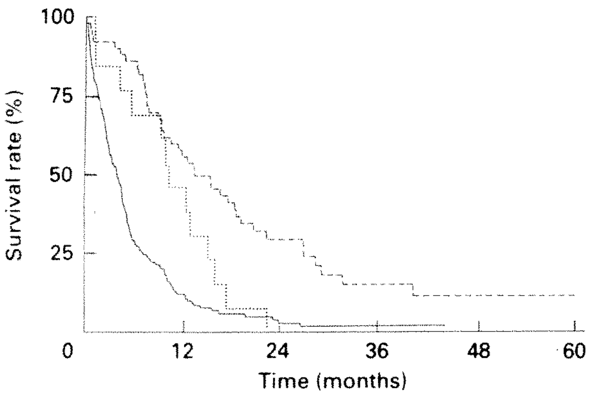
Pathology

Histological investigation of resection specimen margins revealed a high proportion containing tumour, 18 per cent in cancer of the head of the pancreas and 7 per cent in that of the periampullary region. A tumour-containing resection margin was found in five of ten pylorus-preserving pancreatic resections, but no duodenal resection margins containing tumour were found. Almost all tumours were moderately to poorly differentiated adenocarcinoma. In 56 of 78 patients with liver metastases and in 11 of 22 with peritoneal carcinomatosis, histological confirmation of the metastases was obtained.

Survival and prognostic factors

Cancer of the head of the pancreas. Overall survival in this group of patients was 23 per cent at 1 year and 3 per cent at 5 years, with a median survival of 5·1 months. There were significant differences in survival depending on treatment. When no resection was performed, the 1-year survival rate was significantly lower than that in patients undergoing palliative resection (11 *versus* 38 per cent respectively). The longest survival was achieved after intentional curative resection, with survival rates of 56, 28 and 11 per cent at 1, 2 and 5 years respectively (median 13·3 months) (*Figure 1*).

Involvement of local lymph nodes (N_{1a}) did not influence survival after resection with curative intent. In 36 patients with stage N_0 and 14 with stage N_{1a} cancer, a 1-year survival rate of 61 and 35 per cent and a 2-year survival rate of 28 and 20 per cent respectively were observed ($P = 0\cdot43$). Higher age ($P = 0\cdot01$) and pain ($P = 0\cdot003$) were of prognostic value for overall survival in pancreatic cancer, as well as a γ-glutamyl transferase level above 250 units/l ($P < 0\cdot02$) and a lactic dehydrogenase concentration greater than 320 units/l ($P < 0\cdot002$). Tumour dimension measured in the resection specimen directly after operation did not have significant prognostic value. In contrast, tumour size measured before operation showed an unexpected trend ($P = 0\cdot08$): patients with larger tumours had a trend towards improved survival. A positive resection margin was found in 11 patients after palliative and in nine after curative resection. Following resection with curative intent, survival was not influenced by microscopic tumour growth in the resection margin ($P = 0\cdot48$). After multivariate analysis of the prognostic factors significant on univariate analysis, age above 70 years, pain and a lactic dehydrogenase level over 320 units/l remained of significant value for prognosis as independent factors.



No. at risk						
Curative	50	28	14	7	6	6
Palliative	13	5	0	0	0	0
No resection	163	18	3	0	0	0

Figure 1 *Survival related to treatment in patients with cancer of the head of the pancreas.* ——, *No resection;* – – –, *curative resection;* ·····, *palliative resection.* $P < 0\cdot001$ (*log rank test*)

Cancer of the periampullary region. The overall survival rate at 1 year was 65 per cent, at 2 years 45 per cent and at 5 years 28 per cent. Significant improvements in survival were found in this group of patients after both palliative and curative resection compared with no resection ($P < 0\cdot001$). After resection with curative intent, survival rates of 78, 64 and 43 per cent were obtained at 1, 2 and 5 years respectively (median 54·8 months).

There was no difference in survival between 40 patients with stage N_0 and 16 with stage N_{1a} cancer, with a 1-year survival rate of 82 and 65 per cent, a 2-year rate of 70 and 50 per cent, and a 5-year rate of 43 and 42 per cent respectively ($P = 0\cdot43$). However, comparison of survival in these two groups of patients with Greenwood confidence intervals suggests that a significant difference would be found if more patients were included. Age ($P = 0\cdot01$) was a significant prognostic factor for overall survival. Pain ($P = 0\cdot83$) and raised γ-glutamyl transferase ($P = 0\cdot77$) and lactic dehydrogenase ($P = 0\cdot31$) levels had no influence on survival. Tumour-containing resection margins ($P = 0\cdot23$) and tumour size ($P = 0\cdot24$) had no prognostic value. Multivariate analysis showed that only age above 70 years was of prognostic value as an independent factor.

Discussion

Only a small proportion of patients with pancreatic cancer will survive more than 3 years after resection. Apparently the tumour process has metastasized beyond the resection area in most patients at the time of surgery, and this cannot be recognized adequately before or during operation. Better selection criteria are therefore needed to achieve successful curative surgery. In this retrospective study, an attempt has been made to identify variables that might predict outcome or help to select appropriate patients for surgery. The authors accept the limitations of the method, but prospective controlled studies are currently lacking.

The chosen definition of operative mortality is reliable as it includes all deaths related to operation, not only those occurring in the 30-day period. The operative mortality rate after resection was 8 per cent in patients with cancer of the head of the pancreas. The lack of any difference between those aged more or less than 70 years probably reflects careful selection for operation in the older patients. In periampullary cancer in patients aged under 70 years, there were no postoperative deaths, which is significantly different from the mortality rate of 23 per cent found in patients over 70 years of age ($P < 0\cdot001$)[8,9]. The operative mortality rate decreased progressively in the last 2 years of the study to 2 per cent in the most recent 40 resections. A similar low operative mortality rate has been reported by others[7].

Surgical drainage procedures for irresectable tumours carry a high operative mortality rate (about 10 per cent) and should therefore be performed only in the presence of gastric or duodenal obstruction when endoscopic stenting for jaundice is impossible. In this situation, when an operation has to be performed, the addition of gastroenterostomy is advised by some authors[10–13]. The present authors' opinion is that bilioenteric anastomosis should not be combined with gastroenterostomy if the patient has no duodenal obstruction[14].

Preoperative relief of jaundice by stenting the CBD by means of ERCP or PTC resulted in a significant reduction in the number of postoperative laparotomies for bleeding and fewer cases of abscess and anastomotic leakage. Jaundice should be treated as early as possible before operation[9,15]. Resection should be performed only in the non-jaundiced patient.

Non-radical resection was demonstrated in 19 patients by pathological examination, which showed tumour cells in regional lymph nodes outside the resection specimen or even distant metastases. Despite this non-radicality, the prognosis of these patients after palliative resection was significantly better than that in those who underwent surgical drainage or exploratory laparotomy. Resection margins that appeared to contain tumour in the definitive pathological specimen did not appear to influence survival in the present study. Attempts to avoid non-radical resection by extending the area of excision have not been very promising so far[5]. Recently, however, a study from Japan[16] showed significantly reduced local recurrence rates after extended clearance of regional (R_2) lymph nodes.

In the present series of 310 patients admitted for pancreatic or periampullary cancer, potentially curative resection could be performed in only 106 (34 per cent). After curative resection for cancer of the head of the pancreas, 56 per cent of patients survived for more than 1 year, and 2- and 5-year survival rates were 28 and 11 per cent. These survival data are similar to those encountered in other studies[17–26]. In a recent review[6] of 4100 pancreatic resections for cancer, a 5-year survival rate of 4 per cent was found.

In the present study, independent prognostic factors for overall survival were found for patients with cancer of the head of the pancreas. Age above 70 years, pain and a lactic dehydrogenase level greater than 320 units/l correlated with a decreased survival rate. In periampullary cancer, only age above 70 years remained as an independent prognostic factor. In both forms of cancer, tumour size had no prognostic value. Thus, a larger tumour does not necessarily imply a worse prognosis; in the present study, a larger preoperative tumour diameter showed a trend towards a better patient survival rate ($P = 0{\cdot}08$). Tumour infiltration of locoregional lymph nodes (N_{1a}) resected together with the primary tumour did not appear to be of prognostic value in patients with cancer of the head of the pancreas.

In conclusion, pancreatic resection should be performed if technically possible, irrespective of tumour size or infiltration of locoregional lymph nodes (in patients with cancer of the pancreatic head). Non-radical resection may benefit selected patients, especially during the first year after resection. Although the present study suggests that surgical resection for cancer of the head of the pancreas is largely a palliative procedure, curing only a small proportion of patients, it is a good operation in centres with low operative mortality rates. As postoperative morbidity and mortality are increased in jaundiced patients and in those aged over 70 years, preoperative drainage of bile by endoscopic stenting of the distal CBD should be carried out in patients with jaundice and great caution is advised in the elderly.

Pancreatic necrosis: assessment of outcome related to quality of life and cost of management

Ten patients with necrotizing pancreatitis admitted consecutively between August 1990 and August 1991 were studied. They comprised eight men and two women of median age 63 (range 29–73) years. One patient died. The median length of hospital stay was 74 (range 40–150) days. The median number of operations and endoscopic procedures performed per patient was 4 (range 2–7). Investigations performed included multiple bacteriological, radiological, haematological and biochemical tests. The mean cost of management was £18 441 (range £9296–£33 796), of which hospitalization accounted for 65 per cent, operations and endoscopic procedures 20 per cent and investigations 16 per cent. Cost–utility analysis demonstrated a mean benefit per patient of 8·55 quality-adjusted life years gained at a cost of £2157 each. The management of pancreatic necrosis is expensive but justified by the excellent outcome in terms of quality of life.

Mr D. Fenton-Lee

Acute necrotizing pancreatitis is associated with significant morbidity and mortality rates. The incidence of this type of acute pancreatitis varies from 4 to 18 per cent; the condition has a reported mortality rate of 9–40 per cent[1–9].

Management of acute necrotizing pancreatitis includes full conservative (supportive) therapy and repeated clinical evaluation requiring multiple haematological, biochemical, bacteriological and radiological investigations. Successful outcome usually involves major surgery and a prolonged hospital stay involving the intensive therapy unit and high-dependency care[1,3,5–9]. Improvements in management have led to a reduction in mortality rates, particularly in specialized units where technical resources and experienced personnel are available. Pancreatic necrosectomy and packing[7] or continuous peritoneal lavage[1] forms the mainstay of surgical treatment. The advent of bolus intravenous contrast-enhanced computed tomography (CT) has enabled better delineation of pancreatic necrosis and, together with percutaneous aspiration of potentially infected necrosis, has aided in determining the extent and timing of surgery[10,11].

Treatment becomes increasingly expensive as more sophisticated and invasive procedures are used and there is a need for critical assessment of outcome with respect to the resources required for successful management. Cost analysis will benefit patient care in supporting the case for adequate funding of units specializing in the management of this condition.

There is accumulating evidence that quality-of-life measurements may be a more sensitive means of assessing outcome than crude survival rates[12]. Several methods have been validated for assessing quality of life[13]. A standard unit termed a quality-adjusted life year (QALY) can be obtained when quality of life is related to life expectancy[14,15]. A QALY represents 1 year of healthy life expectancy gained after treatment. The aim of the present study was to determine the cost of treatment and relate this to outcome in terms of quality of life.

Patients and methods

Patients

The medical records of ten consecutive patients admitted between August 1990 and August 1991 who required operative intervention for pancreatic necrosis were reviewed. All patients were managed by a team of medical, nursing and paramedical staff. Multiple clinical and laboratory data were obtained from patient records. The severity of acute pancreatitis was assessed objectively using the Glasgow system[16] and the aetiology determined from clinical findings in all patients. Bolus intravenous contrast-enhanced CT was performed on all patients. Pancreatic necrosis was confirmed histologically in each patient and the type of infection determined before surgery by percutaneous aspiration or from cultures of the necrosectomy specimens. Patients were seen regularly in the follow-up clinic for up to 2 years after treatment.

Methods

Cost. The cost of management was based on budget estimates made by the Greater Glasgow Health Board for the period April 1991 to March 1992 (personal communication). The cost and services provided for each patient were summarized in three parts: hospitalization, operations, and procedures and investigations. Hospitalization costs included elements for nursing and medical staff, pharmacy, physiotherapy and other support services, catering, administration plus maintenance and service charges. The cost was

Table 1 *Individual costs of services*

Presented to the Pancreatic Society of Great Britain and Ireland in Glasgow, UK, November 1991 and published in abstract form as Gut *1992;* **33**: *A427*

0007-1323/93/121579-04 © 1993 Butterworth-Heinemann Ltd

calculated by multiplying the number of services provided by the cost of each service. The number of services provided was obtained from patient case notes, and operating theatre, radiology department and intensive care records. A cost for endoscopic procedures was not available from the Health Board, so an estimated cost for endoscopic retrograde cholangiopancreatography (ERCP) and upper gastrointestinal endoscopy is given (*Table 1*).

Quality of life. Quality of life was determined using the Rosser disability and distress index[15] at admission and follow-up. This was performed by the senior surgeon who graded patients according to *The QALY Toolkit*[17]. QALYs were derived from the difference in quality of life levels following treatment related to life expectancy. Assumptions made in the calculation of QALYs were that patients would have died without treatment and, having survived, would have a normal life expectancy of 75 years. A 5 per cent annuity factor was used to determine the current value of QALYs gained. The cost of treatment was then related to the number of QALYs gained to give a cost per QALY.

Results

Patients

The ten patients comprised eight men and two women of median age 63 (range 29–73) years (*Table 2*). The aetiology was gallstones in seven patients and alcohol in three. The Glasgow score[16] was 3 or above for all patients, predicting severe pancreatitis; the median score was 4 (range 3–5). The median hospital stay was 74 (range 40–150) days and that in the intensive therapy unit 7 (range 2–29) days. Bolus intravenous contrast-enhanced CT revealed pancreatic or peripancreatic necrosis in all ten patients. Six of the ten had infected pancreatic necrosis, five of whom had gallstone pancreatitis. Seven patients underwent peritoneal lavage after initial debridement; packing of the pancreatic bed was employed initially in three patients. One 66-year-old patient died from Gram-negative septicaemic shock, giving a mortality rate of 10 per cent. On follow-up at 1 year a further patient had died from a cerebrovascular accident.

Cost

The cost and services provided for each patient treated are summarized in *Table 3*. The mean cost of hospitalization was £11 898 (range £4680–£25 540), representing 65 per cent of the total cost. Operations and endoscopic procedures accounted for 20 per cent of the total cost of management. The median number of operations performed per patient was 2 (range 1–4). The operating time for pancreatic necrosectomy, cholecystectomy and feeding jejunostomy was approximately 3 h. The median operating time for pancreatic necrosectomy was 2 h, costing £1200. The mean cost of operations per patient was £3270 (range £1800–5700). The median number of endoscopic procedures performed per patient was 1 (range 0–4). The cost of endoscopic procedures per patient ranged from £0 to £900, with a mean of £400. Investigations performed represented 16 per cent of the total cost with a mean of £2864 per patient. The mean total cost per patient treated was £18 441 (range £9296–£33 796) (*Table 3*).

*Patient died. †The mean quality-adjusted life years (QALYs) gained per patient was 8·55 (applying 5 per cent discount factor)

Quality of life

A summary of the quality of life and the QALYs gained by each patient treated is given in *Table 4*. The mean gain per patient was 8·55 QALYs (applying 5 per cent discount) with a mean cost per patient treated of £18 441, giving a cost for each QALY gained of £2157.

Discussion

The ten patients in this limited series are similar to those in most other studies regarding aetiology of pancreatitis, male preponderance and incidence of infected necrosis[1,4,5,7–9,18]. However, the median age of 63 years in the present series is older than that reported by others (median age range 39–54 years)[1,7–9,18,19].

Costs were divided into three main components to facilitate analysis. Hospitalization is the ward cost for each patient and accounted for 65 per cent of the total expenditure. This included costs of staff, pharmaceuticals, physiotherapy and other support services. The lengthy hospital stay of 40–150 days reflects the severity of the disease and the debilitated state of patients. The incidence of complications is known to increase with more invasive procedures and increased hospital stay[20]. Expensive nutritional supplementation in the form of total parenteral nutrition and enteral feeding is required for patients with acute necrotizing pancreatitis as they are catabolic for long periods of the illness and often suffer from prolonged ileus. Despite the lengthy hospital stay the time spent in the intensive therapy unit was relatively short (median 7 days), similar to the finding of others[1]. Good-quality high-dependency care in the ward helps to shorten the stay in an intensive therapy unit.

Theatre time is expensive and patients may require several operations and endoscopic procedures. These accounted for 20 per cent of the total cost of management. Although operating costs were accurately known, the cost of endoscopy and ERCP were estimated. A 50 per cent error in this estimation would increase the total by 1 per cent.

Investigations accounted for 16 per cent of the total expenditure. This area presents a potential for cost savings by restricting the tests ordered to those that alter management (*Table 2*). Some would say that costing is outside the clinician's remit, a view with which we would tend to agree. However, the ability of the healthcare system to optimize the available resources is reliant on the cooperation of clinicians. Awareness of the cost of treatment has been shown to lead to better utilization of resources without compromise of patient care[21,22].

The 10 per cent mortality rate in this series is encouraging and compares favourably with the experience of other centres. The Rosser index is a measure of quality of life based on the degree of disability and distress that a patient experiences. Disability and distress when combined give an accurate level of disease severity that has been validated in previous studies[15,23]. The levels are given a numerical score from 0 to 1, 0 representing severe illness or death and 1 perfect health. The difference in values following therapy gives a measure of the benefit gained from treatment. This is then related to the patient's life expectancy to derive QALYs gained (*Table 4*). An actuarial discount factor of 5 per cent was applied to future QALYs gained as this was thought to reflect the changing value of the gain from the patient's viewpoint with time.

A cost–utility analysis was also performed; this is a special type of cost–effectiveness analysis expressed in terms of QALYs[14]. This method has several advantages over cost–effectiveness analysis. Outcome when expressed in terms of a standard unit can be used as a tool for comparing and improving the quality of care delivered by different regimens for the same or dissimilar conditions[24]. In broader terms it may aid in the selection of patients for surgery and may help in making policy decisions regarding management[25,26]. In an era of cost consciousness where the healthcare budget is limited this can serve as a useful guide to resource allocation to obtain maximum benefit[27].

The present patients have shown a mean benefit of 8·55 QALYs at a cost of £2157 each. This is similar to the benefit of coronary artery bypass grafting at around £1500 per QALY gained and is more favourable than that of kidney transplantation at £6072 per QALY gained (1988 prices)[28,29]. These figures indicate that the substantial costs involved in managing patients with pancreatic necrosis result in a worthwhile gain in quality of life.

Good long-term results in patients surviving severe acute pancreatitis

Thirty-seven patients treated for severe acute pancreatitis were investigated a mean of 6·2 years after the attack; 30 were found to be in good condition and 24 were working normally. Two-thirds of previously heavy drinkers had either reduced their intake considerably or become abstainers. The main complication observed on follow-up was diabetes mellitus, which affected 20 patients and required insulin treatment in nine. Of the remaining patients, four were taking oral antidiabetic agents and seven were on a strict diabetic diet. Before severe acute pancreatitis none had been diabetic. All patients who underwent resection of the pancreas developed diabetes. In 21 of 24 patients with overt or imminent diabetes, pancreatitis had been primarily alcoholic in origin. Polyneuropathy, as diagnosed by clinical signs and/or neurophysiological tests, was observed in six patients, all of them heavy drinkers. It is concluded that patients with severe acute pancreatitis have a high chance of returning to normal activity and productive work. These results serve to encourage all those involved to persist with the exacting work involved in treating such patients.

Dr M. Doepel

Severe acute pancreatitis always requires intensive care. In many cases such care proves insufficient and it may be necessary to resort to peritoneal lavage or pancreatic resection. Both have been maintained to be superior to conservative treatment alone[1–6], although conflicting views have also been expressed[7]. Nowadays, debridement of necrotic tissue is perhaps the commonest operative treatment[8]. The primary results of various therapies were reviewed in 1986 by Hollender *et al.*[9]. Very few recent reports have been published. Nordback and Auvinen[10] noted a 92 per cent incidence of diabetes in patients who had undergone pancreatic resection. An unexpected finding was a high incidence of peripheral neuropathy, which affected 42 per cent of patients. Gross *et al.*[11] reported four patients with partly reversible polyneuropathy associated with pancreatitis and pancreatic pseudocyst.

One aim of the present study was to determine the outcome for patients surviving severe acute pancreatitis, especially in relation to the incidence and type of complications. According to the authors' practice[3], peritoneal lavage was used as a primary treatment for acute pancreatitis and only those who did not recover (one-third of patients) underwent pancreatic resection; the influence of operative treatment on outcome was also evaluated.

Patients and methods

Between 1974 and 1988, 67 patients with severe acute pancreatitis were treated in the intensive care unit. Severe acute pancreatitis is defined by the presence of multiple organ failure in patients with haemorrhagic and/or necrotic pancreatitis. Diagnosis was based mainly on clinical findings: all patients had abdominal pain, serum amylasaemia and abdominal tenderness on palpation concomitant with a markedly poor general condition. Dynamic sequential computed tomography (CT) and ultrasonography were undertaken, but results were not decisive in relation to treatment. The main indications for laparotomy were peritonitis, renal failure despite aggressive fluid management, respiratory failure, shock, mental confusion and severe ascites. In most patients two such conditions were recorded, as reported previously[2]. The diagnosis was confirmed at laparotomy, carried out primarily or after unsuccessful conservative treatment. In all patients there were varying amounts of discoloured ascitic fluid. Yellow fatty saponification spots were abundant in the mesentery or around the pancreas in all patients. The pancreatic body and tail were exposed through the lesser sac. The gastrocolic ligament was opened to allow thorough inspection of the pancreas. The head of the gland was exposed from the right by means of an enlarged Kocher manoeuvre. If necessary, the pancreas was inspected from below by opening the mesocolon. The gland appeared haemorrhagic or necrotic in all subjects but no biopsies were taken.

Primary treatment included peritoneal lavage in all cases. In the first three patients, catheters were inserted by means of abdominal puncture. The other patients were subjected to laparotomy as described above and catheters placed around the pancreas. If the general condition deteriorated despite such conservative treatment the patient underwent a further laparotomy and pancreatic surgery. In six patients the body and tail were resected and in six subtotal (80 per cent) pancreatectomy performed. The line of resection was determined by the appearance and vascularization of the right part of the pancreas. One patient underwent surgery again 2 years after the attack of severe acute pancreatitis because of chronic pancreatitis; total pancreatectomy was performed.

Of the 67 patients, 23 (34 per cent) died in hospital. Of the 44 survivors, four died after discharge; the mean age at death was 52 (range 38–65) years. Three had suffered from alcohol-related severe acute pancreatitis and one from pancreatitis of unknown origin. All had been treated by lavage and none had undergone resection. One of the four had diabetes, which had been treated by oral medication before pancreatitis developed. Another developed diabetes 7 years after operation. One man succumbed to massive recurrent severe acute pancreatitis. The deaths of the others were not related to pancreatitis.

Three patients could not be contacted for follow-up. The final follow-up examination thus included 37 subjects. According to Ranson's criteria, 60 per cent of the patients who underwent resection compared with 53 per cent of those receiving lavage alone had suffered severe pancreatitis.

Patients were interviewed a mean of 6·2 (range 1–14) years after the attack of pancreatitis. General condition, abdominal or other symptoms, working capacity and alcohol consumption were determined. Patients were examined, with special emphasis on abdominal and neurological status. Those with overt neurological symptoms underwent thorough clinical neurological examination and neurophysiological studies, including electroneuromyography, electroencephalography and CT of the brain.

Laboratory tests included determination of haemoglobin concentration and leucocyte count, and measurement of serum amylase, serum alanine aminotransferase and serum glutamyltransferase levels. Concentrations of blood glucose, C peptide, and of glycohaemoglobin A_1 and A_{1c} were determined. An oral glucose tolerance test was conducted in most non-diabetic patients with fasting blood glucose level below 7 mmol/l. The patients were given a 75-g oral glucose load after a 12-h overnight fast.

The level of alcohol consumption was determined from interview findings and records from nearby hospitals. Patients were classified as

0007-1323/93/121583-04 © 1993 Butterworth-Heinemann Ltd

abstinent if they did not drink; drinking was moderate if the patient took alcohol occasionally and heavy if drinking was almost daily or if there were social or psychological problems arising from alcohol abuse.

Statistical analysis

Statistical analysis was performed using the χ^2 test with Yates' correction when needed and Fisher's exact test. $P < 0{\cdot}05$ was considered significant.

Results

A total of 37 patients comprising 25 men and 12 women of mean age 49 (range 26–90) years were re-examined. Severe acute pancreatitis had been induced by alcohol (heavy drinking) in 28 patients. The cause was biliary in three patients, endoscopic retrograde cholangiopancreatography in two and unknown in four.

Table 1 shows social status and working capacity before pancreatitis and on follow-up. All but one patient had been in normal general condition before falling ill. At follow-up, general condition was found to be normal in 30 of the 37 patients.

At the time of their illness, 31 patients had been working, four had retired because of age and two because of illness (in one case psychiatric problems, in the other cardiac disease). At follow-up, patients' working capacity remained good (*Table 1*). Only four had retired as a result of complications of pancreatitis. Two had continued to drink heavily and had evidence of liver damage and neurological symptoms. One of the four had retired because of postoperative herniation, diarrhoea and spinal problems, and one because of major hernias and poor general condition at age 60 years. One was unemployed, partly because of drink problems.

Of the 28 patients whose pancreatitis was alcohol related, 11 had become abstainers, seven drank only moderate amounts and ten still had a serious drink problem.

Table 1 *Clinical findings in 37 patients*

	Before pancreatitis	At follow-up*
General condition		
Normal	36 (97)	30 (81)
Poor	1 (3)	7 (19)
Working capacity		
Normal	31 (84)	24 (65)
Reduced	0 (0)	2 (5)
Retired		
Age	4 (11)	4 (11)
Illness	2 (5)	3 (8)
Pancreatitis	0 (0)	4 (11)

Values in parentheses are percentages. *Follow-up was a mean 6·2 years after severe acute pancreatitis

At follow-up, eight patients exhibited neurological symptoms; all had diabetes. Six complained of numbness in the legs, of whom four were subjected to electroneuromyography. All six had suffered from alcohol-induced pancreatitis. One man who had undergone pancreatic resection had continued to drink heavily. Polyneuropathy was reflected in an abnormal electroneuromyograph. CT of the brain revealed atrophic changes in the cerebellum; these are usually related to alcohol abuse. Two women treated with peritoneal lavage were still drinking heavily. Both exhibited polyneuropathy, one also had cerebellar atrophy and they had difficulties in walking. A further three complained of numbness in the legs but only one underwent electroneuromyography, which showed polyneuropathy.

One patient had been drinking heavily before the attack of acute pancreatitis and had unknowingly suffered neurological symptoms. CT revealed atrophic changes in the cerebellum. The patient is now an abstainer. One patient had developed hemiplegia during primary hospitalization. The extremities on the affected side were still spastic at follow-up. No explanation for the hemiplegia was found on examination by brain CT or electroencephalography. Three patients with polyneuropathy also had diarrhoea.

Before presentation with severe acute pancreatitis no patient had diabetes. On discharge from hospital 11 of the 37 suffered from diabetes; six were being treated with insulin, one with sulphonylurea and four were on a strict diabetic diet. At follow-up, 20 patients had diabetes; nine were being treated with insulin, four with sulphonylurea and seven were on a strict diet (*Table 2*). Of 17 patients who were not diabetic, four had impaired glucose tolerance as indicated by results of oral glucose tolerance tests.

All 13 patients who had undergone resection of the pancreas developed diabetes compared with only seven of the 24 treated conservatively ($P < 0{\cdot}005$). Of 28 patients whose pancreatitis was alcohol related, 18 had diabetes. Of patients in whom the pancreatitis was not alcohol related, only two had diabetes ($P < 0{\cdot}05$).

The commonest major complications were abscess, fistula and pseudocyst. These occurred in 22 patients. There was no correlation between the appearance of major complications and development of diabetes.

Fourteen patients experienced abdominal complaints, mostly minor dyspepsia or abdominal fullness after eating a fatty meal. Six had diarrhoea, two of whom were permanently disabled because the diarrhoea was resistant to therapy. All patients with diarrhoea also had diabetes ($P < 0{\cdot}05$); five of these exhibited no clear clinical signs of chronic pancreatitis in that severe, constant abdominal pain and weight loss were absent. One patient with clear symptoms of chronic pancreatitis

Table 2 *Diabetes and treatment after severe acute pancreatitis*

		Diabetes		
	No diabetes	Dietary treatment	Oral antidiabetic agents	Insulin treatment
Diabetic status				
Before pancreatitis	37 (100)	0 (0)	0 (0)	0 (0)
Immediately after pancreatitis	26 (70)	4 (11)	1 (3)	6 (16)
At follow-up	17 (46)	7 (19)	4 (11)	9 (24)
Diabetic status at follow-up in relation to treatment				
Lavage ($n = 24$)	17 (71)	4 (17)	1 (4)	2 (8)
Resection ($n = 13$)	0 (0)	3 (23)	3 (23)	7 (54)
Diabetic status at follow-up in relation to aetiology of pancreatitis				
Alcohol ($n = 28$)	10 (36)	7 (25)	4 (14)	7 (25)
Other ($n = 9$)	7 (78)	0 (0)	0 (0)	2 (22)

Values in parentheses are percentages

who underwent total pancreatectomy 18 months after the primary attack of pancreatitis had disease of unknown origin.

The only significant difference in the results of serum biochemical tests between patients who had undergone resection and those treated conservatively was related to diabetes.

Discussion

Severe acute pancreatitis has a high mortality rate of 13–64 per cent[9,10,12–15]. Treatment is extremely laborious, time consuming and costly, involving long periods in an intensive care unit and in the hospital ward and, often, prolonged convalescence. Its utility may be questioned. However, the long-term outcome in the present study was good. Of 37 patients followed up, 30 were in good general condition and 24 were working to full capacity, compared with 31 before the attack. Working capacity after severe acute pancreatitis has rarely been mentioned in previous reports although Nordback and Auvinen[10] found it to be less than in the present study. The difference could be related to types of occupation.

The small percentage of patients found to be heavy alcohol drinkers at follow-up was surprising. It was gratifying to find that two-thirds of subjects had reduced their alcohol consumption. Although no blood alcohol concentrations were measured in connection with re-examination, complications of heavy drinking were sought, partly by reference to county hospital files. Those continuing to drink heavily paid numerous visits to hospital, especially to outpatient clinics.

The main long-term complication of severe acute pancreatitis was diabetes. It usually occurred in patients who had undergone pancreatic resection after failure of peritoneal lavage, and not because of major complications. It is possible that the attack of acute pancreatitis was more severe from the outset in these patients, so that the pancreas had consequently been more damaged. However, no clear evidence was found to support this contention. There are no specific clinical or laboratory parameters that correlate with the extent of necrosis[16].

The present incidence of diabetes was higher than that found in previous studies[3,9,10,12], apparently because of the longer follow-up. A high incidence of diabetes (92 per cent) after pancreatic resection was also found in one other study in which the follow-up was lengthy[10]. Oral glucose tolerance testing showed that four further patients in the present study had impaired glucose tolerance; they were included in the non-diabetic group but will probably develop diabetes[17].

Diabetes after severe acute pancreatitis, especially following pancreatic resection, has been noted by others[3,4,9,10,12,18]. Since the present patients showed no overt signs of chronic pancreatitis[19,20] or markedly decreased liver function that could explain the results, a direct toxic effect of alcohol on pancreatic islets seems possible. During the past few years there has been a tendency to avoid pancreatic resection[21–23]. If surgery is unavoidable, necrosectomy has been advocated[16,24,25]. Pancreatic necrosis as such is not an absolute indication for surgical treatment but, if necrotic tissue is infected, the patient cannot be managed by conservative treatment and operation is usually necessary[26]. Good results have also been achieved with relaparotomy at intervals of 2–3 days (open drainage)[27].

The present study could not verify the high frequency and severity of polyneuropathy (42 per cent) noted by Nordback and Auvinen[10]. Of 37 patients only four cases of polyneuropathy were verified by electroneuromyography. Gross *et al.*[11] have suggested that polyneuropathy associated with pancreatitis is a consequence of insufficient parenteral nutrition, multiple drug therapy (including use of metronidazole) and sepsis as seen in other critically ill patients, or that it is a specific distinct disease. All patients with verified abnormal electroneuromyograms were heavy drinkers. It would seem that polyneuropathy was predominantly alcohol related, as indicated by cerebellar atrophy shown by brain CT, rather than a direct effect of diabetes. Furthermore, the time from the attack of pancreatitis to onset of neurological symptoms seems too short for the development of diabetic polyneuropathy. The heavy drinkers were in poor nutritional condition before the attack. This, together with a possible toxic effect of alcohol, could perhaps explain the polyneuropathy. Patients with normal glucose tolerance test results exhibited no signs of polyneuropathy.

This follow-up study has shown generally good outcome for patients who survive an attack of severe acute pancreatitis. General condition and working capacity were well maintained in the majority. Two-thirds of the patients stopped drinking heavily. The main problem arising after acute pancreatitis was diabetes, the incidence of which increased with time. Diabetes was commoner after operative treatment. It will be interesting to study late results after necrosectomy. We recommend conservative treatment whenever possible. This study supports our belief that patients with severe acute pancreatitis are definitely worth treating.

Acknowledgements

The authors thank the nurses and auxiliary personnel in the Fourth Department of Surgery, especially those in the intensive care unit, for their constant efforts in treating patients with severe acute pancreatitis.

Announcement

European Surgical Fellowships

The Council of *The British Journal of Surgery* is pleased to announce the availability of European Surgical Fellowships for 1994. Last year four Fellowships were awarded, to Dr Jose Luis Aguayo-Albasini (Spain), Mr R. M. Charnley (Nottingham), Mr S. D. Heys (Aberdeen) and Mr T. G. John (Edinburgh).

It is Council's intention to offer European Surgical Fellowships again in 1994. Each Fellowship will have a value of up to £3000 and is intended to allow surgeons working in the UK to visit centres in other European countries or surgeons working in other European countries to visit the UK. Applicants must be under 40 years of age and should submit details of their proposed itinerary and its anticipated cost, together with a copy of their *curriculum vitae* and two letters of support from senior colleagues. They should explain briefly how such a visit might broaden their experience and assist their career. Fellowships will not be awarded solely for the purpose of attending courses or meetings.

Applications should be sent to the Company Secretary, Professor D. C. Carter, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, by 1 February 1994.

Early discharge after operation

**A. Narayan, S. Kumar,
M. P. Singh and
L. K. Sharma**

Department of Surgical Disciplines, All India Institute of Medical Sciences, New Delhi 100029, India

Correspondence to:
Professor L. K. Sharma

To assess the feasibility and advantages of short-stay surgery in India, a policy of early discharge was adopted for 386 patients undergoing various major and minor operations. The mean postoperative and total hospital stays of patients admitted for minor surgery were 1·9 and 3·7 days respectively; the corresponding figures for age- and sex-matched historical controls were 7·4 and 11·3 days. The mean postoperative and total stays of patients who had undergone major surgery were 4·1 and 8·0 days respectively; the corresponding control values were 8·9 and 12·5 days. The use of absorbable subcuticular skin sutures helped to shorten postoperative hospital stay and avoided an extra follow-up visit. The overall complication rate in the study group was 9·6 per cent and in historical controls 13·4 per cent ($\mathrm{P} > 0{\cdot}05$). A total of 2357 hospital bed-days were saved during the study and 95·6 per cent of patients approved of short-stay surgery.

Shortening hospital stay has several advantages. The cost of treatment decreases[1–3] because inpatient treatment is more expensive than outpatient care. Hospital beds, which are expensive to maintain and limited in number, are made available to other patients, thus cutting waiting lists and reducing sick-leave absenteeism[3–5]. Universal adoption of a policy of early discharge could do much to ease the load on the overburdened Indian medical system. However, convalescence at home increases the responsibility of family practitioners and community nurses[6–8], and requires good transport and referral systems, services unavailable to most Indians. In the event of a complication or emergency occurring after discharge, timely medical care would probably be inaccessible. This work was undertaken to study the feasibility and safety of short-stay surgery in India.

Patients and methods

The study was conducted in two phases. The first involved 200 consecutive patients due to have minor operations who were aged between 10 and 60 (mean 31·9) years (male:female ratio 1:0·47) and living close to the hospital. All consented to inclusion in the study. Patients were investigated on an outpatient basis and admitted to hospital on the morning of surgery for the operations shown in *Table 1*. After surgery, patients were discharged when they had recovered from anaesthesia and vital signs were stable. They were called for follow-up 3 and 7 days after discharge and they and their families were given questionnaires to assess opinions about short-stay surgery. These 200 patients were compared with 200 age- and sex-matched historical controls (mean age 33·6 years, male:female ratio 1:0·50) with similar surgical problems and who had undergone similar operations.

After success in the first phase, the second phase included patients due for routine major surgery; those undergoing more extensive operations such as oesophagectomy, Whipple's procedure and so forth were excluded. Some 186 patients of age 10–65 (mean 37·3) years (male:female ratio 1:1·16) were considered appropriate for early discharge after the operations shown in *Table 2*. Twenty patients had associated disease requiring specific treatment but not delaying discharge: ten were hypertensive, two had coronary or rheumatic heart disease, one was diabetic, three had pulmonary tuberculosis and four had a variety of miscellaneous problems. The 186 patients were investigated on an outpatient basis and admitted and subjected to surgery on the first available operating day. They were discharged when bowel function returned to normal and adequate oral intake was achieved, provided no significant complication had occurred. Those with drains *in situ* were not discharged and nasogastric decompression was routine after laparotomy. With these considerations in mind, the following limits were adopted to define short stay after surgery: thyroid, biliary and urogenital surgery – 4 days; mastectomy – 6 days; and gastrointestinal surgery – 7 days. Patients were called for follow-up at 1 week and 1 month after discharge. Polyglactin suture for subcuticular skin closure obviated the need for an extra hospital visit for suture removal. At the 1-month visit the questionnaire was used to assess opinion on short-stay care. The performance of these patients was compared with that of 180 historical controls operated on by the same unit in the year preceding the study. Control patients were matched as far as possible for age (mean 38·9 years) and sex (male:female ratio 1:2·95). Test and control patients belonged to similar diagnostic categories and underwent similar operations; 18 of the control patients had associated medical problems similar to those of the 20 test patients.

Table 1 *Operations on patients in phase 1*

	No. of patients
Hernia repair	75
Hydrocelectomy, orchidectomy or testicular biopsy	24
Interval appendicectomy	18
Hemithryoidectomy	18
Salivary gland excision	16
Breast lump excision	15
Laparoscopy	4
Miscellaneous	30
Total	200

Table 2 *Operations on patients in phase 2*

	No. of patients
Thyroidectomy	31
Mastectomy	34
Cholecystectomy	47
Appendicectomy	21
Bowel surgery	19
Urological surgery	27
Miscellaneous	7
Total	186

Patient care standards were not compromised at any stage. Apart from the use of absorbable subcuticular sutures for skin closure, surgical and anaesthetic techniques were not altered to facilitate early discharge.

Results

Phase 1

The 200 patients were admitted to hospital on the morning of scheduled surgery, but unforeseen factors such as non-availability of operating time caused the postponement of some operations. Affected patients usually chose to stay in hospital

Total	19·9	22·8

*Values are means

until the next operating day. The mean preoperative hospital stay was 1·8 days. Patients were discharged as soon as possible, varying from the evening of the day of operation to 4 days after surgery. The mean postoperative stay in hospital was 1·9 days and the mean total hospital stay therefore 3·7 days. Complications occurred in 17 patients (8·5 per cent): eight had wound infection, two drug rash, two transient fever and five miscellaneous problems. No patient with a complication was discharged and none required readmission. There were no deaths.

All patients attended the first follow-up visit. The mean number of hospital visits per patient was 1·6 (range 1–7), the highest number being in a patient who developed wound infection. The questionnaire revealed that 185 patients (92·5 per cent) approved of short-stay surgery; 12 (6·0 per cent) were dissatisfied and three (1·5 per cent) could not be properly assessed. Of patients' families, 66·5 per cent were satisfied with short-stay surgery; 10·0 per cent were not and 23·0 per cent were unavailable for questioning. Of patients with complications, 29 per cent were dissatisfied compared with 4 per cent of those without ($P < 0·001$, z test). The duration of hospital stay did not relate significantly to patient satisfaction.

In comparison, the mean duration of stay of the control patients was 3·9 days before and 7·4 days after surgery, a mean total of 11·3 days. Thus a mean of 7·6 bed-days was saved for each study patient, or 1520 bed-days for the entire group. The complication rate among control patients was 5·5 per cent, with seven having wound infection. These values are not significantly different from those of the study group (*Table 3*).

Phase 2

The mean preoperative hospital stay of the 186 study patients was 3·9 days. The factor most commonly delaying surgery and prolonging hospital stay was lack of operating time (33 patients). Other important causes were late radiology appointments (nine patients) and associated medical problems that required assessment and treatment on an inpatient basis (12). The mean postoperative stay was 4·1 (range 2–7) days, giving a mean total stay of 8·0 days. The complication rate was 19·9 per cent, including 4·8 per cent that occurred after discharge. Most complications were minor wound collections, non-specific short fevers and stitch sinuses (*Table 4*). One patient who had significant flap necrosis after radical mastectomy and a second who developed adhesive intestinal obstruction after hemicolectomy required readmission. The readmission rate was thus 1·1 per cent.

Table 5 *Summary of results*

No. of patients	386
Age (years)*	34·5
Total hospital stay per patient (days)*	5·8
Net bed-days saved	2357
Patient satisfaction (%)	95·6
Morbidity rate (%)	9·6
Mortality rate (%)	0
Readmission rate (%)	0·5

*Values are means

Follow-up was complete at 1 month, with a mean of 2·3 postoperative hospital visits per patient. Of the patients, 182 (97·8 per cent) approved of short-stay surgery, as did 181 families (97·3). The following factors led to dissatisfaction: inadequate analgesic prescription (three patients and their families), domestic problems (one patient and family) and the occurrence of fever at home (one family). Otherwise the occurrence of complications did not lead to dissatisfaction among patients or families.

In the control group the mean total hospital stay was 12·5 days (3·6 days before surgery, 8·9 days afterwards) and the complication rate 22·8 per cent ($P > 0·05$). There was a mean saving, therefore, of 4·5 bed-days for each of the 186 patients, amounting to 837 bed-days saved for the group, which represented 37·2 per cent of all patients undergoing major surgery in the unit during the period of this phase of the study.

The combined results of both phases of this study are summarized in *Table 5*. Overall, 95·6 per cent of patients were satisfied with early discharge. The complication rate of 9·6 per cent was not significantly different from that of the controls (13·4 per cent). A total of 2357 bed-days were saved during the study.

Discussion

The concept of home convalescence after operation is not new; starting with Nicoll[9] in 1909, there have been a succession of reports on the subject[5,10–13]. These studies dealt mainly with what would now be called minor and intermediate operations, such as hernia repair and stripping of varicose veins. By the 1960s, ambulatory surgery had become accepted for a large number of conditions and up to 40 per cent of all procedures have now been described as suitable for outpatient or day-care surgery[14]. Early discharge of suitably selected patients does not increase complication rates[15]. It has been pointed out that morbidity begins in the operating room, not at home[16], and clinicians may tend to be meticulous with a patient scheduled for early discharge to minimize complications. Patient care standards should, if anything, be improved by a policy of early discharge.

Isolated studies have shown success with major procedures performed on an outpatient or ambulatory basis, such as thyroidectomy[17], mastectomy[2,18] and cholecystectomy[19–22]. Most surgeons would not go so far, but the past few years have witnessed a trend towards diminishing hospital stay following major surgery in both Europe and North America. The mean duration of stay for cholecystectomy in hospitals in England and Wales varied from 9·8 to 10·8 days in 1981; the values for 1986 were 8·4–8·9 days[23]. Similar trends have been noted for many other operations. While turnover in operations performed in England and Wales increased by 39 per cent between 1948 and 1964, there was only a 1 per cent concomitant increase in bed numbers[5].

The two most important factors encouraging such changes have been shortage of hospital beds, resulting in long waiting lists, and economic considerations. About half the cost of inpatient care is related directly to hospital stay[1,2] and, with the diagnostic related group-based prospective payment system in the USA, prolonged hospital stay has become non-remunerative. Reimbursement organizations in the USA encourage their clients to avail themselves of cheaper healthcare options such as ambulatory surgery as far as possible. One North American study estimated that national savings would approach US$ 800 million if 30 per cent of all surgical procedures, instead of the then current 10 per cent, were performed on an ambulatory basis[24].

Success with short stay has been reported in almost all fields, including ophthalmic surgery[1,25,26], paediatric surgery[27], gynaecology[1,24,28,29], orthopaedics[23], otolaryngology[1,30,31], plastic surgery[1,32] and neurosurgery[33]. The age of the patient is no longer an important consideration in assessing suitability for short-stay surgery; in the USA even the elderly will not now be reimbursed for admission to hospital after hernia repair[15]. Similarly, the presence of systemic disease, including heart disease and diabetes mellitus, is no longer a contra-indication to early discharge[34]. For a patient whose only requirement is limited nursing care, prolonged hospitalization is a waste of the time and skills of highly trained personnel.

In India, as in developing countries generally, financial considerations are particularly relevant. The country can ill afford the financial burden even of the inadequate number of beds presently available, and more beds are needed to meet the requirements of the rapidly growing population. It is important, then, to consider the advantages of short-stay surgery, but certain disadvantages must not be forgotten. First, the proportion of more seriously ill patients in hospital increases, which strains hospital resources and imposes an additional burden on hospital personnel[21]. Second, the patient is given less time to adjust to new surroundings. Third, an additional workload is thrust on general practitioners, visiting nurses and outpatient staff[6–8]. Finally, home care increases the number of follow-up visits that the patient makes to hospital, and so increases the patient's costs[35].

In general, patients approve of short-stay surgery. Financial considerations apart, there is emotional support to be derived from the family. Also, the patient's confidence increases with early discharge, and disrupted routines are re-established more quickly. With the local problem of beds in part solved, we are now faced with a lack of theatre time for routine operations. This remains the single most important factor prolonging the hospital stay of those undergoing elective surgery. As a consequence, patients awaiting elective procedures may not profit significantly from the beds created by a policy of early discharge.

Bile duct injury and bile leakage in laparoscopic cholecystectomy

S.-M. Huang, C.-W. Wu, H.-T. Hong, Ming-Liu, K.-L. King and W.-Y. Lui

Division of General Surgery, Department of Surgery, Veterans General Hospital, National Yang-Ming Medical College, Taipei, Taiwan 11 217, Republic of China

Correspondence to:
Dr S.-M. Huang

Between January 1991 and July 1992, 350 laparoscopic cholecystectomies were performed. There were six biliary complications (1·7 per cent): common bile duct (CBD) injury (one patient), delayed CBD necrosis (one), immediate postoperative bile leakage (one) and delayed bile leakage (three). All six patients required laparotomy. Primary repair with long-arm T tube splinting for 3 months was performed for the CBD injury. Religation of the cystic duct was carried out after immediate postoperative bile leakage. Laparotomy with T tube choledochostomy only was performed in the three patients with delayed bile leakage, and hepatojejunostomy Roux-en-Y was undertaken for CBD necrosis. The patient with primary repair of the CBD injury required choledochojejunostomy Roux-en-Y 18 months later for stenosis. Episodes of intermittent cholangitis occurred in the patient with CBD necrosis. The outcome for the four patients with bile leakage was good. There were no deaths.

Since 1987, laparoscopic cholecystectomy has gained wide acceptance and enthusiasm throughout the world[1–4], because of the apparent reduction in postoperative pain and incidence of respiratory complications, shorter hospital stay, reduced recuperation time and possibly lower medical costs[5–7]. However, the incidence of common bile duct (CBD) injury in laparoscopic cholecystectomy (0·33–2 per cent)[8–10] is higher than that of the open operation (0·2 per cent)[11–13]. Among the first 350 laparoscopic cholecystectomies performed in this unit from January 1991, six biliary complications were encountered: two bile duct injuries and four instances of bile leakage. The purpose of the present study was to evaluate these cases retrospectively so as to avoid such complications in the future.

Patients and methods

Between January 1991 and July 1992, 350 laparoscopic cholecystectomies were performed by ten surgeons independently, following the general principles described by Zucker *et al.*[4] with only minor modifications. Briefly, the dissection was begun by releasing the lateral attachment of the gallbladder to the liver. Identification of the cystic duct–CBD junction was not routinely performed. Dissection in Calot's triangle was kept close to the gallbladder to avoid excessive dissection over the major bile duct. Conversion to laparotomy was required in 12 cases. Major complications arose in nine cases (2·6 per cent): subhepatic abscess (three patients), bile duct injury (two) and bile leakage (four). The biliary complications were encountered by three different surgeons.

The charts and available videotapes of the six cases of biliary complication were reviewed retrospectively. The number of previous laparoscopic cholecystectomies performed by the surgeon at the time of complication, the causes of the complications and the management and outcome were thoroughly recorded and followed. Details of biliary anatomy, sites of biliary injury or leakage and possible mechanisms were reconstructed diagrammatically.

Results

The six patients comprised four men and two women of mean age 56·2 (range 35–70) years. All six had symptomatic gallstones diagnosed by abdominal ultrasonography. Results of preoperative liver function tests were within normal limits.

The findings are summarized in *Table 1*. Bile duct injury and early bile leakage occurred in the early learning phase of the surgeon, all within the first five procedures. Delayed bile leakage occurred in the 'maturing' phase of the surgeon.

The sites of bile duct injury and bile leakage are shown in *Figure 1*.

In patient 1, axial traction on the infundibulum allowed the CBD to be mistaken for part of the cystic duct. Injury to the CBD was recognized immediately and primary repair performed after conversion to an open procedure.

In patient 5, the operation was tedious with a total time of 3 h. Excessive use of electrocautery was revealed on review of the videotape. At laparotomy on day 10 after laparoscopic cholecystectomy nearly the whole length of the extrahepatic bile duct was necrotic.

Immediate postoperative bile leakage in patient 4 was caused by an accidental cut to the cystic duct proximal to the clip during dissection of the adjacent cystic artery. The injury was not recognized during operation, although transient bile leakage was noted. Religaton of the cystic duct near the CBD was performed at laparotomy on the second day after operation.

Delayed bile leakage after laparoscopic cholecystectomy was

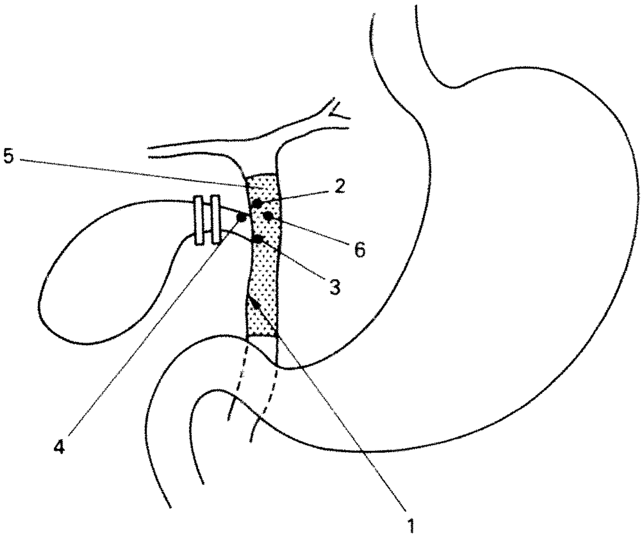

Figure 1 *Sites of bile duct injury and bile leakage in six biliary complications of laparoscopic cholecystectomy. The perforation sites of delayed bile leakage in patients 2, 3 and 6 were within 0·5 cm of the cystic duct–common bile duct (CBD) junction. Numbers relate to the patient numbers in* Table 1. ▨, *CBD necrosis in patient 5*

Table 1 *Bile duct injury and bile leakage in laparoscopic cholecystectomy*

			No. of laparoscopic cholecystectomies at time of injury							
Patient no.	Sex	Age (years)	Surgeon	Hospital	Complication	Mechanism	Day of occurrence	Risk factor	Management	Outcome
1	F	70	5	5	CBD injury	Short cystic duct, axial traction, failed operative cholangiography	0	Inexperience of surgeon	Primary repair with T tube splinting	CBD stricture 18 months later
2	M	65	39	39	Delayed bile leakage	Delayed electrocautery injury of cystic duct–CBD junction	12	Smoky abdomen	Laparotomy, T tube insertion	Good; T tube removed 30 days later
3	M	48	89	100	Delayed bile leakage	Delayed electrocautery injury or pigtail erosion	13	Smoky abdomen, pigtail erosion	Laparotomy, T tube insertion	Good; T tube removed 7 days later
4	M	35	3	113	Early bile leakage	Injury of cystic duct near CBD junction	2	Inexperience of surgeon	Laparotomy, religation of cystic duct	Good
5	F	63	3	119	Delayed CBD necrosis	Delayed electrocautery injury	10	Inexperience of surgeon, low placement of subxyphoid trocar	Laparotomy, hepatojejunostomy Roux-en-Y	Intermittent cholangitis
6	M	56	110	160	Delayed bile leakage	Delayed electrocautery injury of cystic duct–CBD junction	14	Smoky abdomen	Laparotomy, T tube insertion	Good; T tube removed 12 days later

CBD, common bile duct

caused by delayed electrocautery injury in patients 2, 3 and 6. In these cases, dissection at Calot's triangle was tedious and difficult in a smoky abdomen. In two cases, a drain was left in Morrison's pouch. This was removed 48 h later and demonstrated the absence of early bile leakage. These two patients experienced sudden onset of right upper quadrant pain 8–9 days after operation and were taken to the emergency room on the 12th–14th day after surgery. In patient 3, a right subhepatic abscess necessitated percutaneous catheter drainage on day 8 after operation. Bile leakage was absent at that time and did not appear in the drainage tube until the 12th day after surgery. Exploratory laparotomy revealed a CBD perforation within 0·5 cm of the cystic duct–CBD junction. All appeared to be the result of coagulation necrosis. The cystic stump and clips were intact. T tube choledochostomy with adequate drainage was performed in all three cases.

All six patients were followed for 4–22 months, up to November 1992. They were all well except patient 5, who required oral antibiotic treatment for the control of intermittent subclinical cholangitis.

Discussion

Biliary complications during and after laparoscopic cholecystectomy include bile duct injury and bile leakage. They remain the most critical drawbacks of laparoscopic compared with open cholecystectomy[2–10]. It should be the aim of all laparoscopic surgeons to reduce the incidence of bile duct injury[11–14]. Hunter[14] has proposed five steps that should be followed to avoid this type of injury during laparoscopic cholecystectomy.

Major bile duct injury tends to occur within the first ten to 15 operations performed by a laparoscopic surgeon[4,6], as demonstrated by patients 1 and 5 in the present series. Cutting or transection of the major bile duct can take place if the major duct is mistaken for the cystic duct, as in patient 1, which was only the fifth operation performed by the surgeon. Ways to avoid this kind of complication include: (1) avoidance of axial traction on the infundibulum, as this brings the cystic duct parallel to the CBD; (2) identification of the infundibulum–cystic duct junction before division of the cystic duct, even if this means tedious stripping of much areolar tissue; (3) routine performance of intraoperative fluoroscopic cystic duct cholangiography; and (4) assistance from an experienced laparoscopic surgeon for the first ten to 15 procedures.

Excessive electrocautery can cause delayed CBD injury. The potential hazard inherent to this energy source was pointed out by Moossa *et al.*[15]. Delayed necrosis of the extrahepatic bile duct caused by electrocautery injury, as in patient 5, has not been previously reported[15,16]. This complication is avoidable by conversion to open operation rather than persisting with a difficult and tedious procedure.

Although review of the videotapes of patients 2, 3 and 6 did not identify a direct electrocautery injury, the coagulative nature of the pinhole perforation, intact cystic stump and clips found at reoperation suggested that the injury was caused by electrocauterization. Two possible reasons for these delayed electrocautery injuries are: (1) inadvertent electrocauterization of areolar tissue overlying the CBD or common hepatic duct during dissection of the medial aspect of the cystic duct; and (2) 'cross-fire' electrocautery injury from a dissector through the infundibulum grasper down to the cystic duct–CBD junction during dissection of the lateral side of the cystic duct. Suggested methods of preventing delayed bile leakage are: (1) avoid excessive or tedious dissection over the common hepatic duct or CBD, keeping the dissection as close to the gallbladder as possible; (2) during dissection on the lateral side of the cystic duct, avoid contact between the dissector and the cystic duct or infundibulum grasper – grasp the areolar tissue and electrocauterize away from the cystic duct; and (3) use the smoke evacuator to minimize the amount of smoke within the abdomen and keep the visual field clear.

Although several authors[17,18] have reported open surgery to be the procedure of choice in the management of biliary complications following cholecystectomy, percutaneous catheter drainage without biliary stenting is advocated for bile leakage from the accessory duct or duct of Luschka by Dubois *et al.*[1] and Peters and colleagues[9]. Percutaneous drainage of bile leakage with endoscopic biliary stenting are advocated and usually suffice for simple leakage from small perforations in the major bile duct or cystic duct fistula[19,20]. However, emergency laparotomy is necessary when endoscopic biliary stenting fails, as in patient 3, or when delayed bile leakage presents as biliary peritonitis, as in patients 2 and 6.

Immediate operative management of major bile duct injury during and after laparoscopic cholecystectomy includes primary repair or anastomosis of the clean-cut bile duct injury[21], as in patient 1, or hepatojejunostomy Roux-en-Y for CBD necrosis, as in patient 5 and for the classical transection of the CBD that is unrecognized at the time of operation as proposed by Davidoff *et al.*[16].

If the major bile duct injury is recognized in the immediate postoperative period, presenting as bile leakage, fistula or peritonitis, external biliary drainage is the best initial approach to bring local and systemic septic conditions under control. If the bile duct injury presents at an interval after laparoscopic cholecystectomy and the local condition is acceptable, as in patient 5, single-stage repair with a Roux-en-Y jejunal loop may be achieved. The prognosis of patients with major bile duct injury is usually poor, whereas that after bile leakage is uniformly good. The present results confirm this.

Biliary complications occurring during or after laparoscopic cholecystectomy include major bile duct injury and bile leakage. The former usually occurs in the early learning phase of the surgeon. Abiding by Hunter's rules for avoiding bile duct injury, assistance from an experienced laparoscopic surgeon for the first 15 procedures and a liberal policy towards conversion to open cholecystectomy when in doubt are likely to reduce the incidence of duct injury. Avoidance of excessive electrocautery and clear visualization are the best means of preventing delayed bile leakage.

Preventing complications of laparoscopy

A. J. McMahon, J. N. Baxter and P. J. O'Dwyer

University Department of Surgery, Western Infirmary, Glasgow G11 6NT, UK
Correspondence to: Mr P. J. O'Dwyer

Laparoscopy was first performed by Kelling[1] in 1901, but it was not until the 1950s in Europe and the late 1960s in the USA that the technique gained popularity. The past 4 years has seen an explosion in the use of laparoscopic techniques in general surgery. Closed laparoscopy, using a Veress needle for insufflation followed by blind insertion of a sharp trocar and cannula, has been the predominant method of gaining access. The open technique, which is performed by making a small subumbilical laparotomy incision under direct vision and inserting a blunt Hasson's trocar and cannula (with a cone to prevent air leakage), has been reserved mainly for patients with adhesions from previous abdominal surgery.

The most catastrophic and feared complication of laparoscopy is injury to the major retroperitoneal vessels. In gynaecological series the incidence of this disaster is between 3 and 10 per 10000 closed laparoscopies[2–4]. Although the development of disposable trocars with spring-loaded safety shields and improvements in technique may have reduced the risk of this potentially fatal complication, reports from general surgery indicate that they do not prevent it[5–7]. One reason for this is that the external safety shield of the trocar is often held back by a loose layer of peritoneum after it has entered the abdomen, leaving the sharp trocar exposed[5]. In a survey throughout the United States[7], 36 major retroperitoneal vessel injuries – three of which resulted in death – were reported in a series of 77604 laparoscopic cholecystectomies, an incidence of nearly 5 per 10000. These injuries were attributed mainly to trocar insertion. On the other hand, the 35 injuries to other intra-abdominal vessels (incidence 5 per 10000) were attributed mainly to insertion of the Veress needle. Vascular injury at the time of insertion of additional trocars should never occur, as these can be introduced under direct laparoscopic vision. Major vascular injury can be completely eliminated by routine use of open laparoscopy. Penfield[8] reported no vascular injuries in almost 11000 such operations performed by 18 gynaecologists in the United States.

Another serious complication of closed laparoscopy is hollow viscus perforation[4]. Perforation of the small bowel, colon, stomach, bladder, uterus and ureter have all been reported. In the American survey of laparoscopic cholecystectomy previously mentioned[7], 109 bowel injuries (five fatal) were reported, an incidence of 0·14 per cent; this figure is identical with the incidence found in gynaecological experience[9]. These injuries, which are typically unrecognized at the time of operation, often present late with peritonitis, intra-abdominal abscess or enterocutaneous fistula[7], and they may result in death[10]. Although bowel laceration can occur with open laparoscopy (6 in 11000), the major advantage of this method is that accidental perforation is usually recognized and can be repaired at the time of operation (four of six)[8].

Complications related to pneumoperitoneum are gas embolus, cardiovascular collapse, pneumothorax and hypercarbia caused by carbon dioxide absorption. Gas embolus is exceedingly rare, occurring in fewer than 1 in 10000 procedures[11–13]. It is usually secondary to accidental intravascular injection of carbon dioxide during insufflation through a misplaced Veress needle, but it has also been reported as a result of accidental placement of an air-cooled laser tip into a vessel[14]. Embolization to the right ventricle and pulmonary circulation may be delayed by up to 1 h by passage through the portal system[15]. An early sign of air embolism is a sudden fall in end-tidal carbon dioxide[14,16]. When air embolism is suspected, the abdomen should be deflated, the patient tilted head-down and positioned on the left side[17], and nitrous oxide anaesthesia discontinued[18]. A central line should be inserted into the right ventricle for aspiration of gas bubbles[19]. The most sensitive method of identifying air embolism is Doppler ultrasonography, which can detect as little as 0·1 ml air in the right ventricle[20]. Cardiovascular collapse may occur as a result of a profound vasovagal response to rapid peritoneal distension[21]. Tension pneumothorax is usually the result of a congenital defect of the diaphragm (a patent pleuroperitoneal canal)[22], although accidental perforation of the diaphragm by a gallbladder-retracting forceps is another cause[23].

During prolonged laparoscopic procedures, absorption of carbon dioxide may result in significant hypercarbia and acidosis[24,25]. Therefore, careful monitoring of carbon dioxide tension and an increase in ventilation minute volume is required. Measurement of end-tidal carbon dioxide levels gives some indication of the arterial partial pressure, but arterial carbon dioxide tension may range between 2 kPa above and 1 kPa below the end-tidal value[25]. In patients with severe respiratory disease, the rise in arterial carbon dioxide level may be particularly marked[26]. The use of helium instead of carbon dioxide may resolve this problem[25,27,28].

Other major complications encountered during laparoscopic surgery include thermal injury to the abdominal wall, bowel and common bile duct[29–31]. These injuries can occur with the use of either monopolar electrocautery[31,32] or laser[30] and often result from a poor understanding of the basic concepts of these energy forms[33,34]. Another avoidable complication of both open and closed laparoscopy is herniation of bowel through the trocar insertion site[35,36]. This occurrence is more likely when the site is enlarged to remove, for example, the gallbladder at laparoscopic cholecystectomy. Suture closure of the fascial defect is therefore required.

Surgeons have favoured closed laparoscopy because it is thought to be faster and less cumbersome than the open method. This is a misconception; open laparoscopy should have a shorter and safer learning curve for general surgeons in training. Moreover, it also removes the need for urinary catheterization and allows faster insufflation. Finally, open laparoscopy should result in significant cost savings over the closed method in which a disposable Veress needle and trocar are used, as the argument for always having a sharp new instrument does not apply.

Subumbilical hernia following laparoscopic cholecystectomy

P. G. Horgan and P. R. O'Connell

Department of Surgery, Mater Misericordiae Hospital, Eccles Street, Dublin 7, Ireland
Correspondence to: Mr P. G. Horgan

Laparoscopic cholecystectomy has been routine in the authors' unit since 1990. Practice has been to remove the excised gallbladder through the subumbilical trocar site. This fascial incision is made with a 10-mm trocar and cannula, and accommodates the laparoscope throughout the operation. The fascial defect is routinely closed with a non-absorbable suture when enlargement or dilatation is necessary to remove the gallbladder. To date, however, it has not been practice to close this defect after uncomplicated delivery of the gallbladder from the peritoneal cavity. Unexpected development of a subumbilical hernia is reported in two patients following uncomplicated laparoscopic cholecystectomy.

Case reports

Patient 1

A 71-year-old woman with mixed cardiac valvular disease receiving oral anticoagulation therapy presented with biliary colic. Ultrasonography showed multiple gallstones in a thickened gallbladder. The woman had a previous history of intermittent attacks of biliary colic and had been turned down for elective surgery because of anaesthetic risk. She was scheduled for laparoscopic cholecystectomy.

The operation was uneventful and the mobilized gallbladder was easily delivered. The patient remained in hospital while oral anticoagulation was re-established. On day 5 after operation the skin sutures were removed from the subumbilical incision. Approximately 2 h later, three loops of small bowel prolapsed through the subumbilical stab wound. Under local anaesthesia the skin and fascia were incised and the intestine reduced. Nylon sutures were then placed in the fascia and skin. The patient made an uneventful recovery.

Patient 2

A 70-year-old woman presented with a tender central abdominal swelling 18 months after uneventful laparoscopic cholecystectomy. A diagnosis of subumbilical incisional hernia was confirmed at elective operation the following day. The omentum had prolapsed through a 12-mm defect (*Figure 1*); this was enlarged and the omentum reduced. The fascia was then repaired with non-absorbable sutures. The patient was well on discharge the next day.

Discussion

Herniation through the abdominal wall is recognized by gynaecologists as a complication of laparoscopy. However, general surgeons are less aware of the problem. Sauer and Jarrett[1] reported small bowel obstruction after laparoscopy and, while acknowledging that herniation was a rare event, warned that small bowel incarceration in a subumbilical wound should be considered in a patient presenting with relevant signs, irrespective of the intervening time period. Others have noted the development of an incarcerated hernia following laparoscopy[2] and laparoscopic sterilization[3].

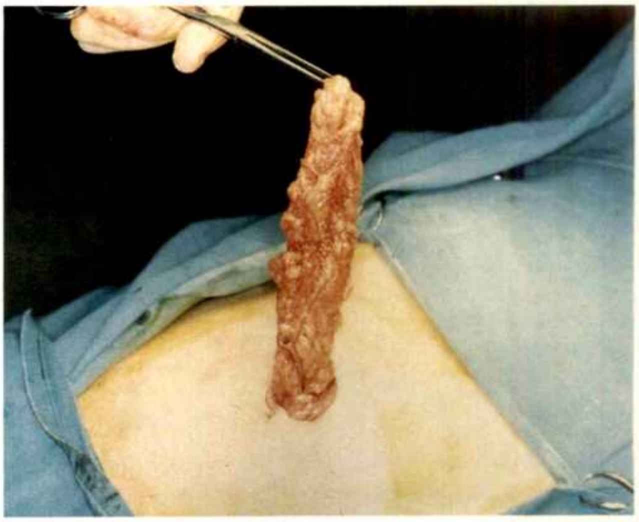

Figure 1 *Patient 2: herniation of omentum via the subumbilical port in a 70-year-old woman following routine laparoscopic cholecystectomy*

Maio and Ruchman[4] reported a case of incisional hernia following laparoscopy that was diagnosed by computed tomography. Such an expensive investigation is neither necessary nor justified in the detection of this complication, except perhaps in a very obese patient. Some authors[5] have suggested that the centre of the umbilicus should be the entry site for the laparoscope, but there is no evidence that this approach prevents incisional hernia.

It is easy to understand why herniation could follow laparoscopy when the subumbilical incision site has been enlarged or stretched to remove the mobilized gallbladder. However, epigastric and femoral hernias commonly occur through fascial defects no larger than those resulting from insertion of 5- or 10-mm trocars. Distension of the abdominal musculature during laparoscopy may contribute to postoperative herniation.

Many surgeons currently remove the gallbladder via the epigastric port; intervening muscle layers between the peritoneal cavity and skin may be less amenable to herniation. This practice may well reduce the incidence of this complication, but only anecdotal evidence supports this theory at present.

We are sufficiently concerned at this stage to recommend routine closure of the subumbilical fascial defect after laparoscopic surgery.

Surgical management of perineal and metastatic cutaneous Crohn's disease

N. Williams, N. A. Scott, J. S. Watson* and M. H. Irving

*Department of Surgery, Hope Hospital, Salford and *Department of Plastic Surgery, Withington Hospital, Didsbury, Manchester, UK*

Correspondence to:
Professor M. H. Irving, Department of Surgery, University of Manchester, Hope Hospital, Salford, Manchester M6 8HD, UK

Skin lesions are the commonest extraintestinal manifestation of Crohn's disease. Lesions that develop at sites remote from the gastrointestinal tract and have granulomas on histological examination are termed metastatic cutaneous Crohn's disease. Management is difficult as medical treatment is often ineffective. This report describes the use of surgical debridement of areas of perineal metastatic cutaneous Crohn's disease in five patients, all of whom had failed to improve after a variety of medical treatments. One patient had a poor result with continuing mild perineal discharge and four had a good outcome with complete resolution of symptoms and satisfactory cosmetic results.

Crohn's disease is a granulomatous inflammatory condition that can affect any part of the gastrointestinal tract. A variety of extraintestinal manifestations are recognized[1], the most frequent being cutaneous involvement. Dermatological complications occur in up to 44 per cent of patients with Crohn's disease[2]. Patients may develop granulomatous inflammation of the skin at sites remote from the gastrointestinal tract: metastatic Crohn's disease[3] or more commonly metastatic cutaneous Crohn's disease[4,5]. Management of cutaneous lesions continues to present a therapeutic challenge. A variety of agents have been reported to be beneficial but no clear-cut therapeutic regimen exists. This report describes five patients with cutaneous Crohn's disease treated by wide local excision of the affected areas after failed medical management.

Case reports

Patient 1

A 25-year-old man underwent panproctocolectomy and formation of a Brooke ileostomy in 1986. He developed increasing discharge from the perineum and the sinuses present were laid open, with minor symptomatic improvement. Skin biopsy revealed the presence of non-caseating granulomas consistent with a diagnosis of Crohn's disease. Prednisolone, azathioprine, dapsone, antibiotics and hyperbaric oxygen failed to control the disease, which extended to the lower lumbar region and both groins, causing penile oedema. In March 1991 the patient underwent extensive debridement of the affected area. Diseased tissue was excised down to deep fascia and the wound was left to heal by secondary intention. After 1 year the wounds healed, the penile oedema subsided and there remained a few sinuses in the area that had not been excised.

Patient 2

A 50-year-old man was referred with a 3–4-year history of chronic discharging sinuses of the perineum and right thigh, and penile oedema. Rectal sinography confirmed a fistula connecting the rectal stump and a right-sided pelvic cavity. Proctectomy did not resolve the problem and perineal sepsis continued (*Figure 1a*). Some 6 months later the patient underwent extensive debridement of the affected skin around the scrotum, perineum and right buttock. A meshed split-skin graft was applied to the defect 48 h later. Histological examination revealed non-caseating granulomas and other features consistent with cutaneous Crohn's disease. The wounds remain healed with no sepsis 16 months later (*Figure 1b*).

Patient 3

A 54-year-old man had had a chronic discharging perineal sinus since 1960. This progressed to the surrounding skin, and in 1986 and 1987 the areas involved were conservatively debrided. Histological analysis confirmed cutaneous Crohn's disease. The man continued to have marked perianal and gluteal sepsis. Azathioprine produced some initial resolution but another gluteal abscess developed. Cyclosporin and subsequently prednisolone failed to control the perianal disease and in September 1990 the patient underwent debridement and split-skin grafting of the affected gluteal skin. After 10 months there is minimal discharge from the perineum.

Patient 4

A 48-year-old diabetic woman was referred with a 5-year history of a chronically discharging 'rash' of the groin and perineum. She had undergone panproctocolectomy and ileostomy for Crohn's disease in 1973. Skin biopsy confirmed the presence of non-caseating granulomas and appearances consistent with a diagnosis of Crohn's disease. Cyclosporin and metronidazole produced limited initial improvement. In November 1991 the patient underwent excision of the affected skin and subcutaneous tissue in the perineum and groin, down to the deep fascia. The defect was allowed to granulate and by 12 months the wounds were completely healed.

Patient 5

A 23-year-old woman was referred in 1985 with severe perianal Crohn's disease. Following subtotal colectomy and ileostomy she developed persistent perianal and vulval discharge. This continued despite medical treatment with steroids, azathioprine, prolonged metronidazole and mercaptopurine. Skin biopsy had demonstrated active, severe, chronic inflammation associated with many non-caseating granulomas, consistent with cutaneous Crohn's disease. In January 1992 the perineal disease worsened. Examination under anaesthesia revealed marked perineal and vulval cutaneous disease with radial ulceration (*Figure 2a*). The patient underwent wide excision of the affected perineum and approximately two-thirds of the vagina circumferentially, leaving the cervix and a longer anterior than posterior vaginal wall. The perineum and vagina was reconstructed with a gracilis myocutaneous and a posterior thigh fasciocutaneous flap (*Figure 2b*). The cosmetic and functional results have been more than satisfactory at 6-month follow-up.

The chronological sequence of disease progression and surgical intervention in the five patients is shown in *Table 1*.

Table 1 *Chronological summary of events*

	Patient no.				
	1	2	3	4	5

Discussion

Metastatic cutaneous Crohn's disease is histologically similar to direct contiguous cutaneous disease but occurs at sites remote from the gastrointestinal tract and appears as ulcers in flexural[2] and non-flexural[6,7] sites and as nodular lesions on the extremities[4,8]. Metastatic lesions are associated with disease that involves the colon; extraintestinal complications of Crohn's disease are more commonly associated with colonic disease[1]. These lesions nearly always follow the onset of gastrointestinal disease. The differential diagnosis of cutaneous Crohn's disease includes other causes of granulomatous inflammation such as syphilis, tuberculosis, actinomycosis, sarcoidosis and hidradenitis suppurativa. Histopathological assessment therefore has a particularly important role in diagnosis. The lesions of Crohn's disease are characterized by granulomatous inflammation with giant cells and discrete non-caseating granulomas within the dermis, occasionally extending into the subcutaneous tissue[8,9]. The granulomas are arranged in a perivascular manner with normal vessel walls[8] and sometimes associated with a granulomatous perivasculitis[10]. The association of Crohn's disease and cutaneous polyarteritis nodosa has been described[11], but it is difficult to ascertain whether the vascular changes are secondary to the granulomatous inflammation or whether they represent a primary vasculitis. The aetiology of Crohn's disease may be vasculitic[12].

The consequences of cutaneous manifestations of Crohn's disease can produce some of the most debilitating complications. There is no consistent relationship between the appearance of the cutaneous lesion and the underlying disease activity of the gastrointestinal tract. Little is known about the natural history of the lesions and empirical treatment is directed at the primary disease process affecting the bowel and local therapy to the cutaneous lesions. The use of immunosuppressive agents[13–15] and metronidazole[3,16] has been associated with good results and hyperbaric oxygen has been reported to be successful in two patients[17,18]. Possible complications of hyperbaric oxygen therapy include middle ear barotrauma, ocular effects, claustrophobia, pulmonary oxygen toxicity and central nervous system oxygen toxicity[17]. Local therapy is predominantly supportive. Intralesional steroids have been used with some success[19,20].

Surgical management has usually included removing bowel affected with Crohn's disease and local procedures such as laying open fistulas, draining of abscesses and local debridement. Surgery has also been used in patients after failed medical management. Surgical treatment was possible in the present group because the disease did not spread below the deep fascia, a feature that has been observed by others[21]. This therefore allows a relatively radical resection of affected tissue down to the deep fascia, which permits healing by secondary intention or skin grafting. Patient 3 had a less than satisfactory result, which was probably caused by an unhealed presacral cavity present at the time of surgical debridement.

Results from this small series of patients demonstrate the utility of surgical debridement in patients with cutaneous Crohn's disease refractory to medical treatment.

Randomized controlled trial comparing laparoscopic and open appendicectomy

A study was carried out of 137 patients with a diagnosis of acute appendicitis who were randomized to either laparoscopic or open appendicectomy. Patients found to have perforated or normal appendices at histological examination were excluded. Fifty-two patients undergoing laparoscopic appendicectomy and those receiving 57 open procedures were analysed. Laparoscopic appendicectomy took no longer than the open procedure (mean 43 versus *40 min). The number of doses of pethidine (1 mg per kg body-weight) required in the immediate postoperative period did not differ between the two groups but the mean number of doses of oral analgesic (naproxen sodium 550 mg twice daily) required was less in patients undergoing laparoscopic appendicectomy (2·8* versus *5·0,* $P < 0{\cdot}05$*). There was no significant difference between time to resumption of fluid and diet intake and length of hospital stay. There were five (9 per cent) wound infections after open appendicectomy compared with none after the laparoscopic operation (*$P < 0{\cdot}01$*). Patients who underwent laparoscopy returned to full home (17* versus *30 days,* $P < 0{\cdot}01$*) and social (19* versus *32 days,* $P < 0{\cdot}05$*) activities earlier than those who underwent open operation. Laparoscopic appendicectomy may allow reduction in the number of wound infections and earlier return to normal activities.*

Several series of laparoscopic appendicectomy have been reported in the literature$^{1-4}$, but these are either uncontrolled or non-randomized trials and it remains uncertain whether the laparoscopic approach is superior to the open technique. A randomized trial was conducted to determine whether significant differences occurred between these two procedures with regard to wound infection, duration of the procedure, postoperative analgesic requirement, time to resumption of intake of fluids and diet, hospital stay and return to normal activities.

Patients and methods

Between February and August 1992, all patients over the age of 12 years with a diagnosis of acute appendicitis were randomized to open or laparoscopic appendicectomy. Randomization was achieved with the toss of a coin by independent observers. Seventy-two patients were randomized to open and 65 to laparoscopic operation. Fifteen patients (21 per cent) from the open group were excluded; in 11 the appendix was normal on histological examination and in four it was perforated. Thirteen patients (20 per cent) from the laparoscopy group were excluded; in ten laparoscopy revealed a normal appendix and in three perforation. In patients with a normal appendix, other causes of abdominal pain were found and the appendices were not removed. Patients studied are detailed in *Table 1*. All patients received intravenous gentamicin and metronidazole before surgery. The open technique was performed through a standard right lower quadrant incision, with precautions to avoid unnecessary wound contamination, by registrars or residents with experience of at least 6 months. Of the 52 laparoscopic appendicectomies, 39 were performed by one registrar trained in laparoscopy and the rest by two laparoscopically trained consultants. Only surgeons who had performed more than 15 operations in the respective groups were allowed to participate in the study.

The appendicular artery was secured laparoscopically with Ligaclips (Ethicon, Somerville, New Jersey, USA) before being cut. The base of the appendix was then secured with an Endoloop (Ethicon) and transected. Monopolar diathermy was used sparingly to achieve haemostasis when necessary. Removal of the appendix was achieved through a left suprapubic 10-mm cannula; the wound was not touched in any case. Successful removal of the intact appendix through the cannula was achieved in 43 patients. In nine patients the appendix was too big for the cannula and was placed in the thumb of a size 8 glove and extracted without contamination. There were no conversions to an open procedure. The duration of surgery was defined as the time from skin incision to when the wound was completely dressed.

After the operation, intramuscular pethidine 1 mg/kg every 4 h was given on demand. Oral naproxen sodium (Synflex; Syntex, Auckland, New Zealand) was given as a 550 mg dose twice a day on demand when patients were able to take liquids, and the number of

doses given recorded. Fluids were prescribed on the return of active bowel sounds; diet was resumed when the patients tolerated fluids well. Patients were discharged when diet was tolerated well and reviewed after 1 week in the outpatient clinic. Wound infection was defined as purulent discharge from the incision site. Patients were interviewed at 1 month to determine the period of debility before returning to full activities. For those who had not returned to full activities by 1 month, a second interview was held 2 weeks later.

Data from the two groups were compared using Student's t test. Proportions were compared with the χ^2 and Fisher's exact tests when necessary. $P < 0{\cdot}05$ was taken as significant.

Results

The two groups were comparable in terms of age, sex and weight (*Table 1*), and most patients were classified as American Society of Anesthesiologists grade I. Diagnosis was confirmed on the finding of transmural infiltration with leucocytes in part or all of the appendix. The lengths of the two procedures were not significantly different and there was no difference in the number of doses of pethidine requested by the two groups. Patients undergoing open operation required more doses of oral analgesic than those receiving laparoscopy (*Table 1*; $P < 0{\cdot}05$). There were no significant differences in the time to return of bowel sounds and commencement of fluids and diet intake, or in the length of hospital stay (*Table 1*). Five patients (9 per cent) had a wound infection after open operation but none after laparoscopy ($P < 0{\cdot}01$). No complications were caused by the laparoscopic technique, and no postoperative abdominal or pelvic abscesses were found in either group.

Patients undergoing laparoscopic appendicectomy incurred a mean of £148 more in charges, which was due entirely to the cost of disposable cannulas and instruments. It was not possible to analyse the delay before return to full work as the wide diversity of occupations between the two groups made the results incomparable. The range of home and social activities were, however, similar in both groups. Return to full activity (ability to pursue activity at a level of intensity, duration and frequency similar to that before operation) took much longer for patients undergoing open appendicectomy ($P < 0{\cdot}01$ for home and $P < 0{\cdot}05$ for social activities) (*Table 1*).

Discussion

Laparoscopy helps avoid misdiagnosis of acute appendicitis[5], but some authors[6] believe that the procedure takes much longer. The results of the present randomized trial show that the total time is comparable if surgeons with similar experience are used for each type of operation. Less oral analgesic was needed by patients undergoing laparoscopy, although the clinical significance of the difference between 5·0 and 2·8 doses is debatable. There was no significant difference in the time to resumption of fluid and diet.

Infection of the wound remains the main cause of postoperative morbidity and prolonged hospitalization in those undergoing open appendicectomy[7]. A reduction in the incidence of wound infection may be an advantage of laparoscopic appendicectomy. Removal of the appendix through the cannula effectively prevents seeding of bacteria in the wound. Patients with perforated appendices were excluded as they represent a subgroup of this condition with a different morbidity and mortality pattern. The difference of 1 day in hospital stay between the two groups, although not statistically significant, was contributed to mainly by the extended hospitalization of up to 12 days in patients with wound infection.

Earlier return to full activity appears to be an important benefit of laparoscopic appendicectomy; a reduction of almost 2 weeks was achieved. Although the cost of the laparoscopic procedure was higher, this could be offset by earlier return to productive activity. There is evidence that postoperative adhesions occur less often with the laparoscopic technique[8]. Adhesion-related complications such as intestinal obstruction and subfertility remain the main source of long-term morbidity from open appendicectomy[9]. The laparoscopic method has the bonus of better cosmesis by placement of the two inferior cannulas below the 'bikini line'.

Colonic obstruction in acute myeloid leukaemia

P. Karatsis, M. Farouk, A. Wyman, H. M. Sweetland and K. Rogers

Department of Surgical Sciences, Clinical Sciences Centre, Northern General Hospital, Herries Road, Sheffield S5 7AU, UK

Correspondence to: Professor K. Rogers

Intestinal complications in patients with acute leukaemia are not uncommon; obstructive lesions in the small bowel are the most frequently reported. Intussusception secondary to leukaemic infiltration is thought to be the major precipitating factor in these patients. Large bowel complications are relatively rare: only one case of colonic obstruction has been described previously, in which leukaemic infiltration presented the classical picture of stenosing sigmoid carcinoma[1]. A patient with leukaemia who developed large bowel obstruction requiring surgical intervention is reported.

Case report

A 43-year-old woman with acute myeloid leukaemia presented with haematemesis and melaena during her third course of chemotherapy. At the time she was found to be profoundly depleted of platelets and white cells (haemoglobin level 9·9 g/dl, white cell count $1{\cdot}3 \times 10^9$/l, platelet count 2×10^9/l). Gastroscopy failed to reveal the source of haemorrhage. The patient then proceeded to pass fresh blood rectally and required multiple transfusions of packed red cells and platelets. By 3 days the bleeding had decreased, but the woman started to develop progressive abdominal distension, which was initially thought to be pseudo-obstruction and was treated conservatively. However, the patient developed signs of septicaemia and the abdominal distension progressed. Abdominal radiography revealed right-sided colonic dilatation, which suggested a mechanical obstruction in the proximal transverse colon. To differentiate between mechanical and pseudo-obstruction colonoscopy was performed, but the endoscope failed to advance beyond the descending colon. An urgent barium enema confirmed mechanical obstruction at the site of clinical suspicion. Because of the patient's severe leucopenia and thrombocytopenia surgical intervention was deemed very hazardous and laparotomy seemed inadvisable. Caecostomy was performed to decompress the obstructed colonic segment. The patient's general condition improved rapidly and the bleeding discontinued. Some 2 months later a repeat barium enema revealed a strictured area at the site of the previous obstruction (*Figure 1*). As the patient's haematological parameters had improved (haemoglobin level 10·1 g/dl, white cell count $7{\cdot}1 \times 10^9$/l, platelet count 73×10^9/l), a laparotomy was performed. The proximal transverse colon showed a narrowed thickened area but no signs of continuing obstruction; extended right hemicolectomy was carried out. Histological analysis of the affected segment showed evidence of submucosal thickening, fibrosis and a chronic inflammatory cell infiltrate. However, the inflammatory cells were of normal morphology and there was no evidence of leukaemic cell infiltration. The patient made an uncomplicated recovery and remains well in remission 1 year later.

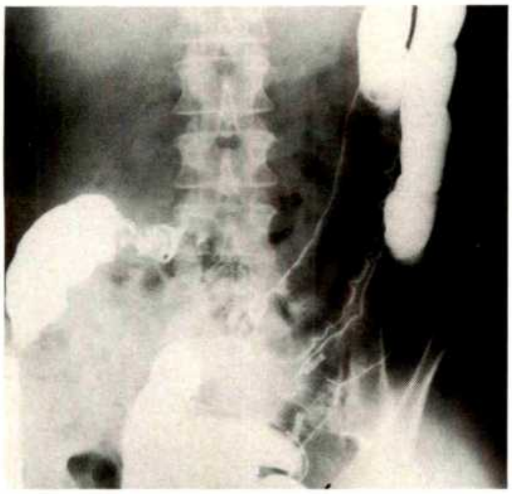

Figure 1 *Contrast enema showing an irregular stricture in the proximal transverse colon*

Discussion

Bleeding, perforation and small bowel obstruction are well recognized gastrointestinal complications in patients with leukaemia. Colorectal complications such as mucosal ulceration, bleeding, caecal perforation, gangrene of the appendix and proctitis have been described[2]. Large bowel obstruction caused by leukaemic infiltration is rare, with only one previous case reported[1]. The present paper describes another case of large bowel obstruction in a patient with acute myeloid leukaemia. Although leukaemic infiltration was not confirmed, only fibrosis of the colonic wall, the fibrosis was thought to be secondary to infiltration that had responded to the chemotherapy administered at the time of presentation of the obstructive episode.

Leukaemic infiltration of the small and large bowel occurs usually as plaque-like thickenings of the submucosa but can manifest as nodular or polypoid lesions[2]. In the small intestine polypoid masses are the most common. Enlargement of these polypoid lesions is thought to predispose to necrosis and subsequent haemorrhage. This complication may occur more commonly in the colon, simulating ulcerative colitis or ileocolitis on microscopic inspection[2]. Previous publications suggest that leukaemic infiltration of the gastrointestinal tract occurs in all types of leukaemia but is less common in the myeloid form[3].

Ischaemia and necrosis of mucosal and submucosal infiltrates has been proposed as the likely cause of pseudo-obstruction, although autonomic dysfunction secondary to a toxic effect of chemotherapy has been implicated. When mechanical obstruction of the small or large bowel has occurred, a nodular leukaemic infiltrate can usually be identified in the submucosa. Luminal occlusion may occur gradually and mimic a malignant lesion, which can be difficult to differentiate on barium enema investigation.

Intestinal obstruction has been well described, especially in acute lymphatic leukaemia. Intussusception is thought to be the mechanism of obstruction in the small intestine[4], the likely cause being a leukaemic infiltration which causes localized thickening of the bowel. In the large bowel, an obstructive lesion or stenosis should always be distinguished from carcinoma.

Laparoscopic colorectal surgery: a prospective assessment and current perspective

Between August 1991 and June 1993, 74 laparoscopic and laparoscopically assisted colonic and rectal operations were performed. A variety of procedures were carried out including 32 total abdominal colectomies (group 1), 32 segmental resections (group 2) and ten constructions of a diverting stoma without formal resection (group 3). Indications for surgery were mucosal ulcerative colitis in 20 patients, carcinoma in 12, polyposis in six, Crohn's disease in seven and other conditions in the remaining 29. The 74 comprised 42 male and 32 female patients of mean age 45 (range 12–88) years. The median (range) duration of the procedure was 3·0 (1·0–6·5) h for the entire group, 3·9 (2·5–6·5) h for group 1, 2·9 (1·5–5·5) h for group 2 and 1·8 (1·0–2·5) h for group 3. The median (range) length of ileus was 3·0 (2–7) days overall; respective times for groups 1–3 were 3·5 (2–7), 3·0 (2–7) and 2·0 (1–4) days. The median (range) length of hospitalization was 7·0 (2–40) days, 8·1 (4–19) days in group 1, 7·0 (4–20) days in group 2 and 6·0 (2–40) days in group 3. Ten patients (14 per cent) developed intraoperative and 15 (20 per cent) postoperative complications; there were no deaths. These results failed to confirm any significant advantages of laparoscopic or laparoscopically assisted colorectal surgery. Specifically, neither the operating time, nor length of ileus, nor length of hospitalization was improved over standard procedures. Advances in technology and surgical technique may improve such findings in the future.

Laparoscopic surgery has been successfully used by gynaecologists for more than 15 years[1]. The majority of these procedures were diagnostic, although therapeutic intervention has recently gained widespread acceptance. General surgeons subsequently adopted pelvic laparoscopic techniques for other intra-abdominal applications; cholecystectomy, appendicectomy and herniorrhaphy have become more widely available. Much of the enthusiasm in both the surgical and lay communities has resulted from claims of decreased pain and shorter hospital stay associated with these minimally invasive procedures[2].

In an attempt to introduce these improvements into the field of colorectal surgery, a variety of procedures have been attempted laparoscopically. Anecdotal evidence suggests that some patients who have undergone laparoscopic procedures fared marginally better than historical controls who had similar operations conventionally[3,4]. Other studies have failed to find a clear benefit from the use of laparoscopy in colonic resection[5–7]. The aims of the present study were therefore to assess prospectively the potential value of laparoscopic colorectal surgery. The study analysed morbidity and mortality, and assessed any demonstrable advantages to the patient.

Patients and methods

In February 1991, two members of the Department of Colorectal Surgery (S.D.W., D.G.J.) embarked on a three-phase programme to introduce laparoscopic colorectal surgery to this institution. Phase I consisted of a 6-month period during which extensive experience with laparoscopic bowel resection was gained in animal models. Phase II overlapped with this and included a 3-month period during which skill was developed with laparoscopic cholecystectomy in humans. Phase III, initiated in August 1991, was the performance of laparoscopic colorectal surgery.

In May 1991, in conjunction with the American Society of Colon and Rectal Surgeons, a prospective registry was established[8]. This registry recorded morbidity, mortality, duration of operation, duration of ileus, length of hospital stay, and standard variables such as the patient's age, sex, diagnosis, indication for surgery and surgical procedure performed. Another goal at this institution was to reveal any differences in results between groups of patients who underwent total colectomy, segmental colectomy and diversion alone without resection.

Preoperative preparation was the same as for open procedures[9]. The techniques for laparoscopic colonic and rectal surgery have been described in detail elsewhere[10–12]. Briefly, all patients underwent standard mechanical cathartic bowel preparation in addition to receiving both oral and broad-spectrum parenteral antibiotics. The patient was placed in the supine modified lithotomy position in Allen

Table 1 *Procedures and indications for laparoscopic colorectal surgery*

stirrups (Allen Medical, Bedford Heights, Ohio, USA) to allow transanal colonic access for colonoscopic identification of the site of the lesion, if needed.

The abdomen was prepared and draped in the standard fashion to provide wide exposure. The patient was then placed in a steep Trendelenburg position. After pneumoperitoneum had been established with carbon dioxide to a pressure of 15 mmHg, the Veress needle was removed and a 10/11-mm trocar placed through a 1-cm paraumbilical incision. A 0° laparoscope was then introduced through the port and all subsequent work performed under direct endoscopic visualization.

Colonic mobilization consisted of dividing the attachments and peritoneal reflections of the appropriate portion of the colon. The colonic mesentery was not routinely divided. However, for laparoscopic stoma creation the mesenteric vessels were divided with haemoclips or pretied Endoloops (Ethicon Endosurgery, Cincinnati, Ohio, USA). Intracorporeal bowel division was accomplished with a 60-mm linear cutting–stapling device (ELC-60; Ethicon). Introduction of the ELC-60 necessitated exchange of the 10/11-mm cannula for one of 18 mm at the preselected stoma site in the left iliac fossa. After bowel transection the proximal end was retrieved through the 18-mm cannula and the colostomy formed in the usual fashion[10].

During laparoscopically assisted procedures, after full mobilization of the appropriate portion of the bowel the remainder of the operation was performed through a small incision. After the bowel was delivered through this incision, division of the mesenteric vessels and bowel (and creation of anastomoses) were all performed in the standard fashion[11,12].

Results

Between August 1991 and June 1993, 74 patients underwent laparoscopic and laparoscopically assisted colorectal surgery. The 74 comprised 42 male and 32 female patients of mean age 45 (range 12–88) years. The procedures performed and indications for surgery are listed in *Table 1*. *Table 2* shows the results for the whole series, and the duration of surgery, ileus and hospital stay in group 1 (total abdominal colectomy), group 2 (segmental colectomy) and group 3 (diverting colostomy). There were no operative or postoperative deaths; however, 25 of the 74 patients (34 per cent) experienced at least one complication (*Table 3*). The most common postoperative complications were prolonged ileus, intra-abdominal abscess and wound infection. Anastomotic leakage was documented by radiographic studies in two of the four patients who developed an intra-abdominal abscess. The remaining two patients who developed an abscess suffered inadvertent enterotomies: one was recognized at the time of laparoscopy and the other discovered on day 4 after operation when a water-soluble enema revealed a full-thickness defect at the top of a defunctioned rectosigmoid pouch. This patient recovered slowly and required multiple antibiotics for persistent fever. She also required repeated percutaneous drainage of intra-abdominal abscesses and parenteral nutrition for prolonged ileus. She was eventually discharged home 40 days after operation in satisfactory condition.

Three procedures were abandoned and converted to open surgery before any dissection and/or mobilization of the colon. The reasons for termination of laparoscopy included an iliac arteriotomy, which was repaired, in one patient and epigastric vessel lacerations in two others; these required vessel ligation to control bleeding. All of these patients did well and were discharged home in satisfactory condition. No other patients required immediate conversion without some colonic mobilization or dissection.

Twelve patients were operated on for carcinoma. The mean number of lymph nodes dissected was 19 (range 3–84). There were three Dukes' A lesions, seven Dukes' B and two Dukes' C. All of these operations were performed with curative intent.

Discussion

Because of the pain, disability and cosmetic insult accompanying traditional open procedures, there has been a great impetus to develop less invasive methods. Laparoscopic surgery appears to be rapidly fulfilling this need. The question is thus no longer whether laparoscopic techniques have a place in general surgery, but rather what are the limits of their application.

The first laparoscopic general surgical procedure to be performed was appendicectomy. Initially these operations were carried out as incidental procedures during gynaecological surgery. However, in some centres laparoscopic appendicectomy has become the accepted treatment for acute appendicitis. In 1987, Mouret performed the first laparoscopic cholecystectomy[1]. This promising new technique rapidly spread after experience in America was reported by Spau and associates[2].

Critical appraisal confirmed the acceptable morbidity rate associated with the technique when performed by appropriately trained individuals. Other general surgical procedures followed and anecdotal reports demonstrated the technical feasibility of laparoscopic enteric and colorectal surgery[13–15]. However, several crucial differences between colorectal surgery and other laparoscopic general surgical procedures must be highlighted. First, all other procedures entail working in only one quadrant, thus limiting or eliminating the need to relocate instruments and personnel. Second, most operations are performed on small spaces or organs, enabling the use of smaller (5 mm) cannulas. All ports should be at least 10 mm for intestinal surgery as

frequent repositioning of both camera and instruments is necessary. Third, most of these procedures involve either no specimen extirpation or removal of a specimen so small that it is easily accomplished through a small cannula or small skin incision. Fourth, none of the other procedures requires anastomosis and thus none of the associated potentially adverse sequelae exists. Fifth, none of the other operations is undertaken for malignancy and so the question of recurrence after resection does not arise. All of these differences mandate that laparoscopic colorectal surgery always be meticulously performed. They also often demand that an incision of some size be made to allow for mesenteric division, bowel resection, anastomosis or specimen retrieval. Such factors may contribute to the lack of dramatic difference between the outcome and recovery period of open and laparoscopic colorectal surgery.

The present results are in many ways consistent with those of recently published reports (*Table 4*). In this study the overall median hospital stay was 7·0 days. However, unlike the series of Jacobs *et al.*[3], no exclusions were made in analysing the data. Again unlike all other published reports, the majority of operations were total rather than segmental colonic resections. When group 2 (segmental colectomy) is analysed independently, the duration of hospital stay is not significantly different from those cited by others. Similarly, when group 1 (total colectomy) is assessed, no differences are noted for length of ileus or duration of hospital stay compared with other patients undergoing laparoscopically assisted total colectomy[4,16]. Similar to the findings of Larach *et al.*[17], the present 34 per cent overall morbidity rate arose primarily in the early stages of development. It was also found that this advanced technology had a steep 'learning curve'.

Another problem with comparative results among different institutions is the definition of 'resolved ileus' and the treatment of these patients before complete resolution. Some confusion may result from the fact that advocates of laparoscopic surgery may treat patients differently after laparoscopy than after standard laparotomy. Specifically, some send patients home on a clear fluid diet with instructions to advance their own diet as tolerated[18]. Binderow *et al.*[19] in a prospective randomized trial demonstrated a trend towards earlier discharge when patients receiving standard laparotomy were allowed to eat a regular diet on the first day after operation. The advent of laparoscopic surgery may alter management of 'standard' patients in the future.

A question of paramount importance is lymph node status and the appropriateness of minimally invasive technology for the treatment of colorectal carcinoma. The current standard of care for the treatment of large bowel cancer is abundant excision of lymph node-bearing tissue. No study has demonstrated that patients have a longer survival when an increased number of positive lymph nodes is removed. Therefore, it is not imperative that studies are compared with respect to the number of nodes harvested. Of significant importance, however, is the fact that there have already been numerous reports of recurrence at the site of cannula insertion after laparoscopic resection of colonic tumours[20–25]. These early reports emphasize the need for established registries to evaluate prospectively variables related to laparoscopic colorectal surgery.

Compromise of established surgical principles cannot be accepted to facilitate technique; technical advances must be made within the constraints such principles impose. These preliminary results are certainly not encouraging; however, it is hoped that continued development of both laparoscopic technology and technique will be associated with improved benefits for patients. Randomized trials will be necessary to demonstrate advantages over open surgery of laparoscopic colonic and rectal procedures. To date no such advantage can be substantiated.

Announcement

The British Journal of Surgery Society SRS Prize

The British Journal of Surgery Society is to make a generous annual donation of £500 to the Surgical Research Society to be used as a prize. The Committee of the SRS, on behalf of its membership, is pleased to acknowledge the gift with gratitude.

The SRS Committee has decided that the prize will be awarded for the best paper published in the *BJS* that originates from an SRS presentation in the preceding year. The Committee of the SRS will judge these papers at its January meeting and the prize will be announced and presented at the dinner of the SRS.

The SRS is pleased to maintain close ties with the Journal. Two months each year are special SRS issues and contain most of the papers from presentations made to the SRS. It is hoped that this prize will encourage more presenters of SRS papers to prepare manuscripts without detracting from the principle of the SRS to enjoy receiving reports of work in progress. Papers not making publication in the SRS issues *will not be ineligible* and the winner of the Patey Prize *may* submit a paper and be equally eligible. It should be noted that any paper submitted as a result of presentation to the SRS passes through the same rigorous process of referee analysis and editorial criticism by the Journal; publication is not guaranteed.

SRS authors should identify the January or July meeting of the presentation on the submitted manuscript. Papers will automatically be collected and reviewed for the prize. Those already published in 1993 issues will automatically be included for consideration of the prize to be awarded for the first time in January 1994.

'Thank you' to The British Journal of Surgery Society for fostering and encouraging surgical research.

A combination of laparoscopic and rectoscopic procedures has enabled complete resection of the sigmoid colon and eliminated the need for minilaparotomy when constructing the anastomosis or withdrawing the specimen. This combined procedure was performed in different ways in a series of animal models until the definitive technique had been standardized. These techniques were then successfully used in 15 consecutive medium-sized pigs. Histological evaluation of the specimens, including the anastomosis (examined 2–3 weeks after operation) confirmed the efficacy and safety of the method.

Laparoscopic techniques have been used to carry out highly selective vagotomy, nephrectomy and colonic resection. Currently, endoscopic colonic resections are laparoscopically assisted: endoscopic preparation of the bowel is combined with anastomosis or withdrawal of the specimen carried out through a minilaparotomy[1–5]. Laparoscopy and rectoscopy allow completion of the endoscopic resection of the left or sigmoid colon, eliminating the need for minilaparotomy.

A combined laparoscopic–rectoscopic approach to sigmoid colectomy was developed and performed in different animal models during a 1-year *in vivo* study approved by the local committee for animal experiments. The procedure is illustrated and discussed.

Materials and methods

Operations were performed in three species: seven minipigs, nine sheep and 16 medium-sized pigs. Seventeen animals were used to determine the optimal animal model, appropriate apparatus and definitive operative technique. The procedure (as an endoluminal or extraluminal variant) was then performed in 15 medium-sized pigs in a standardized animal trial.

Animals were fasted for 3 days and given a preoperative enema. Antibiotic prophylaxis was not used. All animals were operated on under general anaesthesia with central venous catheterization and cardiac monitoring. After operation, fasting continued for 1–2 days. The animals were killed 2–3 weeks after operation and the specimen, including the anastomosis, was sent for histological study.

Operative procedure

The surgeon and camera operator stood to the right and the assistant to the left of the animal. The video equipment was positioned on the assistant's left. After establishing pneumoperitoneum, four ports were placed in the lower abdomen (*Figure 1*). A 10-mm cannula, inserted to the right of the umbilicus, was used to introduce a 50° telescope (Richard Wolf, Knittlingen, Germany). An 11-mm trocar and a 5-mm silicon cannula were introduced into the lower right quadrant: the first was an operative port placed about 7 cm below and laterally to the umbilicus; the second, close by the anterior iliac spine, allowed insertion of a curved grasper. A 5-mm cannula for graspers was placed in the left lower abdomen, opposite the 11-mm port. Suprapubic catheterization of the bladder was performed and a catheter left *in situ*. The operating table was placed in a mild Trendelenburg position and tilted to the right.

The sigmoid colon was grasped and fixed to the abdominal wall by means of two slings passed through the mesocolon with forceps. Each end of the sling was held by a 3-mm needle-holder introduced into the peritoneal cavity through two small incisions in the left lower quadrant. The vessels were ligated and divided. A polydioxanone extracorporeal slipknot developed for monofilament material (*Figure 2*) was used for vessel ligature. The slings were removed and a modified transanal endoscopic microsurgery rectoscope (Richard Wolf)[6,7] (*Figure 3*) introduced up to the rectosigmoid junction.

Endoluminal procedure. The anvil of a Proximate ILS 29-mm stapler (Ethicon, Norderstedt, Germany) was inserted into the left colon via a custom-made introducer (*Figure 4*). Two polydioxanone 0 slipknots were tightened around the sigmoid colon at its proximal and distal levels, keeping the introducer inside. The anvil was fixed to the descending colon by a polydioxanone 2/0 slipknot and the sigmoid colon divided between ligatures. A cable-binding technique was specially developed to fix the anvil safely. This was prelocked extracorporeally (*Figure 5*) and tightened around the colon by means of a special pusher, reinforcing the polydioxanone ligature. After division of the proximal rectum the specimen, fixed around the introducer, was withdrawn through the rectoscope (*Figure 6*). The loop of another prelocked cable-binder was kept around the rectum, held with graspers, and the rectoscope withdrawn and exchanged for the stapler shaft under laparoscopic control. The spike of the stapler was advanced through the open stump and the cable-binder tightened around it. Any excess tissue was carefully resected. Using a new anvil-holder, the anvil was inserted into the shaft and the stapler closed and fired.

Extraluminal procedure. Two polydioxanone 0 slipknots were tightened around the sigmoid colon at its proximal and distal levels. A small cut was made on the upper rectum, just below the distal ligature, and on the left colon, just over the proximal ligature. The anvil of a Proximate ILS 29-mm stapler was introduced up to the left colon, letting the introducer pass through the two cuts (*Figure 7a*) by gently pushing and twisting it through the operative rectoscope. A polydioxanone slipknot was tightened around the left colon to fix the anvil and the introducer withdrawn. The sigmoid colon was divided,

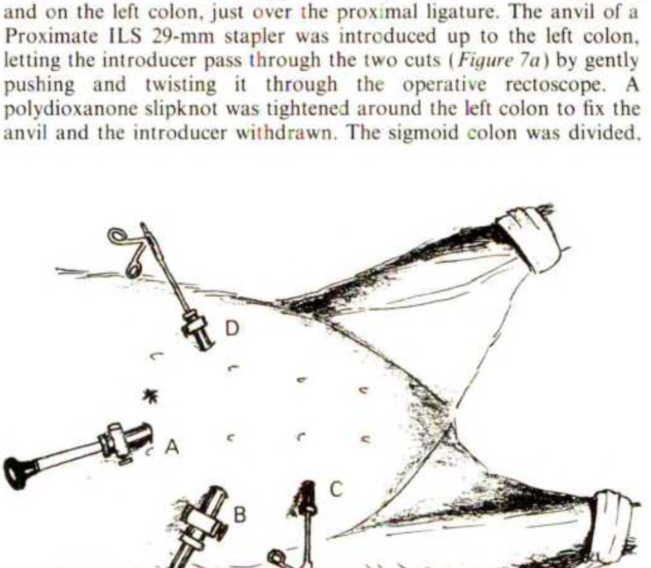

Figure 1 *Positions of the introduction sites. A, 10-mm port for the telescope; B, 11-mm port for operative instruments; C, 5-mm silicon cannula for the curved graspers; D, 5-mm port for grasping forceps*

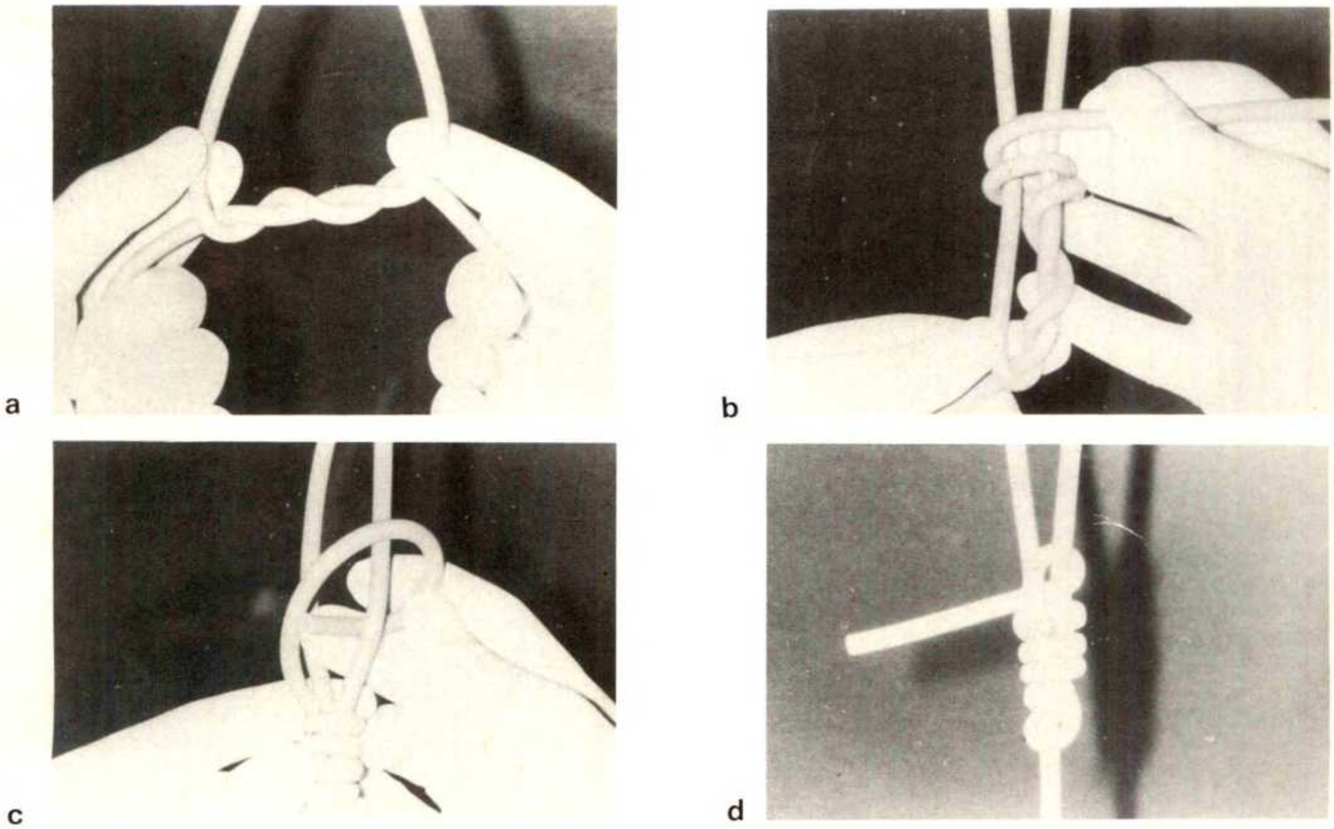

Figure 2 *Technique for the Melzer–Bueß knot.* **a** *First, a surgical knot was made;* **b** *one head of the thread was then twisted twice around the other head, according to the Roeder technique;* **c, d** *the knot was completed by a double-blocking passage*

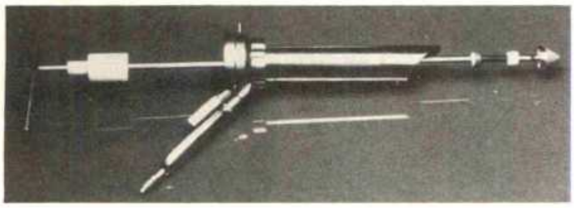

Figure 3 *The Bueß operative rectoscope with the loaded anvil-introducer*

completing the cut between the ligatures. With two graspers holding the upper rectum, the distal cut was completed and the specimen grasped by a forceps inserted through the rectoscope and withdrawn (*Figure 7b*). The spike of the stapler was advanced *per rectum* under laparoscopic control and the cable-binder tightened. A second prelocked cable-binder was tightened around the proximal stump to ensure fixing of the anvil. The anvil was inserted into the shaft, and the stapler closed and fired.

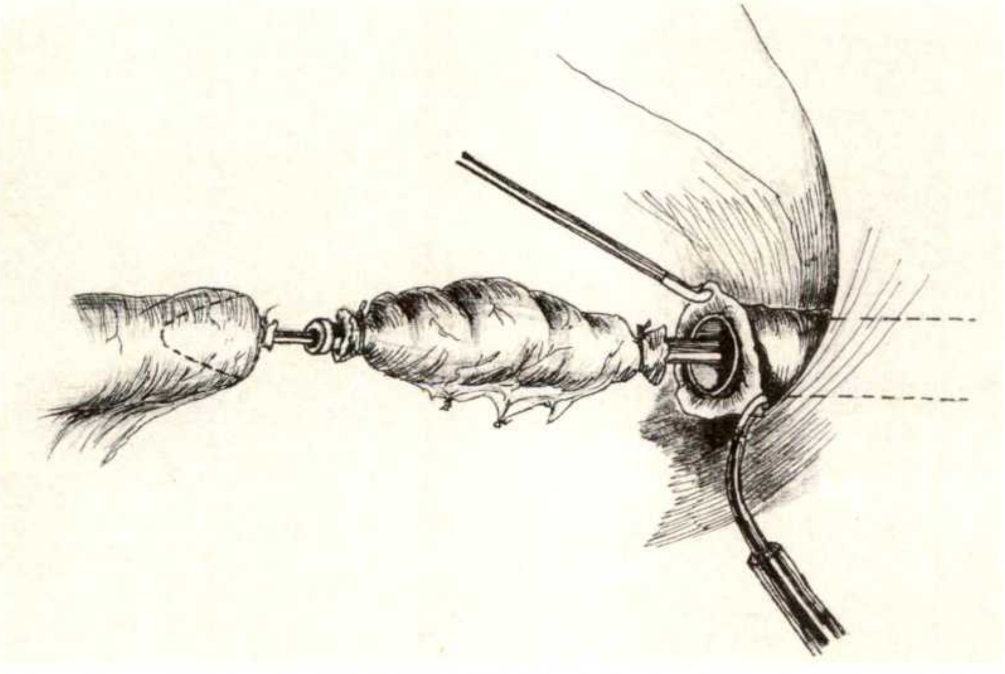

Figure 4 *The anvil was introduced up to the proximal sigmoid colon (endoluminal procedure); the proximal sigmoid was divided between ligatures. A ligature on the proximal stump fixed the anvil temporarily*

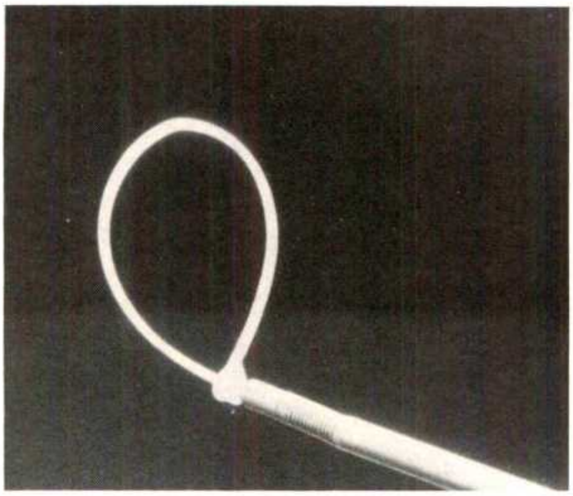

Figure 5 *A prelocked cable-binder inserted into the special pusher. This is a manufactured plastic device with ratchets that do not slip back when tightened*

Results

The mean duration of surgery was 135 (range 100–180) min.

All animals had an uneventful postoperative course with no clinical signs of sepsis. Autopsy in one animal showed a localized encapsulated fluid collection with a few adhesions. In three animals there was a small area of dehiscence with histological signs of abscess formation. These abnormalities were found in the first five animals to be operated on.

Discussion

The main technical difficulties of the laparoscopic approach to left colectomy and sigmoidectomy are formation of the anastomosis and removal of the specimen. Development of the anvil-introducer and the cable-binding technique overcame such problems.

The anvil-introducer is a device with an air-proof system that is fixed to the rectoscope; it avoids any air leakage once the bowel has been opened.

The cable-binding technique has been developed to avoid the intracorporeal purse-string ligature of the two stumps. This

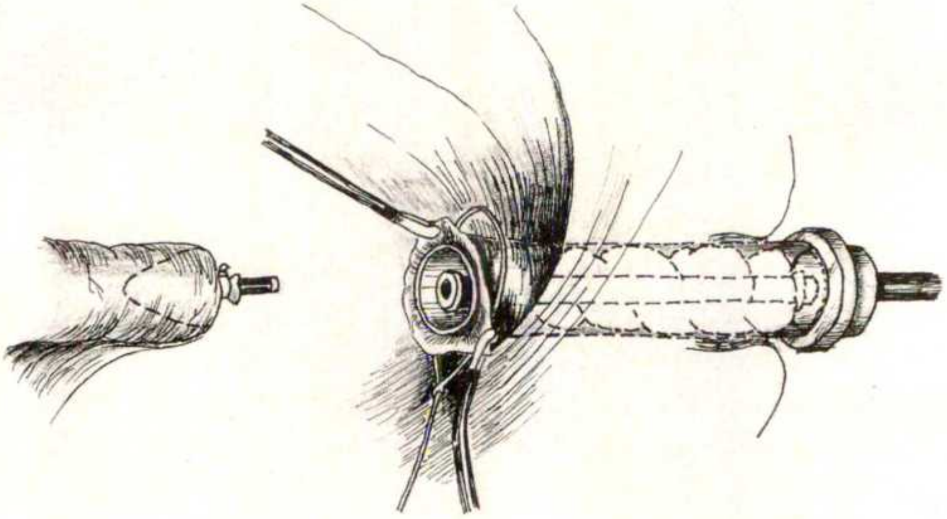

Figure 6 *Specimen retrieval during the endoluminal procedure. A prelocked cable-binder was kept around the distal stump while the resected bowel was withdrawn through the rectoscope via the anvil-introducer*

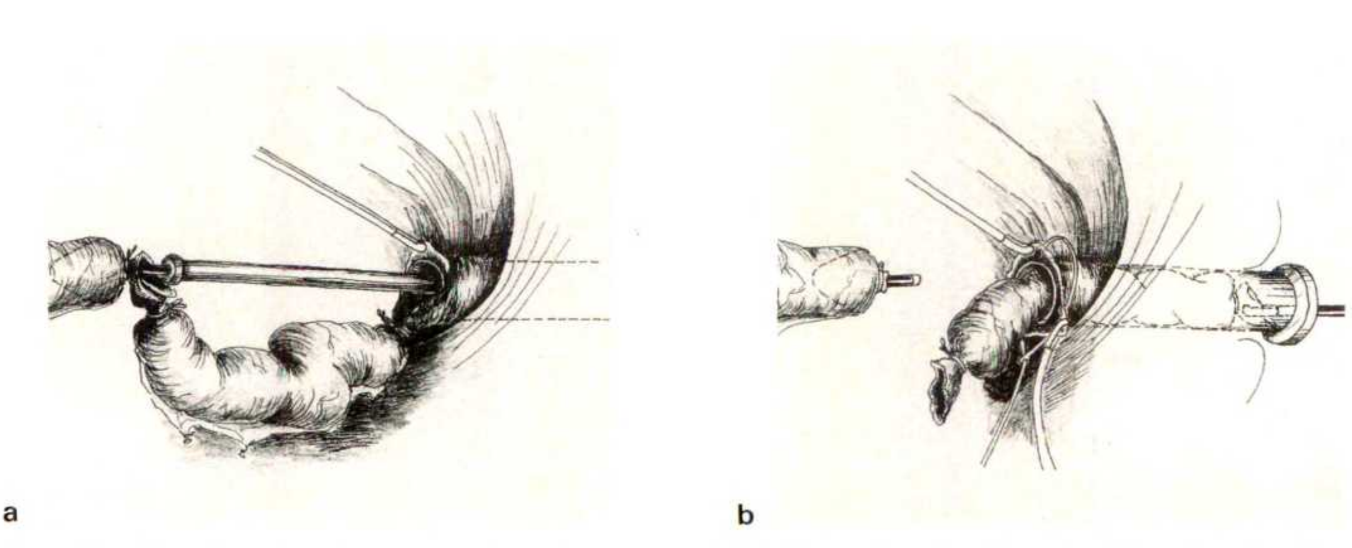

Figure 7 **a** *Introduction of the anvil during the extraluminal procedure: the introducer was gently pushed through two small cuts at the level of the proximal rectum and sigmoid colon.* **b** *Removal of the specimen by means of a grasping forceps inserted through the rectoscope (extraluminal procedure)*

technique is difficult and time consuming when performed laparoscopically. The use of a prelocked cable-binder allows fast and tight closure of the stumps. The use of endoloops or slipknot ligatures is not as safe as that of cable-binders, particularly in the closure of a short rectal stump.

Careful freeing of colonic and rectal stumps from the mesocolon is mandatory: the use of a 50° angled telescope is helpful for a complete check of both sides of the intestinal wall before and after closure of the stapling device.

The extraluminal variant of the combined sigmoidectomy avoids contact between the anvil-introducer and the tumour in case of suspected or proven neoplasm, and such a technique brings the anvil up to the proximal stump in the case of stenosing diverticulitis.

Because of the diameter of the rectoscope, removal of tumours up to 4 cm in size can be performed. Benign and soft neoplasms larger than 4 cm that can be compressed can also be removed.

Laparoscopic lymphadenectomy is possible and safe[8–10] as ligature of the inferior mesenteric vessels is feasible, but extensive and radical lymph node dissection may not be curative.

Clinical application of this method is under way in patients with benign and malignant tumours and complications of diverticular disease.

Acknowledgements

The Alexander von Humboldt Foundation supported M.M.L. with a research fellowship and is acknowledged with gratitude. The BMFT, the Ministry for Science and Technology of the then Federal Republic of Germany, is also thanked for its support.

Thanks are due to Mr Klaus Roth and Mr Marc O. Schurr, who constructed some of the new instruments, and to Miss Birgitte Erker for technical assistance.

Change towards earlier stage at presentation of colorectal cancer

M. H. E. Robinson, W. M. Thomas, J. D. Hardcastle, J. Chamberlain* and C. M. Mangham

*Department of Surgery, University Hospital, Queen's Medical Centre, Nottingham and *Section of Epidemiology, Institute of Cancer Research, Department of Health and Social Security Screening Evaluation Unit, Sutton, UK*

Correspondence to:
Mr M. H. E. Robinson, Department of Surgery, University Hospital, Nottingham NG7 2UH, UK

A study was carried out to investigate the change in stage at presentation of patients with colorectal cancer over 10 years. Cases were identified from the control group of subjects enrolled into a randomized controlled study based on Haemoccult screening for colorectal neoplasia. Of 405 subjects in the control group (presenting with symptomatic colorectal cancer, 206 presented before 1989 and 199 since then. The number of patients with Dukes' stage A carcinoma diagnosed since 1989 rose from 21 (10·4 per cent) to 35 (18·1 per cent); this change occurred for rectosigmoid tumours (9·9 per cent before 1989, 28 per cent after 1989) but not for colonic cancer (10·9 per cent before 1989, 11·5 per cent thereafter). An increase in the proportion of patients with symptomatic early-stage rectosigmoid cancer has been observed in the past 10 years. No such change occurred in those with colonic cancer. This may reflect a change in awareness of the disease and its symptoms by patients and general practitioners.

More than 17 300 people died from colorectal cancer in the UK in 1988, the disease accounting for 12 per cent of all cancer-related deaths[1].

Prognosis is determined largely by the extent of spread of the tumour at diagnosis. Three large studies of consecutive unselected patients with colorectal cancer presenting to non-specialist hospitals have shown crude 5-year survival rates of 25·8–27 per cent. This reflects the substantial proportion of patients presenting with advanced disease, only 5·7–6·3 per cent having Dukes' stage A cancers[2–4].

Cuthbert Dukes observed that:

> 'there is no doubt that the proportion of A and B cases could be increased by earlier diagnosis. The relative proportion of A, B and C cases in the future will provide a delicate indication as to whether or not propaganda for the earlier recognition of malignant disease has been successful in respect of the lower end of the alimentary tract'[5].

Vellacott *et al.*[6] reported, for a 16-year period to 1986, a rising detection rate of symptomatic Dukes' A tumours, and concluded that this was attributable largely to improved provision and quality of diagnostic facilities, increasing use of double-contrast barium enema and availability of a local open-access flexible sigmoidoscopy service.

A large randomized controlled trial[7] of faecal occult blood (FOB) testing in the early detection of colorectal cancer has been taking place in Nottingham since 1981. The population is randomized to test and control groups. The test group is educated as to the importance of rectal bleeding and offered FOB testing, whereas those in the control group are identified but not contacted. The stage at presentation of colorectal cancer in the control group should mirror that of the whole population and the aim of this study has been to describe the change in stage at presentation of these subjects in Nottingham over the past decade.

Patients and methods

Subjects aged 50–75 years were identified from general practitioner (GP) registers. After stratification by age and sex, they were randomized by household into a test group (sent FOB tests) and a control group (no tests). The development of colorectal neoplasia (not just that presenting for surgery) in both groups was monitored by regular scrutiny of the pathology records of the Nottingham hospitals, by the Trent Region Cancer Registry and through information supplied by GPs. The Family Health Services Authority notified the study of those leaving the area and these patients were 'flagged' at the National Health Service Central Registry.

The test group received an explanatory letter from their GP stressing the importance of early detection and stating that 'rectal bleeding is an important symptom of large bowel disease ... including cancer'. A Haemoccult (Rohm, Wietarstadt, Germany) test pack was enclosed, which they were invited to complete and return. Those doing so were termed 'acceptors' and those not responding or returning the tests uncompleted were 'refusers'. The refusers present with symptomatic disease in the same way as the control subjects. Control subjects were not contacted but were identified and followed for the development of colorectal cancer as described above. To minimize 'contamination' of the control group, publicity about the study was kept to a minimum.

Cancers were staged according to Dukes' classification[8], to which was added stage 'D' for patients presenting with distant metastases or locally irresectable disease[9]. When calculating the proportion of cancers at any pathological stage, unstaged tumours were excluded from the denominator.

Rectosigmoid tumours are defined as those within 20 cm of the anal verge, the remainder being colonic.

The study started in 1981 and data were analysed for cancers presenting to 1 September 1991. An arbitrary date of 31 December 1988 was used to divide the study period into two approximately equal halves with respect to person-years of observation and cancers diagnosed. The section before 1989 covered a much longer time period because of slow recruitment and a gap between the pilot study and the start of the main trial.

Statistical comparisons were made using the χ^2 test.

Results

Since 1981, 155 101 subjects from 92 general practices were recruited into the study, 77 670 in the control group. From the test group, 34 448 patients (44·5 per cent) refused the offer of screening.

Of the control group subjects, 405 (5·2 per 1000) presented with symptomatic colorectal cancer: 206 were diagnosed before 1 January 1989 and 199 since then. The earlier period represented 178 476 (49·4 per cent) of the total 361 136 control patient study-years. The two groups were well matched for age and sex (*Table 1*).

There was a significant increase in the proportion of Dukes' stage A cancers diagnosed since 1989 from 10·4 to 18·1 per cent ($\chi^2 = 4{\cdot}77$, 1 d.f., $P < 0{\cdot}05$), and a fall in those presenting with distant metastases from 27·7 to 17·6 per cent ($\chi^2 = 5{\cdot}73$, 1 d.f., $P < 0{\cdot}02$). The proportion of patients presenting with localized

disease (stage A or B) rose from 39·1 to 57·0 per cent (χ^2 = 12·65, 1 d.f., P < 0·001) (*Table 2*).

After 1989, 41·7 per cent of tumours (83 of 199) were in the rectosigmoid – a non-significant decline from 50·5 per cent (104 of 206). These subgroups of patients with colonic and rectosigmoid carcinoma were similarly well matched for age and sex for the two time periods (*Table 1*). There was a significant increase in the proportion of Dukes' A rectosigmoid cancer from 9·9 to 28 per cent (χ^2 = 7·20, 1 d.f., P < 0·01), whereas the proportion of Dukes' A colonic cancers remained static with time (10·9 per cent before 1989, 11·5 per cent thereafter). The proportion of rectosigmoid cancers presenting at stage 'D' decreased from 26·7 to 14 per cent (χ^2 = 4·54, 1 d.f., P < 0·05) (*Table 2*).

The effect of patient and GP awareness was assessed in the test group subjects. Refuser subjects in all screening studies have low levels of health awareness[10]. It is to be expected that this will be reflected in a high proportion of advanced cancers and relatively few stage A tumours. Of 114 staged colonic cancers diagnosed in subjects who did not accept the Haemoccult test, six (5·3 per cent) were Dukes' stage A and 46 (40·4 per cent) had distant metastases or an irresectable primary. Twenty-two (25 per cent) of the 87 staged rectosigmoid cancers in refusers were at stage A while only 22 had stage 'D' disease. At neither site was there a significant difference between the proportions in the two time periods, but patients with rectosigmoid cancer presented significantly more often at stage A (χ^2 = 9·61, 1 d.f., P < 0·01) and less often at stage 'D' (χ^2 = 5·00, 1 d.f., P < 0·05) than their counterparts with colonic cancer (*Table 3*).

Discussion

These results could be explained by: (1) a trend towards less virulent disease; (2) improved radiology and/or endoscopy facilities; or (3) increased awareness of the disease and its symptoms by patients and GPs. If the first were true then the change should occur equally for rectosigmoid and colonic carcinoma. If the second were important, given that most rectosigmoid cancers are first diagnosed by digital examination and/or rigid sigmoidoscopy[6], the change would be more likely in those with colonic tumours. The polypectomy rates in the two time periods may be taken as an indicator of the number and quality of diagnostic examinations performed. Between 1981 and 1989, seven carcinomas were treated by polypectomy in the control group subjects compared with four after 1989 (χ^2 = 0·41, 1 d.f., P = 0·52). The numbers of adenomas treated by polypectomy were 73 and 78 respectively for the two periods (χ^2 = 0·03, 1 d.f., P = 0·85). These data are consistent with no change in the quality of diagnostic investigation with time.

Finally, an important symptom of rectal cancer is bleeding, occurring in 70 per cent of rectal but in only 35 per cent of colonic cancers[2]. Refusers differ from controls in having received the letter of invitation and, in spite of failure to complete and return the tests, the message from the letter may have been absorbed. A further potentially important factor is the impact of the study on educating local GPs. In 1979, doctor-related delay to diagnosis occurred in up to one-third of colorectal cancers and was longer for rectosigmoid lesions (15·3 weeks) than for colonic tumours (11·2 weeks)[11]. Rectal examination is carried out in general practice to a varying extent[12]. A 10-year review of GP awareness of colorectal cancer from 1978 to 1988 found that fewer than half of all digitally palpable rectal cancers had been noted by the GP (8 per cent of patients being referred without having had a rectal examination)[13]. A questionnaire survey of Nottinghamshire and Leicestershire GPs is currently addressing questions of knowledge and awareness of the disease in the study area and a neighbouring control area.

It is likely that the changes observed result from increasing awareness of the disease and its symptoms. A similar trend towards earlier diagnosis has recently been reported for gastric cancer[14]. These encouraging trends may reflect nationwide change and probably relate to local special interest in the diseases in question.

Follow-up after inguinal herniotomy or surgery for hydrocele in boys

J. A. Morecroft,
M. D. Stringer,
M. Higgins,
S. J. K. Holmes and

WC1N 1EH, UK

A retrospective review of 556 boys who had undergone inguinal herniotomy or surgery for hydrocele was carried out to assess the value of early routine postoperative follow-up. Of 386 children given an appointment, 319 (82·6 per cent) attended. The testis was no longer palpable in the normal scrotal position in 12 boys; eight were normal on further review and four required orchidopexy. Six hydroceles, all of which resolved, and four contralateral hernias were detected. Nineteen boys (4·9 per cent) were referred later with recurrent hernia (two patients), ipsilateral high testis (two), or contralateral hernia or hydrocele (15). Of 170 children not given a routine appointment, ten (5·9 per cent) were subsequently referred back with a transient hydrocele (two) or a contralateral hernia (eight). After a total of 440 appointments, eight boys (1·8 per cent) were found to have a significant abnormality. The rate of referral back to hospital was similar in both groups. Early discharge would make more efficient use of outpatient resources without significantly affecting overall outcome.

The policy of routine follow-up after all surgical operations has been superseded by a more selective approach. Many surgeons continue to follow boys who have undergone inguinal herniotomy or ligation of a patent processus vaginalis because of possible damage to the vas deferens and vessels, either by hernia incarceration or during dissection, and the consequent risk of testicular atrophy or malposition[1]. A difference in attitudes to routine follow-up after such operations during the past 5 years has allowed a retrospective examination of its value.

Patients and methods

Boys who underwent inguinal herniotomy or ligation of a patent processus vaginalis between August 1986 and December 1990 were identified from the hospital operation register. One surgeon did not arrange routine outpatient follow-up appointments. Clinical characteristics in the case notes were reviewed: age at operation, incarceration of hernia requiring reduction by taxis, side of hernia or hydrocele, grade of surgeon, whether a follow-up appointment was made, attendance for review, findings at the outpatient clinic and any subsequent related problem for which the patient attended. Boys who had undergone orchidopexy for a simultaneous ipsilateral undescended testis were excluded. The two groups were compared by the χ^2 test using Statistics (Blackwell Scientific Software, Oxford, UK).

Results

A total of 559 boys were identified as having undergone inguinal herniotomy or processus vaginalis ligation. The case notes of one child could not be located and orchidopexy had been performed on two, leaving 556 patients for analysis. Outpatient follow-up appointments were given to 386 boys and 170 were discharged to general practitioners. There was no difference between the two groups with regard to age at operation, incarceration at the time of presentation, side of operation or grade of operating surgeon (*Table 1*).

Some 319 boys (82·6 per cent) attended for review after a median interval of 6 (range 3–15) weeks and after a mean of 1·1 (range 1–5) appointments. Of those who attended, 158 (49·5 per cent) were seen by the surgeon who performed the operation. In 12 boys the testis was no longer palpable in the normal scrotal position; on further review, between 3 and 6 months later, eight were normally positioned and four required orchidopexy. Six testes were surrounded by a hydrocele but these resolved after 3 months. Four contralateral hernias were detected. Nineteen boys (4·9 per cent) were later referred back: two with recurrent hernia, two with a high testis and 15 with a contralateral hernia or hydrocele (*Table 2*).

Of the 170 boys not given a routine follow-up appointment, ten (5·9 per cent) were subsequently referred back: two with an

ipsilateral hydrocele, one of which resolved spontaneously, and eight with a contralateral hernia.

Discussion

From 440 appointments only eight patients with significant abnormalities requiring further intervention were identified, a yield of one abnormality for every 55 appointments offered. This does not represent efficient use of outpatient resources.

The potential benefit of routine follow-up after inguinal surgery in boys is the detection of iatrogenic testicular malposition or atrophy, contralateral hernia or hydrocele, and wound complications. This must be balanced against the use of finite outpatient resources, the inconvenience to patients and parents, the child's anxiety of returning to hospital and the false reassurance that is felt if a related problem subsequently develops.

Follow-up at 6–12 months might reduce the number of self-limiting problems that are seen, such as transient hydrocele, and allow better assessment of testicular atrophy and malposition, but would probably lead to a higher non-attendance rate.

Five of the six boys who subsequently required orchidopexy were under 18 months of age at the time of surgery. Increased awareness about testicular position and early orchidopexy[2], by parents and primary healthcare teams, might allow these children to be referred back if discharged without early postoperative follow-up.

Routine follow-up allows audit of results[3], but only 50 per cent of the present patients who attended were reviewed by the operating surgeon. Only 25 per cent of wound complications following adult elective hernia repair are detected at outpatient follow-up and a rigorous community-based postoperative surveillance programme is needed to collect accurate and comparable information for audit[4].

The possible complications of inguinal surgery should be outlined in an information sheet given to parents and in a discharge summary sent to the general practitioner. An invitation to discuss or review any specific problem would reduce unproductive outpatient visits for most patients and improve the service to others by making available additional outpatient time.

Total pelvic exenteration: a justified procedure

J. Th. Plukker, J. G. Aalders*, H. J. A. Mensink† and J. Oldhoff

*Departments of Surgical Oncology, *Obstetrics and Gynaecology, and †Urology, Groningen University Hospital, The Netherlands*

Correspondence to:
Dr J. Th. Plukker, Division of Surgical Oncology, Groningen University Hospital, North Netherlands Comprehensive Cancer Centre, 9700-RB Groningen, The Netherlands

Twenty patients with advanced primary or locally recurrent pelvic tumours treated by total pelvic exenteration are described. There were no operative or postoperative deaths. The most frequent postoperative complications appeared to be related to previous irradiation. Four patients developed non-fatal intestinal complications within 30 days of operation that required further surgery. After a mean follow-up of 19 months the crude 2-year survival rate was 40 per cent. This procedure is judged to be useful in a selected group of patients.

Mutilating radical resections such as total pelvic exenteration are occasionally justified. This procedure can be used to remove locally advanced pelvic tumours *en bloc* with the rectum and sigmoid colon, bladder, distal ureters and internal reproductive organs. It is sometimes possible to perform a modified procedure by saving the anal sphincters or partially preserving the bladder without compromising radicality[1-6].

The best candidates for total pelvic exenteration are patients with a locally invading central pelvic tumour without evidence of distant metastases. Without this procedure these patients will have a miserable death as a result of internal fistula, bleeding, pain caused by tumour invasion into the lumbosacral plexus, and a rectal syndrome. Total pelvic exenteration may offer them a chance of local tumour control with improved quality of life and, possibly, cure[4-7]. However, this procedure may result in serious morbidity and even death, and the question of whether it is worth while has to be asked. This study reports experience with 20 patients.

Patients and methods

Between August 1981 and September 1990, 20 patients underwent total pelvic exenteration in the Department of Surgical Oncology. They comprised 15 women and five men of median age 58 (range 38-70) years. Disease in each patient was staged by physical examination, chest radiography, thoracic and abdominal computed tomography, urography and cystoscopy.

The indications for total pelvic exenteration are summarized in *Table 1*. In nine patients the procedure was carried out for primary pelvic malignancy and in 11 for recurrent disease. The mean interval between the first treatment for cancer and total pelvic exenteration in patients with recurrence was 24 months. Previous surgery included anterior resection in three patients, abdominoperineal resection in one and hysterectomy in three.

Thirteen of the 20 patients had been treated previously with radiotherapy of the pelvic organs in doses ranging from 40 to 65 Gy with conventional fractionation.

The original technique of total pelvic exenteration as described by Brunschwig[8] was performed in nine patients. In the other 11 a modified procedure was carried out. In seven patients a very small rectal stump beneath the levator muscle was left *in situ* (Hartmann's procedure) and in four other patients colorectal anastomosis was performed. In 17 patients total cystectomy was needed. Urinary diversion was achieved by means of an ileal conduit as described by Bricker[9] in 11 patients and by means of a sigmoid conduit in six. In three patients partial cystectomy with a U shaped ileocystoplasty and ureteric reimplantation was performed, with ureterointestinal anastomosis using the Leadbetter technique.

Subsequently, four patients also underwent inguinal lymph node dissection. In two patients the groin dissection was part of the primary strategy in the treatment of recurrent vaginal and rectal cancer. In the other two this dissection was carried out for inguinal node metastases that developed during follow-up at 5 and 6 months after pelvic exenteration for vaginal melanoma.

Disease in patients with colorectal carcinoma was staged by the Dukes-Astler-Coller classification[10]. Survival was expressed by a Kaplan-Meier life-table.

Results

The mean operating time was 5·5 (range 5-7) h and the mean blood loss 2900 (range 1500-6500) ml. The mean postoperative hospital stay was 27 (range 13-90) days.

Although some patients showed significant postoperative morbidity (*Table 2*), there were no hospital deaths. Nine patients had an uneventful postoperative course. Among the other 11, eight developed one or more early complications within 30 days of operation. Serious problems requiring re-exploration in the immediate postoperative period occurred in four patients.

Small bowel obstruction and enterocutaneous fistula were the major complications most frequently encountered. Abscess formation in the abdominal wall or the perineum was another frequent problem. Two of three patients with small bowel complications in the early postoperative phase had a history of intensive radiotherapy to the pelvis. *Table 3* shows the rate of complications according to whether previous radiotherapy was given. The overall morbidity rate was substantially lower in the unirradiated group.

Enterocutaneous fistula occurred twice after standard total pelvic exenteration and once after the modified procedure.

In one very obese woman, necrosis of the ileal loop required reconstruction using an ileocaecal conduit. None of the patients with a sigmoid conduit developed small bowel problems.

Presented to the European Society of Surgical Oncology in Brussels, Belgium, October 1990

Depression	1		

Table 3 *Complications and previous irradiation*

	No problems	Major problems		Minor problems	
		Early	Late	Early	Late
Previous radiotherapy ($n = 13$)	5	3	4	5	1
No previous radiotherapy ($n = 7$)	4	1	0	2	0
Total ($n = 20$)	9	4	4	7	1

Late complications requiring readmission to hospital were observed in five patients. There were two stoma-related complications, a parastomal hernia and a colostomy stenosis in one patient each. Relaparotomy was required in three patients because of late small bowel obstruction, and in one patient nephrectomy was necessary for chronic pyelonephritis. One patient was treated for extensive bacterial spondylitis of L1–L4.

Follow-up was complete in all patients, with a range of 7–98 months. In 12 patients recurrent disease developed after a median of 8 (range 5–29) months. These recurrences were usually in the lung and liver. Pelvic recurrence was seen in only three patients after a mean follow-up of 19 months. Two of these patients, one with locally advanced recurrent rectal cancer and the other with recurrent carcinoma of the cervix, are still alive after 31 and 18 months respectively. The third patient had recurrent endometrial carcinoma and died 14 months after surgery.

The median overall survival period was 18 (range 7–98) months with a crude 2-year survival rate of 40 per cent. Ten patients died a mean of 12 months after operation (*Figure 1*). Eight patients are still alive without evidence of disease 17–98 (median 35) months after surgery. The median survival was 7 months after total pelvic exenteration when the lymph nodes were involved and 26 months in patients with histologically negative nodes. The survival time was similar in colorectal and gynaecological malignancy.

Of the nine patients with rectal cancer four, all with a primary advanced tumour, are free from recurrence a mean of 51 months after operation. Of these, three had Dukes' B_2 and one Dukes' C tumours. Of the five patients who underwent total pelvic exenteration for recurrence of Dukes' C rectal carcinoma (four) or locally advanced primary Dukes' C rectal cancer (one), four died with distant metastases without local recurrence a mean of 12 months after operation. One patient is alive 31 months after total pelvic exenteration with local pelvic recurrence combined with distant tumour.

Of the six patients with cancer of the cervix, three have no evidence of disease a mean of 50 months after operation. Two patients died with distant recurrence after 7 and 16 months, and one patient is alive with local recurrence 18 months after total pelvic exenteration.

Two patients with vaginal melanoma and one with vaginal carcinoma died from remote disease but without local recurrence at 7, 17 and 8 months respectively. The patient who has been treated for advanced bladder cancer is alive with no evidence of disease after 26 months.

Discussion

Local pelvic recurrence can produce extremely distressing and usually disabling symptoms such as deep pelvic pain, urinary or faecal fistula and abscess. To improve quality of life in these patients by achieving local control, an extended surgical procedure such as total pelvic exenteration can sometimes be performed to resect the tumour along with invaded adjacent organs.

The first single-stage total pelvic exenteration was performed by Alexander Brunschwig in 1946. Later, he reported 22 patients of whom seven died in hospital[8]. Despite many improvements in operative and anaesthetic techniques and better preoperative and postoperative management, there is still a relatively high postoperative morbidity rate, whereas the reported mortality rate is about 5–10 per cent[11–13].

Candidates for pelvic exenteration should have no evidence of extrapelvic spread. Total pelvic exenteration is usually performed for the treatment of recurrent cervical and vaginal carcinoma. There is only a thin layer of loose connective tissue between the perirectal fat and the vaginal wall with its lymphatic connections[14]. Owing to the proximity of these organs and the trigone of the bladder, it is necessary to perform total pelvic exenteration for these locally advanced or early recurrent central pelvic tumours.

The 5-year survival rates in the literature in patients undergoing total pelvic exenteration range from 30 to 40 per cent[7]. The present results are consistent with this, with three of seven patients with cervical and vaginal carcinoma still alive with no evidence of recurrence a mean of 50 months after operation.

After resection of rectal cancer, local pelvic recurrence is also a significant problem. It is arguable whether total exenteration is suitable for local recurrence after abdominoperineal resection[2,15]. In many of these cases total pelvic exenteration has to be combined with sacral resection[16–19]. There is also some doubt about the applicability of the procedure to locally extensive primary colorectal carcinoma[5,15,20,21], but we believe that it should be considered in the absence of extrapelvic metastases. When there is tumour invasion in the trigone, at the ureterovesical junction or in the periprostatic region, total pelvic exenteration will offer the only possibility of local cure. Of the present four patients who underwent the procedure for recurrent rectal carcinoma, one developed local pelvic recurrence after 29 months. Distant metastases were observed in all of these patients after a mean of 8 months.

In the literature, there seems to be agreement that total pelvic exenteration should be reserved for patients younger than 70 years with biologically favourable malignant tumours. Suitable patients should not have demonstrable remote metastases or preoperative signs of invasion of the pelvic side wall such as sciatic nerve pain, venous obstruction of the legs with oedema and ureteric obstruction at the pelvic rim[3,4,22–27]. Patient factors such as general condition, obesity and concomitant disease also have to be taken into consideration.

At laparotomy, peritoneal carcinomatosis and extrapelvic visceral involvement have to be excluded. Better assessment of resectability can be made by bimanual palpation[28] and opening of the planes along the pelvic side walls between the bladder and the obturator fossa with frozen-section examination of any suspicious lymph node along the aorta and common iliac vessels. As the median survival was found to be very low for patients with histologically proven nodal metastases, it is now our policy to abandon total pelvic exenteration when para-aortic lymph nodes appear to be involved.

Most of the reported major complications requiring surgery are related to the small bowel, and occur in approximately 20–30 per cent of patients[12,15,29,30]. We have confirmed that the reported frequency is even higher after previous irradiation[29]. The majority of the early complications were intestinal obstruction, enterocutaneous fistula and inflammatory processes that developed within 3 weeks of surgery. These early complications are usually caused by technical failures or enteral anastomosis in a denuded part of the pelvis. Filling of the deperitonealized pelvic cavity with omentum or myocutaneous flap may prevent small bowel entrapment in this area at risk. Bricker[6,9] has suggested the use of a colonic conduit. Apart from avoiding a small bowel anastomosis, use of the colon provides a better external stoma with less chance of reflux at the ureterointestinal anastomosis. In this study we did not observe small bowel problems in any of the six patients with a ureterosigmoid conduit. Although the number of patients studied is relatively small, we recommend the use of a sigmoid conduit if it is oncologically justified and technically safe.

When it is oncologically sound, Hartmann's procedure should be performed by transecting the rectum at the level of the levator muscles[31]. By preserving the pelvic floor, this modification of the original total pelvic exenteration technique may also reduce complications.

In conclusion, total pelvic exenteration appears to be a relatively safe and effective option for an experienced team in the treatment of locally advanced pelvic malignancy. However, optimal criteria for patient selection are required because serious complications are common, affecting particularly the small bowel after previous irradiation. To reduce the risk of these complications, we recommend the use of Hartmann's procedure and a sigmoid urinary conduit if these modifications do not compromise the radicality of the resection.

Randomized controlled trial of the effect of sulindac on duodenal and rectal polyposis and cell proliferation in patients with familial adenomatous polyposis

Twenty-four patients with familial adenomatous polyposis who had previously undergone prophylactic colectomy and had advanced duodenal polyposis were entered into a randomized trial to assess the effect of the non-steroidal anti-inflammatory drug sulindac on duodenal and rectal polyps. Polyp size and number were assessed by videotaped duodenoscopy (and rectoscopy in 14 patients) at entry and after 6 months of treatment; the tapes were compared by two assessors who were unaware of the randomization and the shuffled chronological order of the recordings. Mucosal cell proliferation was measured by in vitro *incorporation of 5-bromo-2′-deoxyuridine. Sulindac therapy was associated with a reduction in epithelial cell proliferation in the duodenum (median labelling index (LI) 15·8* versus *14·4 per cent, P = 0·003) and a trend towards duodenal polyp regression (P = 0·12). In the rectum, cell proliferation showed a marked reduction (median LI 8·5* versus *7·4 per cent, P = 0·018), and significant (P = 0·01) polyp regression was seen. Rectal polyposis was less severe than that in the duodenum and responded more dramatically. Sulindac is a possible treatment for patients in whom rectal polyps have failed to show significant regression after ileorectal anastomosis and who are unsuitable for pouch surgery; it may be useful in early duodenal polyposis or as an adjunct after duodenal clearance.*

Duodenal adenomas are seen in 90 per cent of patients with familial adenomatous polyposis (FAP)[1]. Duodenal cancer is the leading cause of death in patients with FAP already treated by colectomy and ileorectal anastomosis[2], causing twice as many deaths as rectal cancer.

Treatment options for these duodenal polyps are limited. They cluster around the ampulla, are often sessile and recur after endoscopic or open surgical treatment. Non-steroidal anti-inflammatory drugs (NSAIDs) inhibit experimental carcinogenesis[3,4] and their use in humans has been linked epidemiologically to a reduced risk of colorectal cancer[5]. There are a few reports[6,7] and two randomized trials[8,9] of the beneficial use of the NSAID sulindac in the treatment of patients with rectal polyposis.

The effect of sulindac on duodenal polyp regression, and rectal polyp regression where appropriate, was examined in a double-blind placebo-controlled trial in patients with advanced (Spigelman stage 3 or 4)[1] duodenal polyposis.

Patients and methods

Twenty-four patients (12 men; mean age 45 (range 27–70) years) with FAP and advanced duodenal polyposis (Spigelman stage 3 or 4)[1] were enrolled into the trial at least 5 years after colectomy. In 14 patients (eight men) who had undergone ileorectal anastomosis the rectum was also examined. Patients with a history of peptic ulcer disease or abnormal liver function were excluded.

Randomization was by sealed cards in blocks of six to receive either sulindac 200 mg twice a day (12 patients) or an identical-looking placebo (12). Sulindac and placebo were provided by Merck, Sharp and Dohme of Hoddesdon, Herts, UK. Videotaped duodenoscopy using an Olympus EVIS JFV10 side-viewing videoendoscope (Olympus, Keymed, Southend, UK) and, in 14 patients, videotaped rectoscopy using an Olympus EVIS CS100 endoscope were performed by the same endoscopist (C.B.W.) before and after 6 months of trial therapy. The endoscopist placed an opened biopsy forceps against any polyps to estimate their size. At the end of the study, paired videotapes from before and after treatment were viewed by two assessors (A.D.S., R.K.S.P.) who were unaware of their shuffled chronological sequence and the randomization. The second tape was recorded as 'better', 'worse' or 'no different' in comparison with the first. Only large changes in polyp status were accepted; any uncertainty resulted in a classification of 'no different'. Statistical analysis was by Fisher's exact test.

During each endoscopy, biopsies were taken from apparently normal mucosa for analysis of cell proliferation by *in vitro* incorporation of 5-bromo-2′-deoxyuridine (BrdU) by the method of Thornton *et al.*[10]. Biopsies were immediately orientated, under a microscope, in culture medium containing BrdU at a concentration of 500 μmol/l. They were placed in a sealed container infused with 95 per cent oxygen and 5 per cent carbon dioxide at 37°C for 1 h before fixation. All biopsies were examined histologically and crypts containing microadenomas excluded from the analysis. The mucosal proliferation rate was expressed as a labelling index (LI); the number of cells in the S phase of the cell cycle, which were labelled with BrdU, were divided by the total number of cells within a crypt. Twenty crypt columns were assessed for each patient at each time point. Statistical analysis to compare LIs before and after treatment with placebo or sulindac was by the Wilcoxon signed rank test.

Results

Duodenum

Endoscopic assessment. After sulindac treatment, polyp status improved in five patients, worsened in one and was unchanged in five. One patient taking sulindac stopped treatment within 6 weeks because of indigestion, although endoscopy did not reveal a duodenal ulcer or erosion. By contrast, after placebo therapy polyp status improved in only

0007-1323/93/121618-02 © 1993 Butterworth-Heinemann Ltd

two patients, worsened in four and was unchanged in six ($P = 0{\cdot}12$). One patient in the control arm of the study developed duodenal cancer.

Cell proliferation. The mucosal BrdU LI fell by 10 per cent after sulindac treatment from a median value of 15·8 (range 14·1–19·8) per cent to 14·4 (range 12·2–15·9) per cent ($P = 0{\cdot}003$). By contrast, the median LI showed no change after placebo therapy, the pretreatment value being 14·9 (range 10·6–19·0) per cent and that after therapy 14·9 (range 11·1–22·1) per cent ($P = 0{\cdot}97$).

Rectum

Endoscopic assessment. After sulindac treatment, polyp status improved in five patients, worsened in none and was unchanged in two. By contrast, after placebo therapy no patients improved, two worsened and there was no change in five ($P = 0{\cdot}01$).

Cell proliferation. The LI fell by 11 per cent after sulindac treatment from a median of 8·5 (range 6·1–17·4) per cent to 7·4 (range 6·0–13·0) per cent ($P = 0{\cdot}02$). The index showed no significant change for patients receiving placebo, the median before therapy being 7·8 (range 6·7–9·1) per cent and that after 9·0 (range 6·9–9·5) per cent ($P = 0{\cdot}24$).

Discussion

This is the first study undertaken to evaluate the effect of sulindac on the duodenum of patients with FAP, although others[6,8] have used this drug to treat colorectal polyps. Patients with advanced duodenal disease were selected as there was an obvious clinical need to find an effective treatment for them and frequent endoscopic re-examination was clinically indicated. Indeed, one patient in the control arm of the study developed duodenal cancer in the interval between the first and second endoscopic assessments.

Sulindac treatment actively reduced mucosal proliferation in both the duodenum and rectum. Cell proliferation is a well validated marker of tumour formation in the gastrointestinal tract[11,12]. An increase in the cell proliferation rate has been shown to equate with a rise in the rate of tumour formation in the colon in both animal and human studies[13,14]. Therefore, a decrease in cell proliferation rate should precede a fall in the rate of tumour formation or a regression in the size and number of tumours present. The fall in mucosal proliferation in the present study was associated with significant polyp regression in the rectum. This is consistent with the findings of others.

Selection of patients with advanced duodenal disease meant that the study was small and lacked statistical power; this is perhaps why the improvement in duodenal polyp stage was not significant. Whereas duodenal polyposis was advanced in all cases, rectal polyposis was not and this might explain the lack of a statistically significant clinical effect in the duodenum. The effect of sulindac on polyps might be similar to that of calcium, where inhibition of cell proliferation is lost as polyps enlarge[15]. If this is so, sulindac may be of more benefit for patients with early duodenal polyps and as an adjunct to other therapy (endoscopic removal, where possible, or after duodenotomy) to prevent recurrence in those with advanced duodenal polyposis.

The mechanism for sulindac-induced inhibition of cell proliferation remains unknown. One hypothesis[9,16] is that, because sulindac inhibits the enzyme cyclo-oxygenase, there is a reduction in the concentration of prostaglandins E_2 and $F_{2\alpha}$. These prostaglandins are found in high concentrations in many tumours[17] and are thought to increase cell proliferation by raising the levels of adenosine 3′,5′-cyclic monophosphate and other intracellular second messengers of growth regulation[18] or by increasing angiogenesis within a tumour.

Finally, there are patients with uncontrollable rectal polyps, after ileorectal anastomosis, who are unsuitable or unwilling to undergo pouch surgery and in whom sulindac may be of benefit. In addition, some patients with intra-abdominal desmoid disease may have an irresectable colon and it would seem sensible to use sulindac in these to attempt to control the colonic polyposis. It must remain a future goal to manage FAP pharmacologically, without recourse to surgery, and also to apply this approach to patients with sporadic colorectal adenomas.

Acknowledgements

The authors thank the staff of the Endoscopy Unit at St Mark's Hospital, Sister M. Boland and Staff Nurse M. Taylor for their help during this trial. They are also grateful to staff at the Polyposis Registry and the surgeons at St Mark's under whose care these patients are being treated: Messrs P. R. Hawley, J. P. S. Thomson, R. J. Nicholls and J. Pouch adenomas in patients with familial adenomatous polyposis

Familial adenomatous polyposis (FAP) represents a human model of the adenoma–carcinoma sequence. Colectomy substantially reduces the cancer risk. Restorative proctocolectomy maintains continence and abolishes the risk of rectal cancer, but there is a price to pay in terms of an increased morbidity rate[1]. Long suture lines are prone to carcinogenesis experimentally, which raises concern that pouches might themselves be at risk[2].

To investigate this hypothesis, this study compared the incidence of ileal pouch adenoma with that of terminal ileal adenoma detected histologically after primary colonic surgery.

Patients and methods

To study adenomas in the ileal reservoir, 38 of 50 patients who underwent restorative proctocolectomy for FAP between 1977 and 1992 were followed by rigid sigmoidoscopy at 6 weeks, 3 months and subsequently yearly. All suspected adenomas were biopsied, the pathology being reviewed by one pathologist (I.C.T.).

To investigate adenomas in the intact terminal ileum, all pathology reports of colonic resection for FAP since 1918 were categorized into one of four groups: no record of ileal histology; normal ileum; lymphoid hyperplasia; and tubular adenoma.

Results

Adenoma in the ileal reservoir

The mean age of the 19 men and 19 women was 33 (range 15–57) years, with a mean follow-up of 4·7 (range 0·5–12·0) years. Mildly dysplastic tubular adenomas were found in seven patients at a median interval of 2 years (range 6 months to 7 years) from restorative proctocolectomy.

Four adenomas arose in ileal mucosa; one patient had single adenomas both in ileal and large bowel mucosa, and the other two had adenomas in large bowel mucosa and from no identifiable origin respectively. Thus five of the 38 patients developed true ileal adenomas at a median of 4 (range 1–7) years after pouch construction.

Ileal histology at initial colectomy was available for 27 patients: three had ileal adenomas, of whom one subsequently developed a pouch adenoma; five showed prominent lymphoid follicles only; and 19 were normal.

Adenoma in the intact terminal ileum

Between 1918 and 1992, 189 men and 127 women underwent primary colonic surgery for FAP with a mean age at operation of 28 (range 12–65) years. There was no record of ileal histology in 113. Of the remaining 203 patients, 143 were normal, 42 showed lymphoid hyperplasia and 18 (8·9 per cent) had ileal adenomas.

There was no significant difference between the proportion of ileal pouch adenomas and ileal adenomas at the time of colectomy (five of 38 *versus* 18 of 203; Yates' $\chi^2 = 0{\cdot}10$, 1 d.f., $P = 0{\cdot}75$).

Discussion

This study was not designed prospectively to detect the frequency of small pouch adenomas, which might be overlooked in an unprepared reservoir, but the findings are supported experimentally by the failure of carcinoma to develop preferentially in ileal pouches of mice given dimethylhydrazine[3]. Ileal carcinoma in FAP is rare, there being only five recorded cases in the literature[4,5]. It seems unlikely that ileal pouch carcinoma will be a problem in patients with FAP, but follow-up is short and cancer may still arise from retained large bowel mucosa.

Conversion of ileorectal anastomosis to ileal pouch–anal anastomosis (IPAA) was indicated in 29 patients with familial adenomatous polyposis but technically impossible in three because of unsuspected pelvic desmoid tumours. There was no operative mortality and overall postoperative morbidity and late complication rates were no different from those in a group of 120 patients who underwent IPAA as a first operative procedure. Unsuspected adenocarcinoma (one invasive, three in situ) *was found in four patients. The functional results in patients with IPAA did not differ from those of ileorectal anastomosis before conversion or from those obtained after IPAA as a first-choice procedure. Secondary proctectomy and IPAA can be safely offered to patients with ileorectal anastomosis and a high risk of rectal cancer.*

Familial adenomatous polyposis (FAP) is an inherited condition characterized by the development of at least 100 colorectal adenomas with an inevitable progression to carcinoma. The disease requires prophylactic treatment based on colectomy[1].

The development of restorative proctocolectomy with ileal pouch–anal anastomosis (IPAA) provides a treatment that eradicates all colorectal mucosa while preserving continence and ensuring good functional results[2]. IPAA is now established as the procedure of choice in patients with FAP presenting with numerous rectal polyps or in those unsuitable for follow-up[3].

Total colectomy with ileorectal anastomosis is still carried out in a number of centres since it provides more than acceptable prevention of colorectal cancer, it is easy to perform, it is associated with few complications and it gives good functional results[4,5]. Rectal excision following ileorectal anastomosis may be required for those with uncontrollable rectal polyposis or difficulty attending for regular follow-up. Conversion to IPAA, if possible, would represent an alternative to proctectomy with end ileostomy.

This study examined a series of patients with FAP who underwent conversion of ileorectal anastomosis into IPAA to determine the indications, feasibility, postoperative and late complications, and functional outcome. The results were compared with those from a larger group of patients undergoing IPAA as an initial surgical procedure.

Patients and methods

Between 1983 and 1991, 181 patients underwent surgery for FAP: IPAA, 148; ileorectal anastomosis, 21; proctocolectomy with ileostomy, eight; and laparotomy, four.

Conversion of ileorectal anastomosis to IPAA was indicated in 29 patients. These patients were reviewed with regard to the indication for secondary proctectomy, feasibility and technical difficulties, operative and pathological findings, mortality and morbidity, and functional results.

Operative procedure

During rectal dissection, care was taken to follow the muscular wall to avoid nerve damage, except in patients with rectal carcinoma in whom a large mesorectal excision was performed. Abdominal proctectomy left a short muscular cuff; a stapled J pouch was constructed and anastomosed manually to the dentate line following perineal mucosectomy[6]. A diverting loop ileostomy was performed and closed after 3 months, following pouchography.

Operative findings

Small bowel adhesions, perirectal sclerolipomatosis, mesenteric fibrosis and manoeuvres for mesenteric lengthening were noted.

Pathological findings

Preoperative rectal examination with multiple biopsy was performed and all proctectomy specimens reviewed by the same pathologist. Staging was based on Dukes'[7] classification.

Mortality and morbidity

Postoperative complications included all events occurring within 30 days of ileostomy closure and were classified according to treatment (medical or surgical). The length of hospitalization included the time for IPAA and ileostomy closure.

Bowel function

All patients undergoing IPAA were followed prospectively at 1, 3, 6 and 12 months and then annually, documenting daytime and night-time stool frequency, continence, ability to delay defaecation for more than 15 min, the need for a strict diet and the use of antidiarrhoeal medication. Incontinence was classified as none, minor (non-faecal staining of undergarments with fewer than three episodes per week) or gross (faecal staining with more than three episodes per week).

Comparison of data

Operative findings, mortality and morbidity, and the functional results at 1 year were compared with those obtained in a group of 120 patients who underwent IPAA for FAP as an initial surgical procedure. The functional results following conversion of ileorectal anastomosis to IPAA were compared with those obtained with ileorectal anastomosis before conversion in the same patients.

Statistical analysis

Comparisons between different groups were made using χ^2 analysis or Fisher's exact test as appropriate. $P < 0.05$ was considered significant.

Results

Indications for secondary proctectomy

Secondary proctectomy following ileorectal anastomosis was indicated in 29 patients. In 16 patients, rectal polyps were recurring in greater numbers at each successive examination. Eight patients wished to discontinue regular surveillance and proctectomy was required in three because of the discovery of rectal carcinoma (one Dukes' A tumour 3 years after ileorectal anastomosis, one Dukes' B 14 years after, one Dukes' C 17

Bowel obstruction	0 (0)	4 (3)
Miscellaneous	3 (12)	28 (23)
Late complications	4 (15)	18 (15)

Values in parentheses are percentages. IPAA, ileal pouch–anal anastomosis. There were no statistically significant differences

years after). Revisional surgery was indicated in two patients with a stricture producing poor functional results.

Feasibility

Proctectomy was impossible in three patients because of intra-abdominal desmoid tumours that had not been detected by preoperative ultrasonography and computed tomography. These patients refused end ileostomy and were left with ileorectal anastomosis with a large number of confluent rectal polyps. In the remaining 26 patients (14 male, 12 female), conversion to IPAA was performed a mean(s.d.) of 119(60) (range 4–276) months after ileorectal anastomosis, at a mean(s.d.) age of 35(12) (range 11–67) years.

Operative difficulties

Operative difficulties encountered were compared with those in the 120 patients who underwent IPAA as a first-choice procedure (*Table 1*).

Pathological findings

In addition to the three patients with known carcinoma, unsuspected neoplastic lesions were found in four other patients: one Dukes' A and three *in situ* tumours. All seven patients were alive without evidence of recurrence or metastatic disease after a mean follow-up of 54 months.

Mortality and morbidity

There was no operative mortality after conversion of ileorectal anastomosis to IPAA. Postoperative complications consisted of malaria crisis (one patient), pulmonary embolism (one), wound abscess (one) and pelvic sepsis requiring reoperation (one). Two patients had anastomotic stricture requiring dilatation under general anaesthesia, one had bowel obstruction and one developed an incisional hernia. There were no sexual or urinary problems. No patient developed a fistula and no pouch had to be removed. There was no increase in the rate of postoperative morbidity or late complication (*Table 2*).

Bowel function

Functional results were assessed in 23 patients (one was lost from follow-up after 6 months and two were excluded because they had a large mesorectal excision for known rectal carcinoma). The results are summarized in *Table 3* and compared with those for ileorectal anastomosis before conversion and for IPAA as a first surgical procedure in patients with FAP. During follow-up, two (8 per cent) abdominal desmoid tumours were diagnosed in the 26 patients undergoing conversion and seven (6 per cent) in the 120 who had IPAA without previous ileorectal anastomosis.

Table 3 *Bowel function*

	Ileorectal anastomosis before conversion ($n = 23$)	IPAA after ileorectal anastomosis ($n = 23$)	IPAA initially ($n = 120$)

Discussion

Since its introduction[8] for the treatment of patients with FAP, some centres have advocated restorative proctocolectomy as the procedure of choice while others have chosen a pouch procedure only when the risk of rectal cancer was perceived to be high: in dense rectal polyposis, colonic cancer and old age at operation or when poor follow-up was anticipated.

The cumulative risk of developing rectal carcinoma is age related and patients with an established ileorectal anastomosis need IPAA or more frequent rectal screening[9] after the age of 45 years. Patient desire to discontinue regular endoscopic examination, uncontrolled rectal polyposis, dysplasia or carcinoma in rectal adenoma, and poor outcome after ileorectal anastomosis are other reasons why reoperation is required.

Conversion to IPAA is not always feasible because of malignant disease or abdominal desmoid tumours. Desmoid tumours occur in 6·5–13 per cent of patients with FAP[10,11], mainly after previous surgery, and preoperative imaging techniques often fail to reveal these lesions. In the present series, the incidence of abdominal desmoid tumours found after conversion of the anastomosis did not differ from that after IPAA as a first surgical procedure. Desmoid tumours that developed after ileorectal anastomosis precluded secondary restorative proctectomy in 10 per cent of patients, and this may argue in favour of IPAA as the first surgical procedure.

Technical difficulties were significantly more frequent after secondary proctectomy than after initial IPAA but involved only the small bowel and rectal dissection. There were no difficulties in making the pouch or bringing it down to the anus. These difficulties did not prevent the formation of an IPAA and were not responsible for increased numbers of complications.

The finding of four previously unsuspected rectal neoplasms underlines the difficulties in surveillance. A careful and regular rectal examination every 6 months with systematic destruction of all newly found polyps does not preclude the onset of rectal cancer. Others[9] have documented cancer of the rectum developing in 22 of 224 patients with ileorectal anastomosis, in 14 despite careful 6-monthly follow-up. Nine of the tumours were Dukes' C lesions when discovered. There may be a need to change the frequency of screening and to propose rectal excision as soon as moderate or severe dysplasia is found.

The functional results of secondary IPAA differ slightly from those of ileorectal anastomosis before conversion, and other studies[12,13] have shown that ileorectal anastomosis and IPAA produce similar results. In a previous study[14] it was shown that after conversion of ileorectal anastomosis to IPAA 90 per cent of patients felt that bowel function was unchanged or improved.

Bowel function following conversion of ileorectal anastomosis did not differ from that following IPAA as a first operative procedure. This differs in patients with ulcerative colitis, in whom poor results occur after conversion of ileorectal anastomosis into IPAA[15]. This is probably explained by the lack of subsequent rectal inflammation in those with FAP.

In patients with a high risk of rectal cancer, ileorectal anastomosis should be readily converted to IPAA. The postoperative complication rate and the functional results do not differ from those observed after IPAA as a primary procedure, and proctectomy may reveal unsuspected rectal carcinoma.

SURGERY ABSTRACTS

Br. J. Surg. 1993, Vol. 80, December, 1624–1625

A selection from the November issue of the American journal.

Shear stress increases the release of interleukin-1 and interleukin-6 by aortic endothelial cells

Antonio V. Sterpetti, MD, Alessandra Cucina, PhD, Anna Rita Morena, PhD, Silvia Di Donna, PhD, Luciana Santoro D'Angelo, PhD, Antonino Cavallaro, MD, *and* **Sergio Stips, MD,** *Rome, Italy*

Background. *The aim of this study was to determine the correlation between shear stress and the release of interleukin-1 (IL-1) and interleukin-6 (IL-6) by endothelial cells (EC).*

Methods. *Bovine aortic EC were seeded in fibronectin-coated cylinders at 1.0 × 10^6 cells/tube and allowed to reach confluence and to adhere for 48 hours. The experimental groups were subjected to a laminar flow of 100 ml/min (6 dyne/cm^2). The control group was subjected to similar incubation conditions without flow. The release of IL-1 and IL-6 by EC was measured by enzyme-linked immunosorbent assay.*

Results. *Shear stress increased significantly ($p < 0.01$) the release of IL-1 and IL-6 by EC. The release of these two cytokines had different kinetics.*

Conclusions. *Increasing shear stress facilitates release of IL-1 and IL-6 by EC. Previous reports have shown that IL-1 and IL-6 promote vascular smooth-muscle cell proliferation. Thus abnormal flow conditions with increasing shear stress may predispose to smooth-muscle cell proliferation that characterizes early atherosclerotic plaque development by an interleukin-mediated mechanism. (*SURGERY *1993;114:911-4.)*

Tyrosine inhibits intestinal-phase gastric-acid secretion

Eric Y. T. Yang, MD, *and* **David L. Nahrwold, MD,** *Chicago, Ill.*

Background. *Intestinal infusion of leucine augments the maximal gastric-acid secretory response to pentagastrin and serves as a bioassay for intestinal-phase acid secretion. Another action of leucine is to decrease tyrosine flux into neural tissues. We hypothesized that the mechanism of leucine-stimulated acid secretion involves its ability to alter tyrosine absorption.*

Methods. *We administered tyrosine intrajejunally and intravenously to anesthetized, vagotomized rats during maximal pentagastrin stimulation and measured acid output in response to intrajejunal infusion of leucine.*

Results. *Intrajejunal tyrosine produced a dose-dependent inhibition of leucine-stimulated acid secretion but only mild effects on acid secretion in response to pentagastrin alone. Intravenous tyrosine infusions also decreased acid secretion in response to intestinal leucine but required much higher doses.*

Conclusions. *Tyrosine exerts a specific inhibitory effect on leucine-stimulated acid secretion, which is mediated intraluminally. Because tyrosine is an important regulator of adrenergic nervous system activity, we speculate that the mechanism of leucine-stimulated acid secretion may involve modulation of the sympathetic nervous system, thereby affecting acid secretion. (*SURGERY *1993;114:915-20.)*

Characterization of cholecystokinin receptors on the human sphincter of Oddi

Yukihiko Tokunaga, MD, Kenneth L. Cox, MD, Hidetoshi Itasaka, MD, Waldo Concepcion, MD, Paul Nakazato, MD, *and* **Carlos O. Esquivel, MD, PhD,** *San Francisco, Calif.*

Background. *The present in vitro study investigated the interaction between cholecystokinin (CCK) and receptors on human sphincter of Oddi tissue obtained from donated human livers that were being transplanted.*

Methods. *Radiolabeled ligands with cholecystokinin receptor specificity, autoradiography, and crystal scintillation counting were used to directly characterize cholecystokinin receptors on tissue sections.*

Results. *The binding of ^{125}I-BH-CCK-8 to the tissue was saturable, specific, and dependent on time, pH, and temperature. Saturable binding of ^{125}I-BH-CCK-8 was localized on the smooth muscle layer, and binding was inhibited only by cholecystokinin-related peptides. Computer analysis of ^{125}I-BH-CCK-8 binding indicated the presence of two classes of binding sites, one with a high affinity and the other with a low affinity for CCK-8. CCK-8 caused relaxation (half-maximal concentration, 6 nmol/L) and carbachol caused contraction (half-maximal concentration, 10 nmol/L) of circular, cross-sectional strips of the tissue. Longitudinal strips were less responsive. The relative ^{125}I-BH-CCK-8 binding inhibition potency of CCK-8 agreed closely with its relative ability to cause sphincter relaxation. Tetrodotoxin (1 μmol/L) and atropine (1 μmol/L) caused a rightward shift of the dose-response curve for CCK-8-stimulated sphincter relaxation.*

Conclusions. *The present results indicate that cholecystokinin receptors on the human sphincter of Oddi are sulfate dependent and mediate sphincter relaxation. (*SURGERY *1993;114:942-50.)*

Nitric oxide–mediated, endothelium-dependent vasodilation is selectively attenuated in the postischemic extremity

W. Charles Sternbergh III, MD, Raymond G. Makhoul, MD, *and* **Burt Adelman, MD,** *Richmond, Va.*

Background. *Attenuation of endothelium-dependent relaxing factor (EDRF) release may contribute to adverse sequelae commonly seen after reperfusion of an acutely ischemic* *extremity. The purpose of this study was to identify the compound responsible for the EDRF activity in the extremity and to evaluate its modulation by ischemia and reperfusion.*

Methods. *Isolated rat hindlimbs were perfused at constant pressure with an albumin-enriched crystalloid buffer. Increasing log dose infusions of acetylcholine and nitroprusside were used to measure endothelium-dependent (EDRF-mediated) and endothelium-independent vasoreactivity, respectively.*

Results. *Graded reductions in total vascular resistance were seen in response to both agonists in the control group ($n = 11$). In the postischemic group ($n = 7$), 60 minutes of normothermic ischemia and 10 minutes of reperfusion reduced endothelium-dependent vasodilation to acetylcholine by approximately 40% ($p < 0.01$). Endothelium-independent vasodilation to nitroprusside was unaffected. N^G-monomethyl-L-arginine (L-NMMA), a competitive inhibitor of nitric oxide release, attenuated vasodilation to acetylcholine ($p < 0.01$) but not nitroprusside in both control and postischemic groups.*

Conclusions. *Endothelium-dependent vasodilation in the rat hindlimb, mediated by nitric oxide, was selectively impaired by injury from ischemia and reperfusion. Strategies designed to minimize postischemic attenuation of nitric oxide release may be beneficial in the management of acute limb ischemia. (SURGERY 1993;114:960-7.)*

Clinical significance of routine imaging of iliac and calf veins by color flow duplex scanning in patients suspected of having acute lower extremity deep venous thrombosis

Louis M. Messina, MD, Mary S. Sarpa, MS, RVT, Mary A. Smith, RVT, *and* **Lazar J. Greenfield, MD,** *Ann Arbor, Mich.*

Background. *Because duplex ultrasonography is used increasingly to evaluate patients suspected of having acute deep venous thrombosis of the lower extremity, the clinical significance of limiting venous duplex scanning to the common femoral, superficial femoral, and popliteal veins becomes an important question.*

Methods. *We prospectively studied by venous color flow duplex ultrasonography 181 patients referred for evaluation to rule out acute deep venous thrombosis in determine (1) the frequency with which the iliac and calf veins could be imaged adequately to determine the presence or absence of acute deep venous thrombosis, (2) the frequency of acute venous thrombosis in these venous segments, and (3) the time required to scan these additional segments.*

Results. *In 79% of the patients studied, one segment of the iliac venous system was imaged adequately to determine the presence or absence of venous thrombosis. In the lower extremity, the common femoral vein, the superficial femoral vein, and the popliteal vein were imaged adequately in 94% of the patients. In 76% of the patients all three calf veins were imaged adequately to determine whether acute deep venous thrombosis was present or absent. The anterior tibial vein was the most difficult vein to image consistently and was imaged adequately in 76% of the patients referred. The mean time to scan the affected limb was 8 minutes 37 seconds. Forty-seven patients (26%) of the 180 patients studied had positive venous scans. Twenty-three percent of the patients who had positive scans were found to have iliac vein involvement. Thirty-two percent who had positive venous scans were found to have thrombosis of the calf veins. Fifteen percent of the 47 patients who had positive scans had either an isolated iliac or calf vein thrombosis.*

Conclusions. *We believe this frequency of isolated iliac or calf vein thrombosis coupled with the frequency of successful imaging of these venous segments and the short additional time required to image these segments justifies the inclusion of routine imaging of the iliac and calf veins in patients undergoing venous duplex scanning to rule out acute deep venous thrombosis. (SURGERY 1993;114:921-7.)*

Technical considerations and complications associated with the placement of 180 implantable hepatic arterial infusion devices

Steven A. Curley, MD, Judy L. Chase, PharmD, Mark S. Roh, MD, *and* **David C. Hohn, MD,** *Houston, Texas*

Background. *Treatment regimens with hepatic arterial chemotherapy infusion are being investigated in an attempt to improve survival and quality of life for patients with primary and metastatic liver malignancies. The successful delivery of chemotherapeutic drugs through an implantable hepatic arterial infusion device depends on the surgeon's understanding of hepatic arterial anatomy, the proper cannulation technique, and the operative measures necessary to prevent misperfusion of drug.*

Methods. *Between January 1, 1987, and December 31, 1991, we placed implantable hepatic arterial infusion devices in 180 patients. The records of these patients were reviewed to determine (1) the incidence and surgical management of variant hepatic arterial anatomy and (2) the complications associated with surgical placement of these devices.*

Results. *Variant hepatic arterial anatomy requiring ligation of the variant vessel or nonstandard cannulation was seen in 66 patients (36.7%). Treatment response rates and duration of treatment were no different for these 66 patients than for the 114 patients with standard hepatic arterial anatomy ($p = 0.94$). There were no operative deaths in this series. Operative or early postoperative (within 30 days) complications occurred in 10 patients (5.5%). However, late complications or device-related malfunctions developed in 52 patients (28.8%).*

Conclusions. *An understanding of regional arterial anatomy is required to surgically place a catheter to achieve bilobar hepatic arterial perfusion and avoid gastroduodenal misperfusion of drug. Placement of hepatic arterial infusion devices has a low rate of early morbidity, but surgeons should be aware of late complications that may develop in patients undergoing hepatic arterial chemotherapy infusion through an implantable device. (SURGERY 1993;114:928-35.)*

Correspondence

Oesophagogastric intramural implantation anastomosis after oesophagectomy

Sir
I found the Surgical Workshop by Dr Cheng and colleagues (*Br J Surg* 1992; **79**: 1325–6) quite enlightening. The authors' ingenuity in creating the flap-valve effect prevents reflux and so ultimately oesophagitis. The risk of stricture as a complication is thus kept to a minimum.

The same principle of a flap-valve was reported by Stepanov[1] in children who had undergone resection of the ileocaecal junction for various lesions in this area, with subsequent ileocolic anastomosis. The method prevents reflux of colonic material into the ileum, forcing passage of intestinal contents in a unilateral direction. Our initial unpublished experimental studies on rats gave satisfactory results, and the method was subsequently introduced into paediatric clinical surgery. Complications are similar to those highlighted by Cheng and colleagues, namely stricture (stenosis), and are caused by oversewing, crushing by the clamp, poor apposition and local infection.

This method should find wide application when resecting lesions in the ileocaecal region.

Sutureless circumcision

Sir
I am surprised that the Journal (*Br J Surg* 1993; **80**: 859) allows such an inaccurate anatomical term as 'mucocutaneous approximation'. When I studied anatomy the glans penis was covered with skin, and I doubt that it has changed.

Non-therapeutic operations for penetrating trauma: early morbidity and mortality

Sir
We were interested to read the findings of Professor Demetriades and colleagues (*Br J Surg* 1993; **80**: 860–1) regarding the complications of non-therapeutic surgical intervention for penetrating trauma. We make the following comments.

First, we would question the implication that a negative operation, as defined by them, adds little to management. Negative findings can contribute importantly to overall management of the patient.

Second, we are confused by the authors' concluding paragraph about their selective conservative policy. The study did not investigate this policy, and the authors did not state whether such a policy was in force during the study. In any case an appreciable number of non-therapeutic procedures (12 per cent) were performed.

Finally, it would be nice to know the complication rate in patients with penetrating injuries who were not operated on during the study period, and how many of these came to operation later. This information should be available if the study was prospectively conducted.

Penetrating injuries sufficient to warrant surgery are far less common in the UK than in South Africa. There can be few hospitals here that undertake annually almost 300 abdominal or thoracic explorations for trauma. This fact, combined with the organization of UK trauma services, means that one would expect the non-therapeutic operation rate here to be much higher. Knowledge of the attendant complication rate is salutary and represents another argument for greater concentration of trauma services within the UK.

Authors' reply

Sir
We would like to thank Messrs Saha and Scriven for their comments on our paper. We did not imply that a negative operation adds little to management. We wrote that non-therapeutic operations may be associated with important risks and that these should be avoided whenever possible. Clinical examination is reliable in detecting serious injuries, and a selective conservative policy is recommended. This policy is supported by previous studies from our institution[1–3]. In the present publication we did not study the complications in patients treated non-operatively. However, we looked into this matter in three previous prospective studies[1–3]. The complication rate in patients treated conservatively was low (less than 1 per cent) and, most importantly, there were no deaths.

Anal fistula

Sir
The Review by Messrs Seow-Choen and Nicholls (*Br J Surg* 1992; **79**: 197–205) acknowledges that hydrogen peroxide may be of use in locating the internal openings of anal fistulas and refers to reports of possible dangers. They mention other more frequently used agents in the same breath, but rightly only to condemn.

It would be regrettable if the impression were conveyed that hydrogen peroxide is in the same category as the other agents. Hydrogen peroxide has provided instant recognition of all chronic fistulas in which it has been used. More importantly, it has differentiated between fistulous and non-fistulous acute abscesses in almost all, if not all, instances and eliminated exploratory probing, its attendant ills and subsequent examination under anaesthesia. If the abscess is of fistulous origin, the involved anal gland is also indicated.

Designation of the concentration of hydrogen peroxide as 3 per cent, while possibly more scientific, does not alert the unwary to the evolution of ten volumes of oxygen per unit volume, as the older '10-volume' designation emphasizes. It is essential for this reason to use a *small volume*, as advised[1]. In neither of the cases quoted by Beavis[2] was hydrogen peroxide used as advised. Even safe materials require to be used with due respect for their properties.

> 'For when the groaning girder lets down the sagging span the fault lies not with the metal, the fault lies with the man'

... or words to that effect.

Authors' reply

Sir

Contrary to what Dr Glen would have us believe, hydrogen peroxide is indeed in the same category as the other agents mentioned in our Review. Hydrogen peroxide has its place in surgery, but it has its dangers as well. It may be more useful than methylene blue or saline in the assessment of internal openings of anal fistula, but its potential dangers are greater than those of these other agents.

I have found exploratory probes to be of immense value and without attendant ills so far in my practice, and I use them routinely in the surgery of anal fistula and abscess[1]. No doubt the probe is dangerous if due respect is not accorded. As Dr Glen would say: 'The fault lies not with the metal, the fault lies with the man'.

Diaphragm-like strictures of the colon induced by non-steroidal anti-inflammatory drugs

Sir

Mr Pucius and colleagues (*Br J Surg* 1993; **80**: 395–6) published a Case Report on diaphragms in the caecum and strictures in the ascending colon, claiming that this was 'the first description of a patient with (such) strictures in the colon'. We draw their attention to a previous paper[1] in which we carefully stated that 'to our knowledge such a case has not been observed before'. Our caution was justified because we learned that earlier publications of two such cases had appeared[2] in 1989, and this condition has also been reported in endoscopic studies[3] and elsewhere[4,5].

We fully agree with an editorial stating that colonic damage by non-steroidal anti-inflammatory drugs (NSAIDs) is probably very common[6]. We recently published a more extended report including seven patients seen in our departments who were treated with diclofenac in slow-release form[7]. It is possible that we saw all such cases in the past 10 years as this drug is manufactured in Switzerland and is the most commonly used NSAID in our country.

Cytodiagnosis of breast disease using a liquid suspension medium

Sir

Although Mr Ross and colleagues (*Br J Surg* 1993; **80**: 866–7) indicate that preparing slides from a fine-needle aspirate taken from a breast mass is highly operator dependent, they fail to mention that the technique of needle aspiration of breast lumps is likewise operator dependent[1–3]. When cytology is performed by experienced aspirators the results obtained are better than those reported by Ross and colleagues[1,3–5]. Surely it would be more sensible to ensure that fine-needle aspiration cytology is performed by experienced aspirators who have learned how to prepare their own slides rather than to allow inexperienced surgeons to perform fine-needle aspiration and thereafter to use a liquid suspension medium.

Authors' reply

Sir

Thank you for the opportunity to reply to the comments of Mr Dixon. We agree that fine-needle aspiration biopsy is highly operator dependent. We stressed this point in the first paragraph of our Introduction and again early in the Discussion. We further concur with his sentiments that more experienced clinicians would be desirable, but this is an uncommon luxury outside teaching hospitals. Like so much in surgical practice, the performance and results of fine-needle aspiration biopsy will be optimized by experience, and it was neither stated nor implied that the Cytospin method (Shandon Scientific, Runcorn, UK) compensated for a lack of such experience.

The central tenet of this paper is that the Cytospin technique provides an inherently simple and flexible method of processing fine-needle aspiration biopsy samples. It may have additional benefits in terms of resource allocation and infection control. It has proved to be as diagnostically accurate as conventional cytology in our unit and in larger series also quoted in our paper.

Mechanical properties of the aneurysmal aorta

Sir

I am grateful to Mr MacSweeney and Dr Powell for their reply (*Br J Surg* 1993; **80**: 672) to my letter regarding the article by themselves and others (*Br J Surg* 1992; **79**: 1281–4). I am surprised to find myself accused of thinking that the aortic wall exhibits simple elastic mechanical properties when I stated the contrary in the final paragraph of my letter; my only mention of the aorta behaving as a simple elastic structure is written in the subjunctive ('if we imagined ...').

This hypothetical proposition is, however, necessary to permit a mathematical understanding of the effect that Laplace's law will tend to exert on the pressure–strain elastic modulus. The fact that increasing stiffness with distension of the vessel exerts an opposite effect on this modulus does not allow one to disregard the effect of Laplace's law, still less to suggest that the law itself determines this opposite effect.

Far from being irrelevant, appreciation of this fact is crucial if conclusions regarding the behaviour and structure of the aorta are to be drawn from various values of the pressure–strain elastic modulus. The actual stress on the vessel wall varies not just with pressure, but also with the diameter and thickness of the wall; it can be estimated only with a correct understanding of Laplace's law.

I took issue with the statements following and in the same paragraph as the introduction of Laplace's law. These appeared to be discussing the effects of the law. If the intention was simply to reiterate the undisputed fact that the wall becomes stiffer as it is stretched, there would seem little point in mentioning Laplace's law. This law determines tension, i.e. the force that tries to overcome the increasing stiffness of the wall. Of course, tension is required to stretch any structure, but the change in resistance offered by the stretched vessel wall is the result of elongation rather than tension *per se*. At any moment, tension acts in one direction and the resistance of the vessel wall in the opposite direction.

Their defence of the extraordinary statement that increased wall tension 'would resist further distension' reminds me of a small boy sitting opposite a fat man on a see-saw and complaining that gravity is lifting him up in the air! Such a statement is as true as it is untrue as it is ambiguous.

F. L. Hinson

Department of Surgery
Derbyshire Royal Infirmary
Derby DE1 2QY
UK

Authors' reply

Sir

Mr Hinson has provided us with another opportunity to reiterate the dependence of the mechanical properties of the aorta on the composition and microanatomy of this vessel.

In the normal young aorta the principal load bearing is attributable to the elastic fibres but, as the aorta ages and distends, the much stiffer collagen fibres are recruited to aid in load bearing. In our paper, comment concerning Laplace's law was introduced at the request of peer review. Mr Hinson appears to have misunderstood us to imply that Laplace's law is the cause of the non-linear properties of the aorta; of course it is not. The structure of the arterial wall determines its mechanical properties. We believe this to be clear from attentive reading of our paper. We have already commented about 'resisting further distension' in our previous correspondence. However, we are in agreement in the direction in which the see-saw would move.

Superselective intra-arterial chemotherapy with mitomycin for gallbladder cancer

Sir

We read with interest the article by Drs Mäkelä and Kairaluoma (*Br J Surg* 1993; **80**: 912–15) on regional chemotherapy in the treatment of gallbladder cancer. The authors state that superselective intra-arterial chemotherapy with mitomycin can be useful for patients with cancer restricted to the gallbladder wall and cite the successful result of mitomycin used intra-arterially in advanced gallbladder cancer by von Eyben *et al.*[1]. Although gallbladder cancer is thought to be resistant to chemotherapy, the sensitivity rate to mitomycin and cisplatin were 75 and 60 per cent respectively in our series (*Table 1*).

Table 1 *Sensitivity to anticancer drugs in carcinoma of the gallbladder*

	Sensitivity
Mitomycin	3 of 4
Cisplatin	3 of 5
Carboquone	2 of 5
Doxorubicin	1 of 5

Sensitivity was evaluated as a reduction in succinate dehydrogenase activity to less than 50 per cent of the untreated control value

This fact must surely reflect the potential advantage of regional chemotherapy in the treatment of gallbladder cancer.

Book reviews

Minimally Invasive Therapy in Five European Countries

H. D. Banta (ed.). 270 × 195 mm. Pp. 177. Not illustrated. 1993. Amsterdam: Elsevier Science Publishers. US $212·50.

This book could not be more timely because of the rapid changes occurring in surgical management, with the introduction of minimally invasive therapy across a range of specialties. There is also current disquiet in the medical literature as well as in the media about isolated anecdotal evidence of adverse effects of new treatments. The book contains an excellent introduction by Mr J. Wickham, well known for his pioneering efforts both in clinical applications and in bringing the changes consequent upon new treatments to the attention of a wider audience. The other contributions are all from various health economists in the European countries studied.

The disadvantage of this book is that there is no contribution from a practising clinician (other than that from Mr Wickham in the Introduction) experienced in any of the new therapies discussed. Specialist societies for minimally invasive therapy and specialist journals are now well established; it would surely have been sensible to have included comments from leading clinicians in some of the areas studied. This omission leads inevitably to the book failing to cover some of the problems raised by the rapid rate of progress. There is no discussion of the problem of necessary changes in surgical training. Some of the examples chosen for study, such as the treatment of bladder tumours by laser, are at such an early stage that it is difficult to see why they were included. Other obvious examples of dramatic but long-standing change (briefly mentioned by Mr Wickham), such as the replacement of open bile duct surgery by endoscopic treatment, are not considered at all.

Several contributors make the point that more studies of clinical efficacy and cost–effectiveness are needed, and that knowledge of the results needs to be disseminated widely to doctors so that appropriate referral decisions can be made. The coordinating author in his final contribution states that 'few organisations are actively involved in evaluations to affect clinical practice'. This is an extraordinary statement in the light of efforts made by many specialist societies to study, discuss and criticize new minimally invasive techniques. However, the policy changes suggested do seem sensible. Indeed, these are already being addressed in the UK by the formation of centres across the country for specialized training in minimally invasive therapy with the help of the Wolfson Foundation.

ABC of Colorectal Diseases

D. J. Jones and M. H. Irving (eds). 295 × 210 mm. Pp. 103. Illustrated. 1993. London: BMA. £12·95.

This book is based on the popular *ABC* series of articles published in the *British Medical Journal* last year. Revised and updated, it provides an overview on diseases of the colon and rectum, with chapters on trauma, tropical and sexually transmitted diseases, and paediatric problems. The authors are to be congratulated on their clear style, the simple and easy to read English and the informative tables and illustrations used, making this book essential reading for students, and physicians and surgeons in training. It would be especially valuable as a quick revision aid to those about to sit the Part II FRCS examination. Frankly, there is little to criticize in this excellent book, which contains up to date information on management policies, practical hints that would be useful in everyday clinical life as well as several 'tricks of the trade'. However, I was somewhat disappointed to see that some chapters, such as that on faecal incontinence, do not receive the detailed attention they deserve. All in all, I found the book very enjoyable to read and thoroughly recommend it.

Microvascular Surgery of the Extremities

Zhongjia Yu (ed.). 240 × 155 mm. Pp. 521. Illustrated. 1993. Heidelberg: Springer. DM 398.

This book appears to be the natural successor to *Microsurgery*[1]. The present editor, Dr Zhongjia Yu, has succeeded Dr Chen Zhong-Wei as chief of the orthopaedic department in the Shanghai Sixth People's Hospital. The scope of microsurgery in this book is restricted to upper- and lower-limb reconstruction, of which Dr Yu has experience of hundreds of cases. The depth of this experience is reflected in examples of reconstruction of many rare traumatic conditions, such as reconstruction of the digitless hand. There is a fascinating description of the techniques, which Dr Yu has pioneered, of metacarpal reconstruction with a two- or three-pronged endoprosthesis. The proximal single stem is inset into the fenestrated radial medullary cavity, while either single- or double-toe transplants are attached to the distal prongs, giving functional pinch or key grip depending on the number of digits used.

The book is well set out with accurate and informative chapters on basic anatomy and transplant dissection techniques, and large sections on thumb and hand reconstruction. There is a generous section on cross-leg free flaps, used when the vessels in the damaged limb are unsuitable for anastomosis; anastomosis is carried out on the opposite undamaged limb (so-called cross-bridge procedure).

The quality of photographs, illustrations and printing is excellent and although some of the reconstructive procedures may not be acceptable to Western patients this book is, I believe, something that every plastic or orthopaedic reconstructive surgeon carrying out microsurgical repair would like to own.

P. L. G. Townsend

Frenchay Hospital
Bristol BS16 1LE

Surgical Decision Making

F. T. de Dombal. 215 × 136 mm. Pp. 157. Illustrated. 1993. Oxford: Butterworth–Heinemann. £14·95.

It is a pity that the habit of giving subtitles to books seems to find less favour than it did in Victorian times. A first-class subtitle to de Dombal's book would be: 'Letters to a young surgeon concerning some of the things that you were not taught at medical school'. The author tries to make the young surgeon think. Doctors, he writes, must first of all acquire information from patients – by taking a history and doing a physical examination. They must analyse this information and make a decision about management: What special tests are needed? What intervention is appropriate? There is an interesting chapter on the development of Bayes' theorem, particularly in relation to abdominal pain; de Dombal stresses its application to surgical decision making. One starts with a prior probability that more people with new pain in the right lower abdomen have appendicitis than any other single disease, for example. One then reaches a conditional probability as more information is gathered and, ultimately, a final probability (but never a certainty) on which to act. At the same time the utility of opposing decisions is judged and the course that promises the most utility chosen.

The author is at pains to draw a distinction between making a diagnosis and making a decision, and this is one of the strengths of the book. There is practically no mention of computer-assisted decision making and none of the equations that would only confuse non-mathematical surgeons. This is a book that I would like to think will be read and enjoyed by every new surgical house officer. I also hope that senior people will take in the message and pass it on to their trainees.

Instructions to authors

The British Journal of Surgery publishes original articles, reviews and leading articles. Short notes, case reports and surgical workshops are also accepted. All manuscripts are submitted to editorial review.

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another journal, has not been accepted for publication elsewhere and has not already been published. **Any detected attempt at dual publication will lead to automatic rejection and may prejudice acceptance of future submissions.** Articles and their illustrations become the property of the Journal unless rights are reserved before publication. The title page should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies of original articles and other editorial matter to: The Senior Editor, *The British Journal of Surgery*, Blackwell Scientific Publications Ltd, 25 John Street, London WC1N 2BL, UK. Telephone: 071-404 1831. Facsimile: 071-404 1927.
Books for review should be sent to the same address.

A covering letter must accompany all submissions and must be signed by all authors. The covering letter should state if an abstract of the work has been published and whether the authors wish the manuscript and/or illustrations to be returned if the work is not accepted. The first named author is responsible for ensuring that all authors have seen and approved the manuscript and are fully conversant with its contents.

Rejected manuscripts will not be returned to the authors, unless this is specifically requested.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached. Written consent must be obtained from the patient, legal guardian or executor for publication in *The British Journal of Surgery* of any details or photographs which might identify an individual. Evidence of such consent should be submitted with the manuscript.

Preparation of manuscripts

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; **296**: 401–5 or the *Annals of Internal Medicine* 1988; **108**: 258–65, or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from The Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR, UK (cost £1·00 per copy).

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. **When quoting specific materials, equipment and proprietary drugs, authors must state in parentheses the name and address of the manufacturer.** Failure to do so will result in delay in publication as the Journal considers that this information is essential for any reader who wishes to obtain similar material. Generic names should normally be used.

Original articles

Original articles should normally be in the format of introduction, methods, results, discussion. Each manuscript should contain a summary on a separate page. Authors are reminded that there is considerable pressure on editorial space in the Journal. Lengthy manuscripts are likely to be returned to authors for shortening. The discussion in particular should be clear and concise, and should be limited to matters arising directly from the results. Authors should avoid discursive speculation.

Reviews

The Editorial Board of *The British Journal of Surgery* encourages submission of review articles on topics of interest to its readers. Any topic will be considered, but priority will be given to those addressing a major current problem. The author of each accepted review will receive an honorarium. Potential authors seeking advice on the suitability of review topics are advised to contact: Mr J. A. Murie, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK.

Leading articles

The Editors commission signed leading articles to *The British Journal of Surgery*. These articles are 600–1000 words in length, address controversial topics of current interest and are supported by key references. Submissions may be subjected to external review and assessment by the Editorial Board before acceptance. The Editors retain the right to alter style and shorten material for publication. An honorarium is payable on publication.

Short notes

These are original observations presented in brief form. They should follow the standard format of introduction, methods, results and discussion, but no summary is required. Short notes should not exceed 500 words with a maximum of five references and one table or one figure.

Case reports

The British Journal of Surgery receives an increasing number of case reports each year. Space within the Journal remains at a premium and the rejection rate is high. Case reports should be no more than 400 words (300 if accompanied by a figure), with no more than five references and one illustration.

Surgical workshops

These describe technical innovations or modifications which may be useful in surgical practice. These articles should be less than 500 words long; they may be accompanied by no more than two figures and up to five references.

Typescripts

It is *essential* that manuscripts be clearly reproduced with adequate space for editorial notes. **Papers must be typewritten or printed on A4 paper (210 × 297 mm) on one side of the paper only with double spacing and 4 cm margins. Manuscripts which do not conform to these requirements will be returned to the authors for recasting.** Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations. The text should usually follow the standard sequence of introduction,

methods, results and discussion. These sections should run sequentially through the text, avoiding blank space between them.

Title page

The title page should give: (1) the title of the article; (2) the name and initials of each author; (3) the department and institution to which the work should be attributed; (4) the name, address, and telephone and facsimile numbers of the author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; and (6) the category in which the manuscript is being submitted (original article, case report etc.).

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytical methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Three copies of all illustrations and tables should be submitted. Each table with an appropriate brief title should be typed on a separate page. At least one set of illustrations (line drawings, radiographs, photomicrographs etc.) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Photocopies should be of sufficient quality to enable the Journal's referees to judge their content and value. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers of patients involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full. Permission to use published work must be obtained from the original author and the publisher before submission.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension. Abbreviations should be used consistently throughout the text and must be clearly defined on first use.

Numbers and units

The decimal point, not a comma, is used, e.g. 5·7. A space and not a comma follows thousands and multiples thereof, e.g. 10 000. SI units (International System of Units) should be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points.

References

References should be typed with double spacing and cited in the Vancouver style (see above: Uniform Requirements for Manuscripts Submitted to Biomedical Journals). Reference to abstracts from meetings is discouraged; reference to unpublished communications is not acceptable. Personal communications should be cited in the text, in parentheses. The first author is responsible for confirming the acceptability of the material quoted with the originator.

In the text, references should be numbered consecutively by superscript: ^{1,2} or $^{1-3}$. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication; volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; **66**: 184–6. The sequence for the chapters of a book should be: author(s); chapter title; editors; book title; place of publication; publisher; year of publication; page numbers. For example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In: Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications*. New York: Springer-Verlag, 1981: 123–63.

Statistics

For detailed guidance on the handling of statistical material, authors should consult *The British Journal of Surgery* 1991; **78**: 782–4. The Editors and statistical referees in evaluating a manuscript will consider the *design* of the study, the *presentation* of the data, the *analysis* of the data, and the *interpretation* of the results.

Design

Authors should set out clearly the objectives of the study, should identify the primary and secondary hypotheses, and should explain the rationale for the choice of sample size.

Presentation

Whenever possible a graphical presentation should be used to illustrate the main findings of a study. The use of standard deviation and standard error should be clearly distinguished. The use of the '±' symbol should be avoided; these statistics should be presented in parentheses after the mean value.

Analysis

There should be a clear description of which methods were used for which analyses, and any methods not in common usage should be supported by references. Results of statistical tests should be reported by stating the value of the test statistic, the number of degrees of freedom and the P value. For example, '$t = 1{\cdot}34$, 16 d.f., $P = 0{\cdot}20$' might be reported. Actual P values should be reported, to two decimal places, especially when the result is not significant, rather than stating 'not significant'.

Whenever possible, the results of the primary analyses should be reported using confidence intervals instead of, or in addition to, P values.

Interpretation

Statistical significance should not be confused with clinical significance. In particular, 'negative' findings should be interpreted through the use of confidence intervals.

Authors should beware of placing undue emphasis on secondary analyses, especially when they were suggested by an inspection of the data.

Subject index

Abscess

Percutaneous ultrasound-guided drainage of intra-abdominal abscesses, 336

Achalasia

Oesophagomyotomy for achalasia: a 22 year experience, 882
Short myotomy for vigorous achalasia, 1540

Adrenal

Adrenal incidentaloma, 422
Laparoscopic removal of an adrenocortical adenoma (surgical workshop), 874
Phaeochromocytoma associated with thymoma (case report), 223

AIDS

Splenectomy in human immunodeficiency virus-related thrombocytopenia, 330

Anaesthesia

Ventilatory and blood gas changes during laparoscopic and open cholecystectomy, 1252

Anastomosis

Continuous single-layer serosubmucosal anastomosis in the upper gastrointestinal tract, 1416
Effect of suture material on tumour cell adherence at sites of colonic injury, 774
Intraoperative testing of the Valtrac biofragmentable anastomotic ring (surgical workshop), 618
One-layer continuously sutured colonic anastomosis (surgical workshop), 1450
Purse-string suture for stapled oesophagogastric anastomosis: hand sewn *versus* automatic, 734

Anatomy

Anal endosonography and correlation with *in vitro* and *in vivo* anatomy, 508

Aneurysm

Abdominal aortic aneurysm: still missing the message, 450
Abdominal aortic aneurysm in the elderly, 1122
Autologous predonation, haemodilution and intraoperative blood salvage in elective abdominal aortic aneurysm repair, 313
Comparison of long-term survival after successful repair of ruptured and non-ruptured abdominal aortic aneurysm, 585
Emergency aortic aneurysmectomy in a renal transplant recipient (case report), 201
High prevalence of unsuspected abdominal aortic aneurysm in patients with confirmed symptomatic peripheral or cerebral arterial disease, 582
Influence of type III collagen genotype on aortic diameter and disease, 1246
Intraoperative thrombolysis in the management of thrombosed popliteal aneurysm (surgical workshop), 858
Natural history of abdominal aortic aneurysm detected by screening, 718
Popliteal aneurysm: morphology and management, 1531
Preoperative coagulopathy in ruptured abdominal aortic aneurysm predicts poor outcome, 974
Rupture of a true profunda femoris artery aneurysm (case report), 721
Screening for abdominal aortic aneurysm, 1363
Ultrasonographic screening for abdominal aortic aneurysm in an urban community, 1406

Angioplasty

Interventional radiology in the maintenance of infrainguinal vein graft patency, 187
Laser angioplasty, 550

Anorectal function

Anorectal function after preoperative intraluminal brachytherapy and colonic J pouch-anal anastomosis for rectal carcinoma, 933
Idiopathic slow-transit constipation, 1107
In vitro response of the human anal canal longitudinal muscle layer to cholinergic and adrenergic stimulation: evidence of sphincter specialization, 1337
Internal anal sphincter dysfunction in neurogenic faecal incontinence, 259
Possible role of the autonomic nervous system in sphincter impairment after restorative proctocolectomy, 631
Randomized trial comparing three forms of pelvic floor repair for neuropathic faecal incontinence, 794
Relationship between intra-abdominal and intrarectal pressure in the proctometrogram, 1070
Simultaneous dynamic electromyographic proctography and cystometrography, 115
Sphincter rupture in childbirth, 392

Anorectal physiology

Effect of anorectal eversion during restorative proctocolectomy on anal sphincter function, 121

Antibiotic

Antibiotic prophylaxis is indicated for chest stab wounds requiring closed tube thoracostomy, 464
Imipenem prophylaxis in elective colorectal surgery, 1196
Prophylactic use of cefuroxime in biliary tract surgery: randomized controlled trial of single *versus* multiple dose in high-risk patients, 917

Anus

Anal endosonography and correlation with *in vitro* and *in vivo* anatomy, 508
Physiological and histochemical adaptation of the electrically stimulated gracilis muscle to neoanal sphincter function, 1342

Aorta

Abdominal aortic aneurysm: still missing the message, 450
Abdominal aortic aneurysm in the elderly, 1122
Abdominal aortic thrombosis following a fall (case report), 214
Aortic anastomosis made easier (surgical workshop), 970
Autotransfusion in aortic surgery: the Haemocell System 350 cell saver, 32
Comparison of long-term survival after successful repair of ruptured and non-ruptured abdominal aortic aneurysm, 585
High prevalence of unsuspected abdominal aortic aneurysm in patients with confirmed symptomatic peripheral or cerebral arterial disease, 582
Myocardial infarction after reconstruction of the abdominal aorta, 28
Natural history of abdominal aortic aneurysm detected by screening, 718
Preoperative coagulopathy in ruptured abdominal aortic aneurysm predicts poor outcome, 974
Risberg retroperitoneal approach to the abdominal aorta, 971
Screening for abdominal aortic aneurysm, 1363
Ultrasonographic screening for abdominal aortic aneurysm in an urban community, 1406

Appendix

Carcinoid tumours of the appendix in children 1957–7986: incidence, treatment and outcome, 502
Contemporary management of the appendiceal mass, 18
Controlled trial of wound infiltration with bupivacaine for postoperative pain relief after appendicectomy in children, 110
Conventional *versus* laparoscopic surgery for acute appendicitis, 761
Early discharge from hospital after open appendicectomy, 1192
Non-operative treatment of small bowel obstruction following appendicectomy or operation on the ovary or tube, 1310
Randomized controlled trial comparing laparoscopic and open appendicectomy, 1599
Randomized study of the value of laparoscopy before appendicectomy, 922
Unusual case of large bowel obstruction (case report), 744

Arterial disease

Long-term results of a single protocol for thrombolysis in acute lower-limb ischaemia, 1262

Artery

Access to convalescent beds in vascular surgery (short note), 186
Acute limb deterioration during intra-arterial thrombolysis, 1118
Changing trends in the management of lower-limb ischaemia: a 17-year review, 1269
Choice of agent for peripheral thrombolysis, 25
Congenital arteriovenous malformations, 2
Early results and 1-year follow-up after intra-arterial thrombolysis, 194
Femoroaxillary bypass for cerebral ischaemia caused by occlusion of the innominate artery (case report), 717
Intermittent claudication incites systemic neutrophil activation and increased vascular permeability, 181
Interventional radiology in the maintenance of infrainguinal vein graft patency, 187
Intraoperative measurement of vascular graft resistance as a predictor of early outcome, 854
Intraoperative streptokinase: a useful adjunct to balloon- catheter embolectomy, 21
Low-dose aspirin fails to inhibit increased platelet reactivity in patients with peripheral vascular disease, 1266
Management of superficial femoral artery occlusive disease, 959
Mesothelial seeding of knitted Dacron, 587
Peripheral arterial thrombolysis: intermediate-term results, 592
Prospective randomized comparison of *in situ* and reversed infrapopliteal vein grafts, 173
Protein C deficiency and rapidly progressing peripheral arterial disease (case report), 466
Role of the leucocyte in the pathogenesis of vascular disease, 1503
Vibration white finger, 705

Artery - carotid

Benefits of carotid endarterectomy: the message is not getting through (short note), 722
Carotid endarterectomy improves haemodynamics on the contralateral side: implications for operating contralateral to an occluded carotid artery, 170
Characterization of symptomatic and asymptomatic carotid plaques using high-resolution real-time ultrasonography, 1274
Serial imaging of the carotid bifurcation and cerebrovascular reserve after carotid endarterectomy, 1278
Sources of air embolization during carotid surgery: the role of transcranial Doppler ultrasonography (short note), 1121
Vein-patch rupture after carotid endarterectomy: an avoidable catastrophe (for debate), 852

Artery - femoropopliteal

Infrainguinal revascularization in the diabetic patient, 1237

Artery - popliteal

Intraoperative thrombolysis in the management of thrombosed popliteal aneurysm (surgical workshop), 858

Audit

Access to convalescent beds in vascular surgery (short note), 186
Changing trends in the management of lower-limb ischaemia: a 17- year review, 1269
Comparative audit: fact *versus* fantasy (for debate), 1424

Early discharge after operation, 1587
Helicopter Emergency Medical Service operating from the Royal London Hospital: the first year, 218
Profiles of workload in general surgery from linked hospital statistics, 1073
Survey of minor surgery in general practice in the West of Scotland, 202

Axilla

Axillary nodal metastases from an occult primary consistent with breast carcinoma, 1299
Intraoperative assessment of nodal status in the selection of patients with breast cancer for axillary clearance, 457
Treatment of the axilla in patients with screen-detected breast cancer, 436

Bacteriology

Bacterial translocation in acute liver failure induced by 90 per cent hepatectomy in the rat, 66
Colonic bacteria and bacterial translocation in experimental colitis, 512
Translocation of enteric bacteria in humans (short note), 901

Bile

Bile acid absorption after restorative proctocolectomy (short note), 1068

Bile duct

Biliary stent failure after 42 years (case report), 908
Changing trends in the management of extrahepatic cholangiocarcinoma, 1434
Common bile duct stones: a controversy revisited (for debate), 759
Complete common bile duct division at laparoscopic cholecystectomy: management by percutaneous drainage and endoscopic stenting (case report), 1053
Diagnostic value of cytology for biliary stricture, 414
Easy technique for cholangiography during laparoscopic cholecystectomy (surgical workshop), 211
Minimally invasive treatment for common bile duct stones, 103
Operative cholangiography and laparoscopic bile duct exploration, 957
Palliation of biliary obstruction in patients with advanced breast cancer using endoscopic stents, 1188
Percutaneously placed Wallstent endoprosthesis in patients with malignant distal biliary obstruction, 1185
Reoperation for biliary tract complications following orthotopic liver transplantation, 1426
Temporary use of a biliary endoprosthesis for unsuspected bile duct stones found at laparoscopic cholecystectomy (short note), 1443

Biliary tract

Perineural invasion of carcinoma of the pancreas and biliary tract, 619

Bladder

Simultaneous dynamic electromyographic proctography and cystometrography, 115

Blood

Autologous predonation, haemodilution and intraoperative blood salvage in elective abdominal aortic aneurysm repair, 313
Autotransfusion in aortic surgery: the Haemocell System 350 cell saver, 32
Perioperative blood transfusion and outcome after resection for colorectal carcinoma, 427

Blood flow

Carotid endarterectomy improves haemodynamics on the contralateral side: implications for operating contralateral to an occluded carotid artery, 170
Changes in liver blood flow associated with the growth of hepatic LV10 and MC28 sarcomas in rats, 495
Effect of foot compression on the velocity and volume of blood flow in the deep veins, 198
Histamine but neither angiotensin nor vasopressin increases antibody uptake into xenograft colorectal liver metastases, 72

Brain

Staging of supratentorial hemisphere glioma using tumour extension, histopathological grade and extent of surgical resection, 1130

Breast - benign

Fungating benign ductal adenoma of the breast (case report), 456

Breast - malignant

Axillary nodal metastases from an occult primary consistent with breast carcinoma, 1299
Centroinferior hemimastectomy (surgical workshop), 44
Correlation between p53 mutations and antibody staining in breast carcinoma, 1410
Cytodiagnosis of breast disease using a liquid suspension medium, 866
Detection and significance of occult metastases in node-negative breast cancer, 459
Effects of surgery on the generation of lymphokine-activated killer cells in patients with breast cancer, 1005
Genetic linkage analysis applied to unaffected women from families with breast cancer can discriminate high- from low-risk individuals, 1381
Intraoperative assessment of nodal status in the selection of patients with breast cancer for axillary clearance, 457
Palliation of biliary obstruction in patients with advanced breast cancer using endoscopic stents, 1188
Role of computed tomography in the staging of primary breast cancer (short note), 1137
Scar formation after breast-conserving surgery for cancer, 1003
Screening for breast cancer detects tumours at an earlier biological stage, 863
Specimen-orientated radiography helps define excision margins of malignant lesions detected by breast screening, 1001
Treatment of the axilla in patients with screen-detected breast cancer, 436

Breast - screening

Screening for breast cancer, 141

Breast - surgery

Centroinferior hemimastectomy (surgical workshop), 44
New needle to simplify removal of impalpable breast tumours (surgical workshop), 729
Randomized trial of laser scalpel for modified radical mastectomy, 871
Scar formation after breast-conserving surgery for cancer, 1003
Silicone gel implants, breast cancer and connective tissue disorders, 1097
Use of silicone implants after wide local excision of the breast, 868

Bronchus

Pneumoperitoneum from a ruptured bronchus in a child (case report), 212

Burn

Acute haemodilution in surgery for burns: a preliminary report, 1294
Early wound excision and skin grafting restores cellular immunity after severe burn trauma, 1296

Calcium

Oral calcium inhibits rectal epithelial proliferation in familial adenomatous polyposis, 499

Calculus

Common bile duct stones: a controversy revisited (for debate), 759

Carcinoma

Medullary thyroid carcinoma, 6
Total pelvic exenteration: a justified procedure, 1615

Carotid

Carotid endarterectomy: confidence restored, 821
Carotid endarterectomy improves haemodynamics on the contralateral side: implications for operating contralateral to an occluded carotid artery, 170
Characterization of symptomatic and asymptomatic carotid plaques using high-resolution real-time ultrasonography, 1274
Factors influencing the hyperaemic response after carotid endarterectomy, 1523
Randomized controlled trial of patch angioplasty for carotid endarterectomy, 1528
Serial imaging of the carotid bifurcation and cerebrovascular reserve after carotid endarterectomy, 1278
Sources of air embolization during carotid surgery: the role of transcranial Doppler ultrasonography (short note), 1121
Vein-patch rupture after carotid endarterectomy: an avoidable catastrophe (for debate), 852

Cell kinetics

Individuals with a strong family history of colorectal cancer demonstrate abnormal rectal mucosal proliferation, 249
Kinetic changes and experimental carcinogenesis after Billroth I and II gastrectomy, 893
Mucosal morphology, cell proliferation and faecal bacteriology in acute pouchitis, 1445
Oral calcium inhibits rectal epithelial proliferation in familial adenomatous polyposis, 499
Prognostic significance of cell culture in carcinoma of the oesophagus, 605

Chemotherapy

Superselective intra-arterial chemotherapy with mitomycin for gallbladder cancer, 912

Chest

Antibiotic prophylaxis is indicated for chest stab wounds requiring closed tube thoracostomy, 464

Coagulation

Preoperative coagulopathy in ruptured abdominal aortic aneurysm predicts poor outcome, 974

Colon

New technique to measure mucosal metabolism and its use to map substrate utilization in the healthy human large bowel, 445

Colon - inflammatory

Colonic bacteria and bacterial translocation in experimental colitis, 512
Diaphragm-like strictures of the colon induced by non-steroidal anti-inflammatory drugs (case report), 395
Effect of putative phospholipase A_2 inhibitors on acetic acid- induced acute colitis in the rat, 1199
Expression of p53 in colorectal cancer and dysplasia complicating ulcerative colitis, 442
Radiological investigation in acute diverticulitis, 560
Ulcerative colitis in familial adenomatous polyposis (case report), 254

Colon - miscellaneous

Colonic obstruction in acute myeloid leukaemia (case report), 1601

Colon - surgery

Bile acid absorption after restorative proctocolectomy (short note), 1068
'Car-crusher colon' (case report), 640
Detection and enumeration of circulating tumour cells in colorectal cancer, 777
Gunshot wounds of the colon: role of retained bullets in sepsis, 772
Imipenem prophylaxis in elective colorectal surgery, 1196
Intraoperative irrigation for acute distal colonic obstruction caused by carcinoma (surgical workshop), 516
Intraoperative testing of the Valtrac biofragmentable anastomotic ring (surgical workshop), 618
Laparoscopic colorectal surgery: a prospective assessment and current perspective, 1602
Laparoscopically assisted reversal of Hartmann's procedure (surgical workshop), 109
Multicentre study of a continent colostomy plug, 930

New technique for sigmoid colectomy, 1606
One-layer continuously sutured colonic anastomosis (surgical workshop), 1450
Randomized trial of drainage of colorectal anastomosis, 769
Treatment of perforated sigmoid diverticulitis: a prospective randomized trial, 505
Unusual case of large bowel obstruction (case report), 744
Use of cotton tapes in laparoscopic intestinal surgery (surgical workshop), 768
Visualization of the ureter during laparoscopic colonic resection (surgical workshop), 1332

Colon - traumatic

Delayed perforation of the colon following colonoscopic biopsy (case report), 1204

Colon - tumour

Change towards earlier stage at presentation of colorectal cancer, 1610
Colonoscopic follow-up after resection for colorectal cancer: a selective policy, 781
Colonoscopic surveillance after curative resection for colorectal cancer, 1330
D-dimer: a useful marker of disease stage in surgery for colorectal cancer (short note), 1404
Delay in diagnosis and prognosis of carcinoma of the right colon, 1327
Detection and enumeration of circulating tumour cells in colorectal cancer, 777
Effect of suture material on tumour cell adherence at sites of colonic injury, 774
Expression of p53 in colorectal cancer and dysplasia complicating ulcerative colitis, 442
Faecal occult blood screening for colorectal neoplasia in a targeted high-risk population, 1399
Faecal occult blood screening for patients with gastrointestinal symptoms (short note), 1326
Growth rate and percentage hepatic replacement of colorectal liver metastases, 1036
Increased risk of colorectal cancer associated with congenital anomalies of the urinary tract, 785
Individuals with a strong family history of colorectal cancer demonstrate abnormal rectal mucosal proliferation, 249
Laparoscopic surgery for colorectal cancer, 1229
Lipomatous polyposis of the colon (case report), 349
Multidrug-resistant colonic cancer cell line LoVoDx is efficiently killed by lymphokine-activated killer cells from patients with carcinoma of the colon, 1259
Oestrogen and progesterone receptors in colorectal cancer and human colonic cancer cell lines, 636
Perioperative blood transfusion and outcome after resection for colorectal carcinoma, 427

Complication

Complications of circumcision, 1231
Preventing complications of laparoscopy (for debate), 1593
Subumbilical hernia following laparoscopic cholecystectomy (case report), 1595

Computed tomography

Computed tomography in the management of blunt abdominal trauma in children, 982
Patient selection and timing of dynamic computed tomography in acute pancreatitis, 1393
Role of computed tomography in the staging of primary breast cancer (short note), 1137

Crohn's disease

Crohn's disease and anastomotic recurrence: microvascular ischaemia and anastomotic healing in an animal model, 226
Crohn's disease involving a rectus abdominis myocutaneous flap (case report), 1069
Intraoperative enteroscopy in Crohn's disease, 897
Suppression of macrophage function by suture materials and anastomotic recurrence of Crohn's disease, 387
Surgical management of perineal and metastatic cutaneous Crohn's disease, 1596

Cyst

Computed tomography and fine-needle aspiration cytology for preoperative evaluation of cystic tumours of the pancreas, 1166

Cytokines

Cytokine gene transcription in renal cell carcinoma, 1322
Cytokines, sepsis and immunomodulation, 289
Granulocyte-macrophage colony-stimulating factor inhibits tumour growth, 1543
Interleukin 2 therapy: current role in surgical oncological practice, 155
Role of the neutrophil in adult respiratory distress syndrome, 10

Cytology

Diagnostic value of cytology for biliary stricture, 414

Day-case surgery

Early discharge after operation, 1587

Defaecation

Idiopathic slow-transit constipation, 1107

Diabetes

Infrainguinal revascularization in the diabetic patient, 1237

Diverticulum

Intraluminal duodenal diverticulum: an unusual cause of acute pancreatitis (case report), 488
Treatment of perforated sigmoid diverticulitis: a prospective randomized trial, 505

Drains

Biliary drainage in obstructive jaundice: experimental and clinical aspects, 834
Randomized trial of drainage of colorectal anastomosis, 769

Drug - side effects

Cocaine 'body packers', 1513

Duodenum

Duodenal duplication causing segmental portal hypertension and massive intestinal haemorrhage (case report), 1031
Randomized controlled trial of the effect of sulindac on duodenal and rectal polyposis and cell proliferation in patients with familial adenomatous polyposis, 1618
Surgical polypectomy of duodenal adenomas in familial adenomatous polyposis: experience of two European centres, 1029

Embolus

Intraoperative streptokinase: a useful adjunct to balloon- catheter embolectomy, 21

Endarterectomy

Carotid endarterectomy: confidence restored, 821
Factors influencing the hyperaemic response after carotid endarterectomy, 1523
Randomized controlled trial of patch angioplasty for carotid endarterectomy, 1528

Endocrine

Genetic testing for multiple endocrine neoplasia, 1092
Management of non-functioning neuroendocrine tumours of the pancreas, 625

Endoscopy

Assessment of main pancreatic duct integrity by endoscopic retrograde pancreatography in patients with acute pancreatitis, 94
Colonoscopic follow-up after resection for colorectal cancer: a selective policy, 781
Colonoscopic surveillance after curative resection for colorectal cancer, 1330
Delayed perforation of the colon following colonoscopic biopsy (case report), 1204
Endoscopic sphincterotomy in acute gallstone pancreatitis, 547
Intraoperative enteroscopy in Crohn's disease, 897
Long-term survival after endoscopic transanal resection of rectal tumours, 1401
Minimally invasive treatment for common bile duct stones, 103

Endoscopy - miscellaneous

Endoscopic sympathectomy, 687

Endothelium

Effect of seeding time and density on endothelial cell attachment to damaged vascular surfaces, 359
Endothelial xanthine oxidase: a radical transducer of inflammatory signals for reticuloendothelial activation, 684
Intermittent claudication incites systemic neutrophil activation and increased vascular permeability, 181
Mesothelial seeding of knitted Dacron, 587

Epidemiology

Increased risk of colorectal cancer associated with congenital anomalies of the urinary tract, 785

Experimental

Biliary drainage in obstructive jaundice: experimental and clinical aspects, 834
Changes in liver blood flow associated with the growth of hepatic LV10 and MC28 sarcomas in rats, 495
Crohn's disease and anastomotic recurrence: microvascular ischaemia and anastomotic healing in an animal model, 226
Effect of antitumour necrosis factor treatment on circulating tumour necrosis factor levels and mortality after surgery in jaundiced mice, 1055
Effect of putative phospholipase A_2 inhibitors on acetic acid-induced acute colitis in the rat, 1199
Effect of suture material on tumour cell adherence at sites of colonic injury, 774
Ischaemia-reperfusion injury in the rat kidney: effect of a single dose of sodium bicarbonate, 112
Nucleolar organizing regions in the operated rat stomach: relationship to metaplasia, dysplasia and carcinoma, 57
Polytetrafluoroethylene patch grafting for closure of stomach defects in the rat (short note), 1013
Purse-string suture for stapled oesophagogastric anastomosis: hand sewn *versus* automatic, 734
Role of reflux oesophagitis and acid in the development of columnar epithelium in the rat oesophagus, 467
Smoking impairs endothelium-dependent relaxation of saphenous vein, 1242
Temporal relationship of acinar and microvascular changes in caerulein-induced pancreatitis, 1174

Femoral

Rupture of a true profunda femoris artery aneurysm (case report), 721

Fistula

Fistula complicating restorative proctocolectomy, 1065
Histological and microbiological assessment of the role of micro-organisms in chronic anal fistula (short note), 1072
Lymphatic fistula and perigraft seroma, 410
Pancreatic fistula cured by an endoprosthesis in the pancreatic duct (case report), 1316
Pouch-vaginal fistula, 936
Total sphincter conservation in high fistula *in ano*: results of a new approach, 802

Fluid and electrolyte balance

Acute haemodilution in surgery for burns: a preliminary report, 1294

Foreign body

Cocaine 'body packers', 1513

Gallbladder - inflammatory

Percutaneous transhepatic cholecystostomy for acute acalculous cholecystitis, 1440
Ultrasonography in the diagnosis of gallbladder polyps (short note), 345

Gallbladder - surgery

Bile duct injury and bile leakage in laparoscopic cholecystectomy, 1590
Cholecystectomy and oesophageal reflux: a prospective evaluation, 50
Comparison of metabolic responses to laparoscopic and minilaparotomy cholecystectomy, 1255
Complete common bile duct division at laparoscopic cholecystectomy: management by percutaneous drainage and endoscopic stenting (case report), 1053
Impact of laparoscopic cholecystectomy in the UK: a survey of consultants (short note), 346
Laparoscopic cholecystectomy, 552
Laparoscopic cholecystectomy with endoscopic retrograde cholangiopancreatography for acute gallstone pancreatitis (short note), 247
Laparoscopic cholecystectomy in the Netherlands, 1180
Long-term follow-up after open cholecystectomy, 100
New technique of open laparoscopy (surgical workshop), 1184
Prophylactic use of cefuroxime in biliary tract surgery: randomized controlled trial of single *versus* multiple dose in high-risk patients, 917
Sclerotherapy of the human gallbladder using ethanol and tetracycline hydrochloride (surgical workshop), 916
Selective cholangiography in laparoscopic cholecystectomy, 244
Subumbilical hernia following laparoscopic cholecystectomy (case report), 1595
Symptomatic outcome after laparoscopic cholecystectomy, 439
Ventilatory and blood gas changes during laparoscopic and open cholecystectomy, 1252

Gallbladder - tumour

Cancer of the gallbladder associated with anomalous junction of the pancreatobiliary duct system without bile duct dilatation, 622
Superselective intra-arterial chemotherapy with mitomycin for gallbladder cancer, 912

Gallstones

Future directions for conservative treatment of gallbladder calculi, 143
Late discharge of stones after laparoscopic cholecystectomy (case report), 1052
Long-term follow-up after open cholecystectomy, 100
Minimally invasive treatment for common bile duct stones, 103
Temporary use of a biliary endoprosthesis for unsuspected bile duct stones found at laparoscopic cholecystectomy (short note), 1443

General

Cocaine 'body packers', 1513
Organization of general surgical services in Britain: strategic planning of workload and manpower, 1377
Profiles of workload in general surgery from linked hospital statistics, 1073
Quality-of-life measurement in surgical practice, 163
Surgical evaluation at the crossroads, 964

Genetics

Correlation between p53 mutations and antibody staining in breast carcinoma, 1410
Gene transfer therapy in cancer, 566
Genetic linkage analysis applied to unaffected women from families with breast cancer can discriminate high- from low-risk individuals, 1381
Genetic testing for multiple endocrine neoplasia, 1092
Influence of type III collagen genotype on aortic diameter and disease, 1246

Geriatric

Gastrointestinal surgery in the aged (short note), 329

Graft

Effect of seeding time and density on endothelial cell attachment to damaged vascular surfaces, 359
Infrainguinal vein graft stenosis, 825
Intraoperative measurement of vascular graft resistance as a predictor of early outcome, 854
Lymphatic fistula and perigraft seroma, 410
Mesothelial seeding of knitted Dacron, 587
Smoking impairs endothelium-dependent relaxation of saphenous vein, 1242

Growth factor

Hepatocyte growth factor/scatter factor, liver regeneration and cancer metastasis, 1368

Haemorrhage

Resuscitation for haemorrhagic shock (for debate), 213

Haemorrhoids

Incidence of haemorrhoids and anorectal varices in children with portal hypertension, 616

Haemostasis

Diathermy in laparoscopic surgery, 1094
Haemostasis after partial hepatectomy using argon beam coagulation, 1563
Use of desmopressin to prevent bleeding complications in patients treated with aspirin, 723

Heart

Cardiac risk and peripheral vascular surgery: new approach based on a multifactorial risk index, 354
Myocardial infarction after reconstruction of the abdominal aorta, 28

Hereditary

Hereditary calcific pancreatitis in an English family (case report), 487

Hernia - femoral

Femoral hernia: intestinal obstruction is an unrecognized source of morbidity and mortality, 230

Hernia - incisional

Herniation at the site of cannula insertion after laparoscopic cholecystectomy (case report), 915
Incisional hernioplasty with a 'lower' polypropylene prosthesis (surgical workshop), 1030

Hernia - inguinal

Factors associated with early discharge after inguinal hernia repair in 500 consecutive unselected patients, 1153
Follow-up after inguinal herniotomy or surgery for hydrocele in boys, 1613
Intestinal obstruction following laparoscopic inguinal hernia repair (case report), 1432
Localized argyria: a complication of the repair of inguinal hernia with silver filigree (case report), 1325
Method of separating the peritoneal sac from the spermatic vessels during laparoscopic repair of inguinal hernia (surgical workshop), 746
Return to work after inguinal hernia repair (short note), 745

Hernia - other

Rectus repair for midline ventral abdominal wall hernia, 614
Small bowel prolapse and incarceration caused by a vaginal ring pessary (case report), 1157

Hormone

Growth hormone therapy initiated before starvation ameliorates the catabolic state and enhances the protein-sparing effect of total parenteral nutrition, 740

Hydatid

Laparoscopic treatment of a liver hydatid cyst (surgical workshop), 907

Imaging

Anal endosonography and correlation with *in vitro* and *in vivo* anatomy, 508
New needle to simplify removal of impalpable breast tumours (surgical workshop), 729
Operative cholangiography and laparoscopic bile duct exploration, 957
Screening for breast cancer detects tumours at an earlier biological stage, 863
Selective cholangiography in laparoscopic cholecystectomy, 244
Serial imaging of the carotid bifurcation and cerebrovascular reserve after carotid endarterectomy, 1278
Specimen-orientated radiography helps define excision margins of malignant lesions detected by breast screening, 1001
Ultrasonography in the diagnosis of gallbladder polyps (short note), 345

Immune system

Changes in major histocompatibility complex class II expression in monocytes and T cells of patients developing infection after surgery, 205
Monocyte expression of class II antigens, 138
Suppression of macrophage function by suture materials and anastomotic recurrence of Crohn's disease, 387

Immunology

Cytokines, sepsis and immunomodulation, 289

Incision

Comparative study of abdominal incision techniques, 233
Herniation at the site of cannula insertion after laparoscopic cholecystectomy (case report), 915
Incisional hernioplasty with a 'flower' polypropylene prosthesis (surgical workshop), 1030
Rectus repair for midline ventral abdominal wall hernia, 614

Incontinence

Internal anal sphincter dysfunction in neurogenic faecal incontinence, 259
Randomized trial comparing three forms of pelvic floor repair for neuropathic faecal incontinence, 794

Infection

Spontaneous staphylococcal peritonitis in an otherwise healthy young man (case report), 1527

Inguinal

Factors associated with early discharge after inguinal hernia repair in 500 consecutive unselected patients, 1153
Method of separating the peritoneal sac from the spermatic vessels during laparoscopic repair of inguinal hernia (surgical workshop), 746
Return to work after inguinal hernia repair (short note), 745

Intestinal obstruction

Non-operative treatment of small bowel obstruction following appendicectomy or operation on the ovary or tube, 1310
Unusual case of large bowel obstruction (case report), 744

Ischaemia

Acute limb deterioration during intra-arterial thrombolysis, 1118
Basic fibroblast growth factor accelerates wound healing in chronically ischaemic tissue, 977
Changing trends in the management of lower-limb ischaemia: a 17- year review, 1269
Critical leg ischaemia: an appraisal of clinical definitions, 177
Endothelial xanthine oxidase: a radical transducer of inflammatory signals for reticuloendothelial activation, 684
Femoroaxillary bypass for cerebral ischaemia caused by occlusion of the innominate artery (case report), 717
Intermittent claudication incites systemic neutrophil activation and increased vascular permeability, 181
Ischaemia-reperfusion injury in the rat kidney: effect of a single dose of sodium bicarbonate, 112
Long-term results of a single protocol for thrombolysis in acute lower-limb ischaemia, 1262
Oxygenation of the gut mucosa, 953
Protein C deficiency and rapidly progressing peripheral arterial disease (case report), 466
Tissue and urokinase plasminogen activators in the

environs of venous and ischaemic leg ulcers, 596
Vibration white finger, 705

Jaundice

Biliary drainage in obstructive jaundice: experimental and clinical aspects, 834

Kidney

Cytokine gene transcription in renal cell carcinoma, 1322
Effect of nifedipine on renal transplant rejection, 1318
High incidence of arteriovenous fistula after biopsy of kidney allografts, 310
Ischaemia-reperfusion injury in the rat kidney: effect of a single dose of sodium bicarbonate, 112
Parathyroidectomy in the treatment of patients with chronic renal failure: a 10-year review, 40

Knot

Laparoscopic ligation of large pedicles (surgical workshop), 1444
New adjustable knot for securing subcuticular running sutures (surgical workshop), 873

Laparoscopy

Bile duct injury and bile leakage in laparoscopic cholecystectomy, 1590
Comparison of metabolic responses to laparoscopic and minilaparotomy cholecystectomy, 1255
Complete common bile duct division at laparoscopic cholecystectomy: management by percutaneous drainage and endoscopic stenting (case report), 1053
Conventional *versus* laparoscopic surgery for acute appendicitis, 761
Diathermy in laparoscopic surgery, 1094
Easy technique for cholangiography during laparoscopic cholecystectomy (surgical workshop), 211
Emergency laparoscopic surgery, 279
Herniation at the site of cannula insertion after laparoscopic cholecystectomy (case report), 915
Impact of laparoscopic cholecystectomy in the UK: a survey of consultants (short note), 346
Intestinal obstruction following laparoscopic inguinal hernia repair (case report), 1432
Laparoscopic appendicectomy: a two-handed technique (surgical workshop), 758
Laparoscopic cholecystectomy, 552
Laparoscopic cholecystectomy with endoscopic retrograde cholangiopancreatography for acute gallstone pancreatitis (short note), 247
Laparoscopic cholecystectomy in the Netherlands, 1180
Laparoscopic colorectal surgery: a prospective assessment and current perspective, 1602
Laparoscopic ligation of large pedicles (surgical workshop), 1444
Laparoscopic mobilization and exteriorization for minimally invasive small bowel resection (surgical workshop), 225
Laparoscopic omental patch repair of perforated duodenal ulcer with an automated stapler (surgical workshop), 1552
Laparoscopic surgery for colorectal cancer, 1229
Laparoscopic treatment of a liver hydatid cyst (surgical workshop), 907
Laparoscopic truncal vagotomy without drainage (surgical workshop), 236
Laparoscopic ultrasonography for hepatobiliary and pancreatic malignancy, 1571
Laparoscopically assisted reversal of Hartmann's procedure (surgical workshop), 109
Late discharge of stones after laparoscopic cholecystectomy (case report), 1052
Method of separating the peritoneal sac from the spermatic vessels during laparoscopic repair of inguinal hernia (surgical workshop), 746
New technique of open laparoscopy (surgical workshop), 1184
New technique for sigmoid colectomy, 1606
Operative cholangiography and laparoscopic bile duct exploration, 957
Preventing complications of laparoscopy (for debate), 1593
Prospective comparison of laparoscopic and conventional anterior resection, 1396
Randomized controlled trial comparing laparoscopic and open appendicectomy, 1599
Randomized study of the value of laparoscopy before appendicectomy, 922
Selective cholangiography in laparoscopic cholecystectomy, 244
Subumbilical hernia following laparoscopic cholecystectomy (case report), 1595
Sutureless laparoscopic treatment of perforated duodenal ulcer (surgical workshop), 235
Symptomatic outcome after laparoscopic cholecystectomy, 439
Use of cotton tapes in laparoscopic intestinal surgery (surgical workshop), 768
Ventilatory and blood gas changes during laparoscopic and open cholecystectomy, 1252
Visualization of the ureter during laparoscopic colonic resection (surgical workshop), 1332

Laser

Intra-abdominal photodynamic therapy: from theory to feasibility, 298
Laser angioplasty, 550
Randomized trial of laser scalpel for modified radical mastectomy, 871

Leg

Critical leg ischaemia: an appraisal of clinical definitions, 177

Liver

Hepatocyte growth factorscatter factor, liver regeneration and cancer metastasis, 1368

Liver - surgery

Bacterial translocation in acute liver failure induced by 90 per cent hepatectomy in the rat, 66
Changing trends in the management of extrahepatic cholangiocarcinoma, 1434
Elective hepatic resection for benign and malignant liver disease: early results, 1039
Emergency liver resection for spontaneous rupture of hepatocellular carcinoma complicating cirrhosis, 747
Extended left hepatectomy: technical aspects of an evolving procedure, 903
Graft size assessment by preoperative computed tomography in living related partial liver transplantation, 489
Haemostasis after partial hepatectomy using argon beam coagulation, 1563
Hepatectomy for liver metastases, 274
Laparoscopic treatment of a liver hydatid cyst (surgical workshop), 907
Liver resection with normothermic ischaemia exceeding 1 h, 1161
Liver transplantation in patients with thrombosis of the portal, splenic or superior mesenteric vein, 81
Pattern of recurrence after hepatic resection for colorectal metastases, 1032
Repeat hepatectomy for cancer, 1557
Repeat liver resection for recurrent colorectal metastases, 340
Resection of presumed benign liver tumours, 380
Surgical options for primary hepatocellular carcinoma, 1365
Ultrasonography during liver resection for hepatocellular carcinoma, 493

Liver - transplantation

Controlled liver splitting for transplantation in two recipients: technique, results and perspectives, 75
Graft size assessment by preoperative computed tomography in living related partial liver transplantation, 489
Liver transplantation in patients with thrombosis of the portal, splenic or superior mesenteric vein, 81
Orthotopic liver transplantation for hepatic complications of Wilson's disease, 909
Reoperation for biliary tract complications following orthotopic liver transplantation, 1426

Liver - trauma

Management of traumatic liver injuries, 86

Liver - tumour

Changes in liver blood flow associated with the growth of hepatic LV10 and MC28 sarcomas in rats, 495
Early detection of occult colorectal hepatic metastases using duplex colour Doppler sonography, 1249
Emergency liver resection for spontaneous rupture of hepatocellular carcinoma complicating cirrhosis, 747
Growth rate and percentage hepatic replacement of colorectal liver metastases, 1036
Hepatectomy for liver metastases, 274
Histamine but neither angiotensin nor vasopressin increases antibody uptake into xenograft colorectal liver metastases, 72
Laparoscopic ultrasonography for hepatobiliary and pancreatic malignancy, 1571
Liver resection for recurrent hilar cholangiocarcinoma (case report), 1433
Pattern of recurrence after hepatic resection for colorectal metastases, 1032
Repeat hepatectomy for cancer, 1557
Repeat liver resection for recurrent colorectal metastases, 340
Resection of presumed benign liver tumours, 380
Ultrasonography during liver resection for hepatocellular carcinoma, 493

Lymph node

Axillary nodal metastases from an occult primary consistent with breast carcinoma, 1299
Extensive *versus* limited lymph node dissection for gastric cancer: a comparative study of 320 patients, 1153
Lymph node metastases in early rectal cancer, 1457
Posterolateral neck dissection: technique and results, 1127
Prognostic relevance of systematic lymph node dissection in gastric carcinoma, 1015
Role of surgery and chemotherapy for peripheral lymph node tuberculosis, 1547

Lymph system - surgery

Lymphatic fistula and perigraft seroma, 410

Lymphocyte

Effects of surgery on the generation of lymphokine-activated killer cells in patients with breast cancer, 1005
Multidrug-resistant colonic cancer cell line LoVoDx is efficiently killed by lymphokine-activated killer cells from patients with carcinoma of the colon, 1259

Lymphoma

Role of surgery in patients with primary non-Hodgkin's lymphoma of the stomach: an old problem revisited, 1101

Management

Elective lymph node dissection in the management of malignant melanoma, 284
Modern management of pancreatic pseudocysts, 573
Radiological investigation in acute diverticulitis, 560

Melanoma

Elective lymph node dissection in the management of malignant melanoma, 284
Low-dose tumour necrosis factor α and melphalan in hyperthermic isolated limb perfusion, 995
Management of malignant melanoma of the head and neck, 998
Plantar melanoma in black South Africans, 992
Safe margins in the excision of primary cutaneous melanoma, 731
Systemic leakage during isolated limb perfusion for melanoma, 1124

Metabolic

Comparison of metabolic responses to laparoscopic and minilaparotomy cholecystectomy, 1255
Effects of tumour necrosis factor on protein metabolism, 1019

Metabolism

Resting energy expenditure in patients undergoing transhiatal or transthoracic oesophagectomy for carcinoma of the thoracic oesophagus, 1413

Metastasis

Cutaneous metastasis from a malignant fibrous histiocytoma to a limb skin graft donor site (case report), 366
Detection and enumeration of circulating tumour cells in colorectal cancer, 777
Growth rate and percentage hepatic replacement of colorectal liver metastases, 1036
Repeat liver resection for recurrent colorectal metastases, 340

Motility

Oesophagomyotomy for achalasia: a 22 year experience, 882
Transit disorders of the gastric remnant and Roux limb after Roux- en-Y gastrojejunostomy: relation to symptomatology and vagotomy, 60
Vagal system involvement in changes in small bowel motility during restraint stress: an experimental study in the dog, 479

Neck

Physical examination and selective conservative management in patients with penetrating injuries of the neck, 1534
Posterolateral neck dissection: technique and results, 1127

Neoplasm

Gene transfer therapy in cancer, 566
Genetic testing for multiple endocrine neoplasia, 1092

Neurological

Prognostic signs in the evaluation of patients with minor head injury, 988

Nutrition

Fully implantable venous access systems, 347
Perioperative nutritional support, 4
Reliability of clinical judgement in evaluation of the nutritional status of surgical patients, 1553

Nutrition - parenteral

Complications and survival of multilumen central venous catheters used for total parenteral nutrition, 1287
Growth hormone therapy initiated before starvation ameliorates the catabolic state and enhances the protein-sparing effect of total parenteral nutrition, 740

Obesity

Obesity: an important prognostic factor in acute pancreatitis, 484
Vertical banded gastroplasty for the treatment of morbid obesity, 1421

Obstruction

Colonic obstruction in acute myeloid leukaemia (case report), 1601
Femoral hernia: intestinal obstruction is an unrecognized source of morbidity and mortality, 230

Occlusion

Management of superficial femoral artery occlusive disease, 959

Oesophagus

Long-term results of treatment of peptic stricture of the oesophagus with the Angelchik prosthesis, 363

Oesophagus - cancer

Non-surgical treatment of cancer of the oesophagus, 412
Thoracoscopy in oesophagectomy for oesophageal cancer (surgical workshop), 320

Oesophagus - congenital

Oesophagomyotomy for achalasia: a 22 year experience, 882

Oesophagus - inflammatory

'Bile' in the oesophagus, 1374
Cholecystectomy and oesophageal reflux: a prospective evaluation, 50
Prospective randomized comparison of teres cardiopexy and Nissen fundoplication in the surgical therapy of gastro-oesophageal reflux disease, 875
Role of reflux oesophagitis and acid in the development of columnar epithelium in the rat oesophagus, 467
Surgical treatment of reflux stricture of the oesophagus, 317

Oesophagus - surgery

Anterior *versus* posterior reconstruction after transhiatal oesophagectomy: a randomized controlled trial, 1141
Erythromycin improves emptying of the denervated stomach after oesophagectomy, 879
Incidence and management of benign anastomotic stricture after cervical oesophagogastrostomy, 471
Intragastric bile acid and symptoms in patients with an intrathoracic stomach after oesophagectomy, 371
Oesophagectomy by a transhiatal approach or thoracotomy: a prospective randomized trial, 367
Outcome 5 years after 360° fundoplication for gastro-oesophageal reflux disease, 46
Prospective randomized study of one- or two-layer anastomosis following oesophageal resection and cervical oesophagogastrostomy, 608
Purse-string suture for stapled oesophagogastric anastomosis: hand sewn *versus* automatic, 734
Resting energy expenditure in patients undergoing transhiatal or transthoracic oesophagectomy for carcinoma of the thoracic oesophagus, 1413
Results of a prospective randomized trial of the Angelchik prosthesis and of a consecutive series of 119 patients, 602
Short myotomy for vigorous achalasia, 1540
Timing of extubation after oesophagectomy, 1537
Venous thromboprophylaxis in oesophageal cancer surgery, 1145

Oesophagus - traumatic

Penetrating external injuries of the oesophagus and pharynx, 1147

Oesophagus - tumour

Oesophagogastrectomy for carcinoma of the oesophagus and cardia, 1305
Prognostic significance of cell culture in carcinoma of the oesophagus, 605
Significance of circumferential resection margin involvement after oesophagectomy for cancer, 1386

Oncogene

Correlation between p53 mutations and antibody staining in breast carcinoma, 1410
Expression of p53 in colorectal cancer and dysplasia complicating ulcerative colitis, 442

Oncology

Effect of antitumour necrosis factor treatment on circulating tumour necrosis factor levels and mortality after surgery in jaundiced mice, 1055
Granulocyte-macrophage colony-stimulating factor inhibits tumour growth, 1543
Interleukin 2 therapy: current role in surgical oncological practice, 155

Oxygen

Endothelial xanthine oxidase: a radical transducer of inflammatory signals for reticuloendothelial activation, 684
Oxygenation of the gut mucosa, 953

Paediatrics

Carcinoid tumours of the appendix in children 1957–1986: incidence, treatment and outcome, 502
Computed tomography in the management of blunt abdominal trauma in children, 982
Follow-up after inguinal herniotomy or surgery for hydrocele in boys, 1613

Pain

Controlled trial of wound infiltration with bupivacaine for postoperative pain relief after appendicectomy in children, 110

Pancreas

Porcine islet isolation: prospective comparison of automated and manual methods of pancreatic collagenase digestion, 240

Pancreas - congenital

Stapling technique for annular pancreas (surgical workshop), 758

Pancreas - inflammatory

Assessment of main pancreatic duct integrity by endoscopic retrograde pancreatography in patients with acute pancreatitis, 94
Endoscopic sphincterotomy in acute gallstone pancreatitis, 547
Good long-term results in patients surviving severe acute pancreatitis, 1583
Hereditary calcific pancreatitis in an English family (case report), 487
Intraluminal duodenal diverticulum: an unusual cause of acute pancreatitis (case report), 488
Laparoscopic cholecystectomy with endoscopic retrograde cholangiopancreatography for acute gallstone pancreatitis (short note), 247
Modern management of pancreatic pseudocysts, 573
Morphological studies of graft pancreatitis following pancreas transplantation, 1170
Native and graft pancreatitis following combined pancreas-renal transplantation, 1429
Obesity: an important prognostic factor in acute pancreatitis, 484
Pancreatic fistula cured by an endoprosthesis in the pancreatic duct (case report), 1316
Pancreatic infection complicating acute pancreatitis, 148
Pancreatic necrosis: assessment of outcome related to quality of life and cost of management, 1579
Patient selection and timing of dynamic computed tomography in acute pancreatitis, 1393
Prospective comparison of C-reactive protein level, Ranson score and contrast-enhanced computed tomography in the prediction of septic complications of acute pancreatitis, 755
Role of serum endotoxin and antiendotoxin core antibody levels in predicting the development of multiple organ failure in acute pancreatitis, 1042
Temporal relationship of acinar and microvascular changes in caerulein-induced pancreatitis, 1174
Acute pancreatitis: the value of life, 1499

Pancreas - surgery

Improved glucose metabolism after subtotal pancreatectomy for pancreatic cancer, 1047
Management of non-functioning neuroendocrine tumours of the pancreas, 625
Morphological studies of graft pancreatitis following pancreas transplantation, 1170
Pancreatoduodenectomy with stapling devices (surgical workshop), 1183
Single-loop biliary and gastric bypass for irresectable pancreatic carcinoma, 237

Pancreas - traumatic

Traumatic pancreatic pseudocysts, 89

Pancreas - tumour

Carcinoma of the pancreas and periampullary region: palliation *versus* cure, 1575
Clinical trial of tamoxifen in patients with irresectable pancreatic adenocarcinoma, 384
Computed tomography and fine-needle aspiration cytology for preoperative evaluation of cystic tumours of the pancreas, 1166
Improved glucose metabolism after subtotal pancreatectomy for pancreatic cancer, 1047
Laparoscopic ultrasonography for hepatobiliary and pancreatic malignancy, 1571
Management of non-functioning neuroendocrine tumours of the pancreas, 625
Perineural invasion of carcinoma of the pancreas and biliary tract, 619
Resection for adenocarcinoma of the body and tail of the pancreas, 1177
Single-loop biliary and gastric bypass for irresectable pancreatic carcinoma, 237
Thoracoscopic pancreatic denervation for pain control in irresectable pancreatic cancer (surgical workshop), 1051

Subject index

Parathyroid

A family with dual inheritance of primary hyperparathyroidism and haemophilia (short note), 222
Parathyroidectomy in the treatment of patients with chronic renal failure: a 10-year review, 40
Reoperation for suspected primary hyperparathyroidism, 453

Parotid

Benign parotid cysts associated with human immunodeficiency virus infection (case report), 39
Tuberculosis in the parotid region (short note), 1008

Pelvic pouch

Anorectal function after preoperative intraluminal brachytherapy and colonic J pouch-anal anastomosis for rectal carcinoma, 933
Fistula complicating restorative proctocolectomy, 1065
Function of ileal J pouch-anal anastomosis in patients with familial adenomatous polyposis, 765
Mucosal morphology, cell proliferation and faecal bacteriology in acute pouchitis, 1445
Pouch adenomas in patients with familial adenomatous polyposis (short note), 1036
Pouch-vaginal fistula, 936
Secondary proctectomy and ileal pouch-anal anastomosis after ileorectal anastomosis for familial adenomatous polyposis, 1621
Transanal division of an apical pouch bridge after restorative proctocolectomy with a J shaped reservoir (surgical workshop), 248
Ulcerative colitis in familial adenomatous polyposis (case report), 254

Pelvis

Total pelvic exenteration: a justified procedure, 1615

Penis

Complications of circumcision, 1231
Sutureless circumcision (short note), 859

Peptic ulcer

Laparoscopic omental patch repair of perforated duodenal ulcer with an automated stapler (surgical workshop), 1552
Proximal gastric vagotomy and anterior seromyotomy with posterior truncal vagotomy assessed by the endoscopic congo red test, 737
Sutureless laparoscopic treatment of perforated duodenal ulcer (surgical workshop), 235

Perforation

Omental patching of a large perforated duodenal ulcer: a new method (surgical workshop), 65
Sutureless laparoscopic treatment of perforated duodenal ulcer (surgical workshop), 235

Perineum

Crohn's disease involving a rectus abdominis myocutaneous flap (case report), 1069
Surgical management of perineal and metastatic cutaneous Crohn's disease, 1596

Peritoneum

Abdominal cocoon: a report of two cases (case report), 1149
Pathophysiology, recognition and management of pneumoretroperitoneum, 1138
Plasminogen activator inhibitor 2 reduces peritoneal fibrinolytic activity in inflammation, 107
Spontaneous staphylococcal peritonitis in an otherwise healthy young man (case report), 1527

Polyposis

Function of ileal J pouch-anal anastomosis in patients with familial adenomatous polyposis, 765
Lipomatous polyposis of the colon (case report), 349
Pouch adenomas in patients with familial adenomatous polyposis (short note), 1036
Randomized controlled trial of the effect of sulindac on duodenal and rectal polyposis and cell proliferation in patients with familial adenomatous polyposis, 1618
Screening practice for familial adenomatous polyposis: the potential for regional registers, 255
Secondary proctectomy and ileal pouch-anal anastomosis after ileorectal anastomosis for familial adenomatous polyposis, 1621
Surgical polypectomy of duodenal adenomas in familial adenomatous polyposis: experience of two European centres, 1029
Ulcerative colitis in familial adenomatous polyposis (case report), 254

Portal hypertension

Duodenal duplication causing segmental portal hypertension and massive intestinal haemorrhage (case report), 1031
Incidence of haemorrhoids and anorectal varices in children with portal hypertension, 616
Subtotal splenectomy with a microwave coagulator (surgical workshop), 612

Portal vein

Liver transplantation in patients with thrombosis of the portal, splenic or superior mesenteric vein, 81
Spontaneous rupture of a normal portal vein causing severe retroperitoneal and intraperitoneal bleeding (case report), 892

Prostate

Transrectal duplex colour Doppler ultrasonography of the prostate: a preliminary report (short note), 1063

Prosthesis

Silicone gel implants, breast cancer and connective tissue disorders, 1097
Use of silicone implants after wide local excision of the breast, 868

Protein

Effects of tumour necrosis factor on protein metabolism, 1019

Pseudocyst

Traumatic pancreatic pseudocysts, 89
Vomiting caused by a dialysis fluid 'pseudocyst' (case report), 224

Radiology

Percutaneously placed Wallstent endoprosthesis in patients with malignant distal biliary obstruction, 1185
Radiological investigation in acute diverticulitis, 560

Receptors

Oestrogen and progesterone receptors in colorectal cancer and human colonic cancer cell lines, 636

Rectum - inflammatory

Effect of anorectal eversion during restorative proctocolectomy on anal sphincter function, 121
Histological and microbiological assessment of the role of micro- organisms in chronic anal fistula (short note), 1072

Rectum - surgery

'Belt loop' stitch (surgical workshop), 1064
Conservative treatment for low rectal carcinoma by local excision with or without radiotherapy, 1452
Effect of anorectal eversion during restorative proctocolectomy on anal sphincter function, 121
Endoscopic transanal resection in the management of patients with sessile rectal adenomas, anastomotic stricture and rectal cancer, 788
Initial report from a Swedish multicentre study examining the role of preoperative irradiation in the treatment of patients with resectable rectal carcinoma, 1333
Prospective comparison of laparoscopic and conventional anterior resection, 1396
Reappraisal of radical local excision for carcinoma of the rectum, 928
Safety of double-stapled anastomosis in low anterior resection, 924
Synchronous abdominoperineal resection without transfusion, 1194
Temporary loop ileostomy for restorative proctocolectomy, 628
Total sphincter conservation in high fistula *in ano*: results of a new approach, 802
Transanal division of an apical pouch bridge after restorative proctocolectomy with a J shaped reservoir (surgical workshop), 248

Rectum - tumour

Anorectal function after preoperative intraluminal brachytherapy and colonic J pouch-anal anastomosis for rectal carcinoma, 933
Conservative treatment for low rectal carcinoma by local excision with or without radiotherapy, 1452
Initial report from a Swedish multicentre study examining the role of preoperative irradiation in the treatment of patients with resectable rectal carcinoma, 1333
Laparoscopic surgery for colorectal cancer, 1229
Long-term survival after endoscopic transanal resection of rectal tumours, 1401
Lymph node metastases in early rectal cancer, 1457
Oral calcium inhibits rectal epithelial proliferation in familial adenomatous polyposis, 499
Randomized controlled trial of the effect of sulindac on duodenal and rectal polyposis and cell proliferation in patients with familial adenomatous polyposis, 1618
Reappraisal of radical local excision for carcinoma of the rectum, 928
Synchronous abdominoperineal resection without transfusion, 1194

Recurrence

D-dimer: a useful marker of disease stage in surgery for colorectal cancer (short note), 1404

Reflux

'Bile' in the oesophagus, 1374
Cholecystectomy and oesophageal reflux: a prospective evaluation, 50
Long-term results of treatment of peptic stricture of the oesophagus with the Angelchik prosthesis, 363
Outcome 5 years after 360° fundoplication for gastro-oesophageal reflux disease, 46
Prospective randomized comparison of teres cardiopexy and Nissen fundoplication in the surgical therapy of gastro-oesophageal reflux disease, 875
Results of a prospective randomized trial of the Angelchik prosthesis and of a consecutive series of 119 patients, 602
Role of reflux oesophagitis and acid in the development of columnar epithelium in the rat oesophagus, 467
Surgical treatment of reflux stricture of the oesophagus, 317

Retroperitoneal

Survival after retroperitoneal necrotizing fasciitis (case report), 981

Screening

Change towards earlier stage at presentation of colorectal cancer, 1610
Faecal occult blood screening for colorectal neoplasia in a targeted high-risk population, 1399
Faecal occult blood screening for patients with gastrointestinal symptoms (short note), 1326
Screening for abdominal aortic aneurysm, 1363
Treatment of the axilla in patients with screen-detected breast cancer, 436
Ultrasonographic screening for abdominal aortic aneurysm in an urban community, 1406

Sepsis

Changes in major histocompatibility complex class II expression in monocytes and T cells of patients developing infection after surgery, 205
Cytokines, sepsis and immunomodulation, 289
Prospective comparison of C-reactive protein level, Ranson score and contrast-enhanced computed tomography in the prediction of septic complications of acute pancreatitis, 755
Role of early and extensive surgery in the treatment of severe necrotizing soft tissue infection, 1190
Survival after retroperitoneal necrotizing fasciitis (case report), 981
Translocation of enteric bacteria in humans (short note), 901

Skin

Crohn's disease involving a rectus abdominis myocutaneous flap (case report), 1069

Small bowel

Laparoscopic mobilization and exteriorization for minimally invasive small bowel resection (surgical workshop), 225
Mesenteric infarction: improved survival rate after temporary enterostomy (short note), 1029
Method for diagnosing rejection in small bowel transplantation, 1024
Oxygenation of the gut mucosa, 953
Small bowel prolapse and incarceration caused by a vaginal ring pessary (case report), 1157
Vagal system involvement in changes in small bowel motility during restraint stress: an experimental study in the dog, 479

Small bowel - tumour

Small bowel obstruction caused by recurrent cystic lymphangioma (case report), 1012

Sphincter

Physiological and histochemical adaptation of the electrically stimulated gracilis muscle to neoanal sphincter function, 1342
Possible role of the autonomic nervous system in sphincter impairment after restorative proctocolectomy, 631
Sphincter rupture in childbirth, 392

Spleen

Splenectomy in human immunodeficiency virus-related thrombocytopenia, 330
Splenectomy for splenomegaly exceeding 1000 grams: analysis of 47 patients, 334
Spontaneous rupture of the spleen secondary to metastatic carcinoma (case report), 613
Subtotal splenectomy with a microwave coagulator (surgical workshop), 612
Symptomatic wandering spleen (case report), 93

Staples

Safety of double-stapled anastomosis in low anterior resection, 924

Stenosis

Infrainguinal vein graft stenosis, 825

Stoma

Life quality and psychological morbidity with an ileostomy, 252
Mesenteric infarction: improved survival rate after temporary enterostomy (short note), 1029
Multicentre study of a continent colostomy plug, 930
Temporary loop ileostomy for restorative proctocolectomy, 628

Stomach

Vomiting caused by a dialysis fluid /pseudocyst' (case report), 224

Stomach - function

Erythromycin improves emptying of the denervated stomach after oesophagectomy, 879

Stomach - surgery

Early gastric cancer: follow-up after gastrectomy in 159 patients, 325
Extensive *versus* limited lymph node dissection for gastric cancer: a comparative study of 320 patients, 1153
Omental patching of a large perforated duodenal ulcer: a new method (surgical workshop), 65
Polytetrafluoroethylene patch grafting for closure of stomach defects in the rat (short note), 1013
Prognostic relevance of systematic lymph node dissection in gastric carcinoma, 1015
Proximal gastric vagotomy and anterior seromyotomy with posterior truncal vagotomy assessed by the endoscopic congo red test, 737
Transit disorders of the gastric remnant and Roux limb after Roux- en-Y gastrojejunostomy: relation to symptomatology and vagotomy, 60
Vertical banded gastroplasty for the treatment of morbid obesity, 1421

Stomach - tumour

Early gastric cancer: follow-up after gastrectomy in 159 patients, 325
Gastric cancer and *Helicobacter pylori* infection, 378
Gastric remnant cancer as a metachronous multiple lesion, 54
Increasing incidence of carcinoma of the gastric cardia in Sweden from 1970 to 1985, 374
Kinetic changes and experimental carcinogenesis after Billroth I and II gastrectomy, 893
Laparoscopic resection of a bleeding gastric tumour (surgical workshop), 373
Norwegian multicentre study of survival and prognostic factors in patients undergoing curative resection for gastric carcinoma, 475
Nucleolar organizing regions in the operated rat stomach: relationship to metaplasia, dysplasia and carcinoma, 57
Oesophagogastrectomy for carcinoma of the oesophagus and cardia, 1305
Pattern and surgical treatment of gastric cancer in Singapore, 886
Prognostic relevance of systematic lymph node dissection in gastric carcinoma, 1015
Prognostic significance of histological type in gastric carcinoma with invasion confined to the stomach wall, 890
Prognostic value of DNA ploidy in primary gastric leiomyosarcoma, 1549
Raised serum CA125 level in leiomyoma and leiomyosarcoma of gastrointestinal origin (short note), 1551
Resection-line involvement in gastric cancer: a continuing problem, 1418
Role of surgery in patients with primary non-Hodgkin's lymphoma of the stomach: an old problem revisted, 1101
Survival following microscopically confirmed radical resection of N_0 gastric cancer, 1150

Stomach -surgery

Laparoscopic truncal vagotomy without drainage (surgical workshop), 236

Stricture

Biliary stent failure after 42 years (case report), 908
Incidence and management of benign anastomotic stricture after cervical oesophagogastrostomy, 471
Surgical treatment of reflux stricture of the oesophagus, 317

Surgical technique

Randomized trial of laser scalpel for modified radical mastectomy, 871

Surgical training

Organization of general surgical services in Britain: strategic planning of workload and manpower, 1377
Perspectives in European surgery, 277

Suture

Continuous single-layer serosubmucosal anastomosis in the upper gastrointestinal tract, 1416
Laparoscopic ligation of large pedicles (surgical workshop), 1444
Monofilament *versus* multifilament absorbable sutures for abdominal closure, 322
New adjustable knot for securing subcuticular running sutures (surgical workshop), 873
Suppression of macrophage function by suture materials and anastomotic recurrence of Crohn's disease, 387
Suture length to wound length ratio and healing of midline laparotomy incisions, 1284

Sympathectomy

Endoscopic sympathectomy, 687

Sympathetic

Electrocautery of the upper thoracic sympathetic chain: a simplified technique (surgical workshop), 862

Technique

Endoscopic transanal resection in the management of patients with sessile rectal adenomas, anastomotic stricture and rectal cancer, 788
Physiological and histochemical adaptation of the electrically stimulated gracilis muscle to neoanal sphincter function, 1342

Thoracoscopy

Diagnosis of traumatic rupture of the right hemidiaphragm by thoracoscopy (case report), 210
Thoracoscopic pancreatic denervation for pain control in irresectable pancreatic cancer (surgical workshop), 1051
Thoracoscopy in oesophagectomy for oesophageal cancer (surgical workshop), 320

Thrombolytic therapy

Acute limb deterioration during intra-arterial thrombolysis, 1118
Choice of agent for peripheral thrombolysis, 25
Early results and 1-year follow-up after intra-arterial thrombolysis, 194
Intraoperative streptokinase: a useful adjunct to balloon- catheter embolectomy, 21
Intraoperative thrombolysis in the management of thrombosed popliteal aneurysm (surgical workshop), 858
Long-term results of a single protocol for thrombolysis in acute lower-limb ischaemia, 1262
Peripheral arterial thrombolysis: intermediate-term results, 592

Thrombosis

Low-dose aspirin fails to inhibit increased platelet reactivity in patients with peripheral vascular disease, 1266

Thymus

Phaeochromocytoma associated with thymoma (case report), 223

Thyroid

Concurrent hyperthyroidism and thyroid carcinoma, 1301
Graves' ophthalmopathy after subtotal thyroidectomy and radioiodine therapy, 1134
Intra-abdominal ectopic thyroid (case report), 316
Medullary thyroid carcinoma, 6
Surgical reintervention for differentiated thyroid cancer, 1009
Thyroid neoplasia coexistent with chronic lymphocytic thyroiditis, 1303

Transplantation - kidney

CD4 and CD8 monoclonal antibody therapy: strategies to prolong renal allograft survival in the dog, 1389
Effect of nifedipine on renal transplant rejection, 1318
Emergency aortic aneurysmectomy in a renal transplant recipient (case report), 201
High incidence of arteriovenous fistula after biopsy of kidney allografts, 310
Native and graft pancreatitis following combined pancreas-renal transplantation, 1429
Probability of rejection predicted from ultrasonographic measurement of renal transplant swelling, 1059

Transplantation - liver

Graft size assessment by preoperative computed tomography in living related partial liver transplantation, 489
Reoperation for biliary tract complications following orthotopic liver transplantation, 1426

Transplantation - pancreas

Morphological studies of graft pancreatitis following pancreas transplantation, 1170
Native and graft pancreatitis following combined pancreas-renal transplantation, 1429
Porcine islet isolation: prospective comparison of automated and manual methods of pancreatic collagenase digestion, 240

Transplantation - small bowel

Method for diagnosing rejection in small bowel transplantation, 1024

Subject index

Trauma

Abdominal aortic thrombosis following a fall (case report), 214
Antibiotic prophylaxis is indicated for chest stab wounds requiring closed tube thoracostomy, 464
'Car-crusher colon' (case report), 640
Computed tomography in the management of blunt abdominal trauma in children, 982
Damage control in trauma surgery, 1501
Diagnosis of traumatic rupture of the right hemidiaphragm by thoracoscopy (case report), 210
Gunshot wounds of the colon: role of retained bullets in sepsis, 772
Helicopter Emergency Medical Service operating from the Royal London Hospital: the first year, 218
Non-therapeutic operations for penetrating trauma: early morbidity and mortality, 860
On-scene medical decision making and overtriage, 1291
Physical examination and selective conservative management in patients with penetrating injuries of the neck, 1534
Pneumoperitoneum from a ruptured bronchus in a child (case report), 212
Prognostic signs in the evaluation of patients with minor head injury, 988
Resuscitation for haemorrhagic shock (for debate), 213
Transatlantic perspectives of trauma systems, 985
Trauma centres, 1225
Use of an accident and emergency department observation ward in the management of head injury, 215

Tuberculosis

Role of surgery and chemotherapy for peripheral lymph node tuberculosis, 1547
Tuberculosis in the parotid region (short note), 1008

Tumour

Adrenal incidentaloma, 422
Carcinoid tumours of the appendix in children 1957–7986: incidence, treatment and outcome, 502
Changing trends in the management of extrahepatic cholangiocarcinoma, 1434
Cutaneous metastasis from a malignant fibrous histiocytoma to a limb skin graft donor site (case report), 366
Endoscopic transanal resection in the management of patients with sessile rectal adenomas, anastomotic stricture and rectal cancer, 788
Low-dose tumour necrosis factor α and melphalan in hyperthermic isolated limb perfusion, 995
Percutaneously placed Wallstent endoprosthesis in patients with malignant distal biliary obstruction, 1185

Ultrasonography

Characterization of symptomatic and asymptomatic carotid plaques using high-resolution real-time ultrasonography, 1274
Early detection of occult colorectal hepatic metastases using duplex colour Doppler sonography, 1249
Laparoscopic ultrasonography for hepatobiliary and pancreatic malignancy, 1571
Percutaneous ultrasound-guided drainage of intra-abdominal abscesses, 336
Probability of rejection predicted from ultrasonographic measurement of renal transplant swelling, 1059
Sources of air embolization during carotid surgery: the role of transcranial Doppler ultrasonography (short note), 1121
Transrectal duplex colour Doppler ultrasonography of the prostate: a preliminary report (short note), 1063
Ultrasonographic screening for abdominal aortic aneurysm in an urban community, 1406
Ultrasonography during liver resection for hepatocellular carcinoma, 493

Vagotomy

Proximal gastric vagotomy and anterior seromyotomy with posterior truncal vagotomy assessed by the endoscopic congo red test, 737
Transit disorders of the gastric remnant and Roux limb after Roux- en-Y gastrojejunostomy: relation to symptomatology and vagotomy, 60

Varicose veins

Cryostripping the long and short saphenous veins (surgical workshop), 1283
Photoplethysmography in the diagnosis of superficial venous valvular incompetence, 351
Recurrent varicose veins: correlation between preoperative clinical and hand-held Doppler ultrasonographic examination, and anatomical findings at surgery, 849
Recurrent varicose veins: a national problem, 823

Vascular surgery

Cardiac risk and peripheral vascular surgery: new approach based on a multifactorial risk index, 354
Eye protection for the vascular surgeon, 1379
The future of vascular surgery (for debate), 185

Vein

Ankle fracture is associated with prolonged venous dysfunction, 36
Congenital arteriovenous malformations, 2
Effect of foot compression on the velocity and volume of blood flow in the deep veins, 198
Hyperaemic response in the skin microcirculation of patients with chronic venous insufficiency, 433
Infrainguinal vein graft stenosis, 825
Patterns of venous reflux in limbs with skin changes associated with chronic venous insufficiency, 725
Prospective randomized comparison of *in situ* and reversed infrapopliteal vein grafts, 173
Role of the leucocyte in the pathogenesis of vascular disease, 1503
Smoking impairs endothelium-dependent relaxation of saphenous vein, 1242
Systemic leakage during isolated limb perfusion for melanoma, 1124
Vein-patch rupture after carotid endarterectomy: an avoidable catastrophe (for debate), 852
Venous assessment using air plethysmography: a comparison with clinical examination, ambulatory venous pressure measurement and duplex scanning, 967

Venous access

Complications and survival of multilumen central venous catheters used for total parenteral nutrition, 1287
Fully implantable venous access systems, 347
Long-term circulatory access via a peripheral implantable port, 600

Venous thrombosis

Prophylaxis of postoperative thromboembolism with low molecular weight heparins, 689
Venous thromboprophylaxis in oesophageal cancer surgery, 1145

Venous ulcer

Foot volumetry and duplex ultrasonography after saphenous and subfascial perforating vein ligation for recurrent venous ulceration, 845
Hyperaemic response in the skin microcirculation of patients with chronic venous insufficiency, 433
Patterns of venous reflux in limbs with skin changes associated with chronic venous insufficiency, 725
Tissue and urokinase plasminogen activators in the environs of venous and ischaemic leg ulcers, 596
Venous assessment using air plethysmography: a comparison with clinical examination, ambulatory venous pressure measurement and duplex scanning, 967

Virus

Hepatitis B immunization and exposure to blood among surgical staff, 714

Wound

Basic fibroblast growth factor accelerates wound healing in chronically ischaemic tissue, 977

Wound - closure

Suture length to wound length ratio and healing of midline laparotomy incisions, 1284

Wound - healing

Comparative study of abdominal incision techniques, 233
Monofilament *versus* multifilament absorbable sutures for abdominal closure, 322

Journal of the Royal College of Surgeons of Edinburgh

Edited by **Alfred Cuschieri**

Published for the Royal College of Surgeons of Edinburgh

The ***Journal of the Royal College of Surgeons of Edinburgh*** covers clinical advances in management within general surgery and other surgical specialities. Each issue of the journal is comprised of a balance between original peer-reviewed publications and state-of-the-art commissioned reviews on major current topics. It also incorporates an Operative and Technology Section with special reference to Minimal Access Surgery.

Journal of the Royal College of Surgeons of Edinburgh is published bimonthly. Subscription prices for 1993 are as follows: £88.50 (Europe), US$170.00 (USA & Canada), and £97.00 (elsewhere).

RECONSTRUCTIVE UROLOGY

Edited by G Webster, R Kirby, L King and B Goldwasser

The minimally invasive techniques of lithotripsy and laparoscopy have eliminated many of the previously traumatic procedures in urology. However, reconstructive urology continues to involve major surgical procedures and remains the largest component of the discipline. Reconstructive urology is concerned with the correction of congenital defects and those caused by malignancy and trauma, as well as incontinence; conditions which often require a considerable amount of surgery and a wide view of the genitourinary system which is only available through traditional surgery. This book is the most exhaustive reference work to date on reconstructive urology.

- written by a distinguished international team;
- despite the dominance of minimally invasive techniques in other branches of urology, reconstructive urology remains a major and growing field;
- provides detailed coverage of every aspect of the field, from functional anatomy to surgical technique.

Contents:

Sectional Contents: Part 1 - Basic Science; Part 2 - Evaluation; Part 3 - Principles of Reconstruction; Part 4 - Renal Reconstruction; Part 5 - Ureteral Reconstruction; Part 6 - Reconstruction of the Bladder; Part 7 - Reconstruction of the Urethra; Part 8 - Urogynecologic Reconstruction; Part 9 Reconstruction of the Penis; Part 10 - Reconstruction of the Testis and Scrotum.

Hardback, £175.00, Jan-93, 1200 pages, 826 illustrations, 086542229X

The official journal of the Society for Minimally Invasive Therapy

Minimally Invasive Therapy

Editor: John Wickham

Assistant Editors: M J Coptcoat, A Adam, E vanSonnenberg, J M Fitzpatrick

Since the founding of the Society for Minimally Invasive Therapy in 1989, the subject has gained rapidly in prominence and importance. A large number of surgeons, radiologists and clinicians are now just beginning to appreciate the benefits, both to patients and practitioners, of minimally invasive techniques. *Minimally Invasive Therapy* includes innovative research papers, expert review articles, topical leading articles, instrumental studies and correspondence. *Minimally Invasive Therapy* is a prestigious base from which workers in any speciality may present their experience for the benefit of their colleagues and patients.

Minimally Invasive Therapy is published bimonthly. Subscription prices for Volume 2, 1993, are as follows: Individual £80.00 (Europe), £88.00 (Overseas), US$173.00 (USA & Canada); Institutional £133.00 (Europe), £146.50 (Overseas), US$258.00 (USA & Canada).

All members of the Society for Minimally Invasive Therapy will receive the journal as part of their annual dues. Further details regarding the Society can be obtained from: Miss Fay Harrison, Minimally Invasive Therapy Unit, 2nd Floor New Guy's House, Guy's Hospital, St Thomas Street, London SE1 9RT,UK

COMPLICATIONS OF LAPAROSCOPY AND HYSTEROSCOPY

Edited by R S Corfman, M Diamond and A DeCherney

086542201X, Hardback, £45.00, Jan-93,
288 pages, 86 illustrations

Many surgical procedures in gynaecology are now performed by means of endoscopy or 'keyhole surgery' rather than by traditional surgery, thereby reducing hospital stays and cutting costs. The number and difficulty of such procedures is growing constantly. This book deals with potential complications of such techniques and how to avoid and rectify them.

The contents deal with all the major procedures, including sections on: preoperative and postoperative considerations, anesthesiology, intraperitoneal insufflation and trocar placement, complications arising from vaginal placement of accessories, operative laparoscopy, specific gynecological procedures, hysteroscopy, general surgery and other surgical complications. Their complications are addressed in detail to help the practitioner better understand each procedure and its potential problems.

- covers all the major procedures;
- deals with increasingly popular and complicated techniques;
- enables the practitioner to operate more safely;
- responds to the growing trend towards day case surgery.

Peritonitis

Edited by D Fry

There have been considerable advances in the care of patients with peritonitis, including major strides in diagnosis, specific surgical care, anaesthetic techniques and supportive measures, including the use of antibiotics.

However, there are still patients who remain unresponsive, typically those with other serious illnesses. The treatment of such challenging cases requires a reexamination of the entire theory and process of treatment of peritonitis. This book furthers such a reassessment and will be of particular benefit to those involved in the front-line care of peritonitis sufferers.

- comprehensive coverage from pathophysiology to methods of treatment;
- a timely review of peritonitis and its management;
- both scientific and practical questions are covered.

Contents:

Pathophysiology of peritonitis; Hemodynamic and metabolic aspects of peritonitis; Diagnosis of peritonitis; Supportive care of the peritonitis patient; Mechanical therapy in peritonitis; Radiologic strategy in the management of intra-abdominal abscess; Antimicrobial chemotherapy in peritonitis; Antibiotic pharmacology in peritonitis; Special problems in peritonitis - primary peritonitis; Special problems in peritonitis - pediatric peritonitis; Special problems in peritonitis - peritonitis from the biliary tract and pancreas; Special problems in peritonitis - endometritis, salpingitis, pelvic peritonitis; Special problems in peritonitis - intercurrent nosocomial infection; Multiple system organ failure and peritonitis; Future considerations in the management of peritonitis

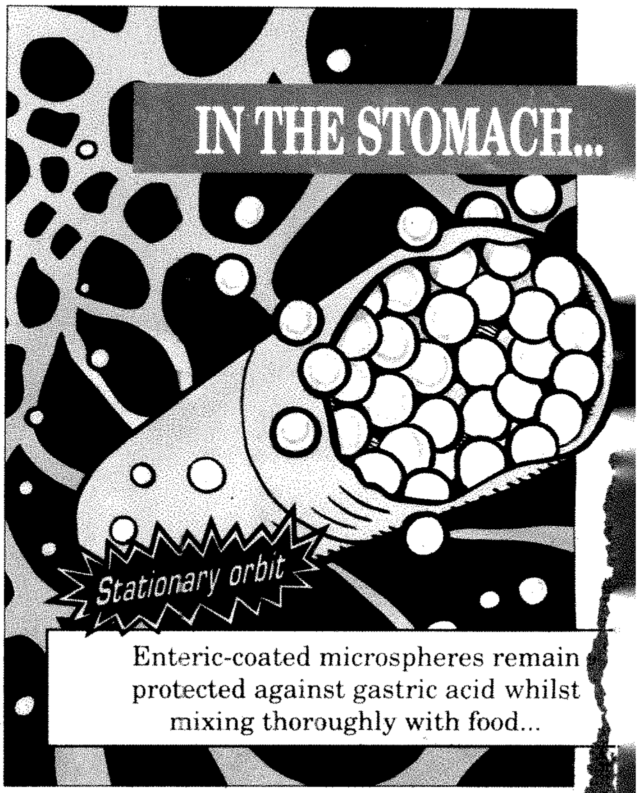
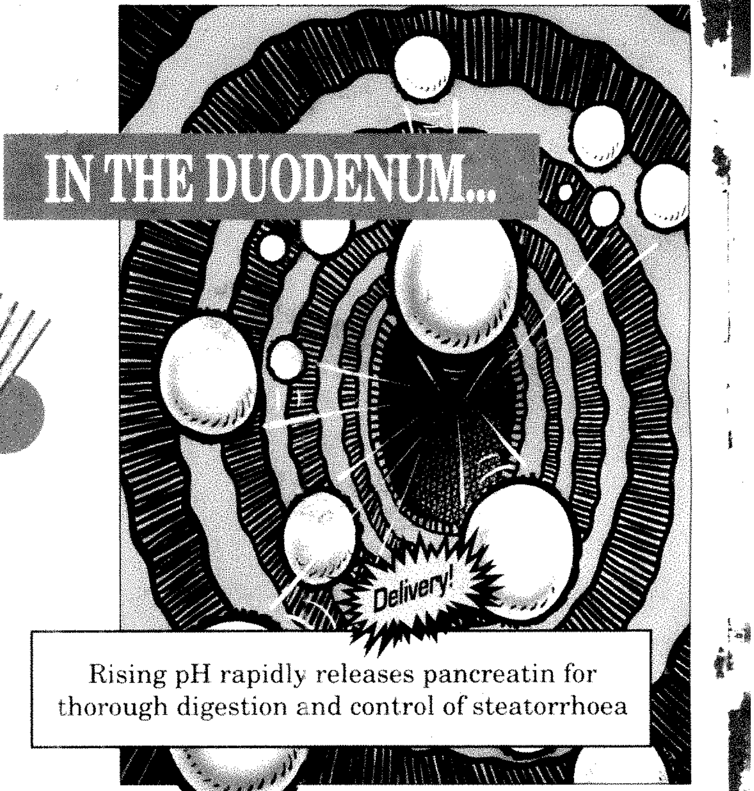
A REAL FORCE IN PANCREATIC EXOCRINE INSUFFICIENCY



IN THE STOMACH...
Stationary orbit
Enteric-coated microspheres remain protected against gastric acid whilst mixing thoroughly with food...



IN THE DUODENUM...
Delivery!
Rising pH rapidly releases pancreatin for thorough digestion and control of steatorrhoea

creon®
pancreatin 25000

Superior control of steatorrhoea†

† Compared with standard enteric-coated tablets in pancreatic insufficiency[1,2]

Prescribing Information

Presentation: Opaque orange yellow hard gelatin capsules containing brownish coloured enteric coated pellets of pancreatin, equivalent to
25,000 PhEur units of lipase
18,000 PhEur units of amylase
1,000 PhEur units of protease (total)
Available in packs of 50. Basic NHS price £19.50

Indication: Pancreatic exocrine insufficiency.

Dosage and Administration: Adults (including elderly) and children. Initially one capsule with meals then adjust according to response. The capsules can be swallowed whole, or for ease of administration they may be opened and the granules taken with fluid or soft food, but without chewing. If the granules are mixed with food it is important that they are taken immediately, otherwise dissolution of the enteric coating may result.

Contra-indications, Warnings, etc. Contra-indications: Substitution with pancreatic enzymes is contra-indicated in the early stages of acute pancreatitis. Warnings: Use in pregnancy: There is inadequate evidence of safety in use during pregnancy. The product is of porcine origin. Rarely cases of hyper-uricosuria and hyper-uricaemia have been reported with very high doses of pancreatin. Overdosage although not experienced until now, could precipitate meconium ileus equiv Perianal irritation, and rarely, inflammation, could occur when large doses are used.

The British
Journal of Surgery

Edited by R C N Williamson, J R Farndon, J A Murie and C D Johnson

The British Journal of Surgery, now in its 80th year of publication, is the premier general surgical journal in Europe. It publishes top quality clinical and research papers on all aspects of general surgery and other related topics, with developing areas such as minimally invasive therapy and interventional radiology being strongly reflected.

Papers include Leading Articles, Reviews, Original Articles, Surgical Workshops, Case Reports, Short Notes and articles For Debate; in addition there are abstracts from key meetings and quarterly Digests from other major journals. **The British Journal of Surgery** is of interest to general surgeons and those working in related fields such as radiologists, oncologists, physiologists and pathologists.

SUBSCRIPTION INFORMATION

The British Journal of Surgery is published monthly. Subscription prices for 1994 are as follows: Institutions £107.00 (Europe), £120.00 (Rest of World), US$179.00 (USA & Canada); Personal £69.50 (Europe), £76.50 (Rest of World), US$114.00 (USA & Canada). Postage and packing is included (air-speeded outside Europe).

Peritonitis

Edited by D Fry

There have been considerable advances in the care of patients with peritonitis, including major strides in diagnosis, specific surgical care, anaesthetic techniques and supportive measures, including the use of antibiotics.

However, there are still patients who remain unresponsive, typically those with other serious illnesses. The treatment of such challenging cases requires a reexamination of the entire theory and process of treatment of peritonitis. This book furthers such a reassessment and will be of particular benefit to those involved in the front-line care of peritonitis sufferers.

- comprehensive coverage from pathophysiology to methods of treatment;
- a timely review of peritonitis and its management;
- both scientific and practical questions are covered.

Contents:

Pathophysiology of peritonitis; Hemodynamic and metabolic aspects of peritonitis; Diagnosis of peritonitis; Supportive care of the peritonitis patient; Mechanical therapy in peritonitis; Radiologic strategy in the management of intra-abdominal abscess; Antimicrobial chemotherapy in peritonitis; Antibiotic pharmacology in peritonitis; Special problems in peritonitis - primary peritonitis; Special problems in peritonitis - pediatric peritonitis; Special problems in peritonitis - peritonitis from the biliary tract and pancreas; Special problems in peritonitis - endometritis, salpingitis, pelvic peritonitis; Special problems in peritonitis - intercurrent nosocomial infection; Multiple system organ failure and peritonitis; Future considerations in the management of peritonitis

Eurosurgery 93

This abstract book is the second supplement of *The British Journal of Surgery* to contain the abstracts selected for presentation at a Eurosurgery congress. Eurosurgery 93 is the Third European Congress of Surgery, with delegates from over 30 countries of Europe and beyond.

The Secretariat and Standing Committee of Eurochirurgie welcome the collaboration with *The British Journal of Surgery*, which reflects a mutual desire to promote work of the highest quality. Over 1000 abstracts were received from all across Europe and from all disciplines of surgery. Of these, 480 have been selected for publication in this supplement, having been judged for their interest and quality by 130 members of the Scientific Committee of Eurochirurgie.

This supplement will be a permanent record of the high scientific standards of the European Congress of Surgery. I am delighted to see the Congress in London this year, after the successes of Paris and Brussels. I hope to see you again at future meetings, in Berlin in October 1994, and subsequently at Barcelona in 1995 and Rome in 1996.

We look forward to the continued growth and development of Eurochirurgie.

Professor Gérard Champault
Secretary-General of Eurochirurgie/Eurosurgery
Supplement Editor

Acquired immune deficiency syndrome

Reducing the risk of virus transmission during surgery by electronic monitoring of the surgeon–patient barrier

I. Anderson, I. Macintyre, J. Currie and D. Smith, *Western General Hospital, Edinburgh, UK*

The surgeon's gown and gloves are a barrier that prevents virus transmission to or from the patient. A report is made of a new electronic device (Elper) which raises an alarm immediately this barrier is broken.

Fifty operations (laparotomy, 18; intermediate grade procedures (e.g. herniorrhaphy), 16; laparoscopy, 16) were monitored, during which 266 alarms occurred. Bench testing confirmed that 45 alarms (17 per cent) were due to glove holes, 86 (32 per cent) to wet gowns, 115 (43 per cent) to glove porosity and 20 (8 per cent) to other causes. The system detected glove holes with a false-negative rate of only 4 per cent. Holes were more likely to occur during laparotomy than in laparoscopy ($P = 0{\cdot}006$, χ^2 test) or intermediate procedures ($P = 0{\cdot}01$, χ^2 test). Wet gowns were also more common during laparotomy ($P = 0{\cdot}006$, χ^2 test). Alarms due to glove porosity correlated with the duration of operation ($P < 0{\cdot}001$, Kendall's rank correlation).

The surgeon was aware of only 15 per cent of glove holes and response to 54 alarms (20 per cent) was delayed for a median of 16 (range 4–91) min.

The Elper machine reliably detects the frequent episodes of potential viral transmission that occur during surgery. Its use encourages surgeons to take prompt action to restore the barrier that safeguards themselves and their patients.

Human immunodeficiency virus and genital warts as risk factors for anal intraepithelial neoplasia in homosexual men

P.S. Carter, A. DeRuiter*, C. Whatrup, G. Kocjan*, D. Katz*, A. Mindel* and J.M.A. Northover, *Imperial Cancer Research Fund, St Mark's Hospital and *Middlesex Hospital, London, UK*

Studies of the epidemiology of anal cancer have demonstrated a positive correlation with single male status. Recently, a study by Biggar has linked occurrence of anal cancer with homosexual men positive for human immunodeficiency virus (HIV). The present study sought to establish whether a link exists between HIV, genital warts (a recognized risk factor in the development of anal cancer) and the incidence of the potentially premalignant change of anal intraepithelial neoplasia (AIN).

A total of 210 homosexual men were recruited from a single London genitourinary clinic. Each patient completed a questionnaire and was examined for evidence of AIN using an anal smear and an operating microscope. All abnormal areas were biopsied and examined histologically.

Of the 210 patients, 73 (35 per cent) had AIN on histology. HIV status was known in 167 patients; of the 90 positive for HIV, 37 (41 per cent) had AIN, as did 20 (26 per cent) of the 77 negative for HIV. The relative risk of AIN for patients with HIV to those negative for HIV was $1{\cdot}58$ ($P = 0{\cdot}06$). In total, 165 of the 210 patients had anal warts. Of these, 69 (42 per cent) had AIN. This gives a relative risk of AIN for patients with warts to those without of $4{\cdot}70$ ($P = 0{\cdot}00008$).

This study demonstrated a high relative risk of developing AIN for patients with genital warts and a weaker but still increased relative risk of developing AIN for those who are HIV-positive.

Role of biopsy for cerebral lesions in patients with acquired immune deficiency syndrome

M. Iacoangeli, A. Pompucci, R. Roselli, R. Trignani and M. Scerrati, *Institute of Neurosurgery, Catholic University, Rome, Italy*

The involvement of the central nervous system (CNS) in patients with acquired immune deficiency syndrome (AIDS) is a problem of increasing clinical impact. The most common brain complications are toxoplasmosis (50–70 per cent), primary CNS lymphoma (20–30 per cent) and progressive multifocal leucoencephalopathy (PML) (10–20 per cent). Some of these are treatable (toxoplasmosis, neurotuberculosis and bacterial infections); others are diseases in which early diagnosis and therapy can allow prolonged high-quality survival (primary lymphoma). By neuroradiological criteria alone it is not possible to distinguish the broad spectrum of lesions reliably. To assess the potential role and timing of brain biopsy we reviewed our casework.

From October 1991 to December 1992, 12 of 50 (24 per cent) patients with AIDS with focal cerebral lesions underwent brain biopsy (seven stereotactic biopsies and five ultrasound-guided biopsies). In this unit, biopsy is performed early in the course of the disease if the patient does not respond to an appropriate empirical course of antitoxoplasmosis therapy.

All patients had a Karnofsky performance score $>0{\cdot}60$. The diagnosis was confirmed in 11 patients: six PML, three primary lymphoma, one mycotic and one tuberculous abscess. Both techniques were safe (mortality and morbidity rates were zero) and reliable. Early diagnosis and treatment may have a significant impact on the quality and survival of patients with AIDS with cerebral complications.

In conclusion, brain biopsy appears to be indicated for the definitive diagnosis of AIDS-associated CNS lesions.

Complications after major thoracic and abdominal surgery in human immunodeficiency virus-positive patients

S. Martinez, A. Sanchez-Pernaute, L. Diez Valladares, F. Hernando, M. Arguello, J.M. Rodriguez, A.J. Torres and J.L. Balibrea, *Hospital Clinico San Carlos, Madrid, Spain*

Surgeons are required with increasing frequency to perform major thoracic and abdominal operations on patients with human immunodeficiency virus (HIV) and on those with acquired immune deficiency syndrome (AIDS).

Between January 1981 and December 1992, 36 major procedures were performed on 12 asymptomatic HIV-positive patients, 23 patients with AIDS and one patient with AIDS-related complex. There were 32 men and four women. The most frequent risk factor was intravenous drug addiction (35 per cent). Patients were divided into two groups. Group A patients ($n = 14$) were submitted to abdominal operations. Subgroup A1 ($n = 11$) underwent therapeutic procedures for perforated ulcer (three), gastric tumour (two), splenomegaly (four), appendicitis (one) and traumatic rectal perforation (one). Subgroup A2 ($n = 3$) underwent diagnostic procedures for iatrogenic abdominal bleeding (one), obstructive jaundice (one) and retroperitoneal mass (one). Group B ($n = 22$) underwent thoracic surgery. Subgroup B1 ($n = 9$) underwent therapeutic procedures for empyema (five), costal tumour (one), thoracic trauma (one) and cavitated pneumonia (two). Subgroup B2 ($n = 13$) underwent open lung biopsy for diagnostic purposes: a diagnosis was made in eight (62 per cent); five pneumocystis carinii, two Kaposi's sarcoma and one candida. Complications occurred in 23 patients (64 per cent), eight in group A (57 per cent), and 15 in group B (68 per cent). The most common complications in group A were pneumonia in four patients (29 per cent) and sepsis in two (14 per cent). In group B the most frequent complications were bronchopleural fistula in six (27 per cent) and pneumonia in six (27 per cent). The overall mortality rate was 36 per cent (13 of 36): 29 per cent (four of 14) in group A and 41 per cent (nine of 22) in group B. In group B1 the mortality rate was 56 per cent, and 31 per cent in group B2. Mortality rate in patients with AIDS was 83 per cent.

We conclude that open lung biopsy has a high mortality rate in HIV-positive patients, and so this procedure should be reserved for selected patients.

Laparoscopic surgery in patients with acquired immune deficiency syndrome

A.G. Tanner, N. Cheshire, G. Glazer, R.D. Rosin and J.R.T. Monson, *St Mary's Hospital, London, UK*

The mortality rate for emergency open surgery in patients with acquired immune deficiency syndrome (AIDS) is approximately 70 per cent and that for open cholecystectomy 33 per cent. The morbidity rate is also high as a result of poor wound healing, chest complications and sepsis. In addition,

0007-1323/93/S002-02 © 1993 Butterworth-Heinemann Ltd

open operation carries a significant risk of virus transmission by direct contact. Laparoscopic surgery may reduce these problems. This study reports experience of laparoscopic procedures in 14 patients with AIDS over a 2-year period. There was only one death in the immediate postoperative period. Seven patients underwent laparoscopic cholecystectomy, two for gallstones and five for acalculous cholecystitis. All patients made uneventful recoveries. Five patients presented with an acute abdomen; one patient was found to have a gangrenous appendix which was removed laparoscopically. A further patient had a perforated Kaposi's sarcoma of the small bowel which was resected at open operation. One patient was found to have disseminated intra-abdominal lymphoma with multiple miliary nodules in the liver. Active therapy was withdrawn and the patient died 3 days later. In two patients peritoneal adhesions were found to be the cause of the acute abdominal pain and they underwent laparoscopic adhesiolysis. There were two further operations: a staging laparoscopy with liver biopsy for high-grade lymphoma and a laparoscopic cholecystojejunostomy for AIDS sclerosing cholangiopathy with ampullary stenosis. These data suggest that laparoscopic surgical techniques are associated with greatly reduced mortality and morbidity rates compared with open surgery and are most applicable to the patient with AIDS.

Appendix

Laparoscopic management of appendicitis: analysis of a consecutive series of 100 cases

M.L. Druart, R. Batrouni and J.M. Limbosch, *CHEI, Brussels, Belgium*

Between January 1991 and January 1993, 100 laparoscopic appendicectomies have been performed by two experienced laparoscopic surgeons. The aim of this work was to assess the feasibility, efficacy and possible advantages of this new technique in cases of appendicitis.

Operating time varied from 20 to 90 min. Mean age of patients was 28·4 (range 13–75) years. The series included 11 patients with chronic appendicitis, 41 with acute appendicitis and 22 with perforated appendicitis, with 16 localized and six generalized peritonitis. Conversion to laparotomy because of technical difficulty was necessary in six patients.

There were no postoperative collections or fistulas and two minor and transient parietal infections. No general postoperative complications were observed. Mean postoperative hospital stay was 2·3 days. The advantages of laparoscopic appendicectomy include complete peritoneal lavage in patients with peritonitis, decrease of postoperative parietal defects and infections, easier access to an ectopic appendix, concomitant treatment of any associated pathology, a comfortable postoperative period and anaesthetic advantage in young women.

In conclusion, these results indicate that laparoscopic appendicectomy performed by experienced surgeons is a safe technique in acute appendicitis.

Ultrasonography in suspected acute appendicitis

S. Eriksson, L. Granström and Å. Tisell*, *Departments of Surgery and *Radiology, Karolinska Institute, Danderyd Hospital, Stockholm, Sweden*

Ultrasonography of the right iliac fossa enhances the diagnostic accuracy of acute appendicitis. In a prospective study in 1989 at Danderyd Hospital it was demonstrated that an experienced ultrasonographer soon learns the special technique with graded compression to evaluate the appendix. The aim of this study was to determine whether diagnostic accuracy was the same when ultrasonography was performed by a radiologist who had performed more than 100 examinations compared with radiologists with less experience.

During 1992, in a prospective study, 127 unselected patients underwent ultrasonographic evaluation for the diagnosis of acute appendicitis. Surgery was performed on 59 patients. The histological and ultrasonographic findings were correlated. The expert ultrasonographer had a diagnostic accuracy of 85 per cent (28 of 33 cases) while the less experienced ultrasonographers had an accuracy of 85 per cent (22 of 26). However, it should be mentioned that the expert acted as a teacher to the other radiologists and this probably improved their diagnostic accuracy.

In conclusion, ultrasonographic evaluation certainly has its place in patients with suspected acute appendicitis. The graded compression method is highly reliable. It seems that inexperienced ultrasonographers soon reach a high diagnostic accuracy if taught by an expert in this field of ultrasonography.

Appendicectomy audit in a district general hospital

N. Evgenikos, C. Evans and G.R. McLatchie, *Hartlepool General Hospital, Hartlepool, UK*

A total of 69 consecutive patients underwent operation with a diagnosis of appendicitis in the first 6 months of 1991. Five case notes were not retrieved. The median age of 64 of the patients studied was 29 (range 5–71) years. The male to female ratio was 33:31. The majority of men (76 per cent) were younger than 25 years of age with only 3 per cent being older than 55 years, whereas 58 per cent of women were younger than 25 years and 6 per cent were older than 55 years of age. Of all patients, 55 per cent presented with acute appendicitis within 24 h of onset of symptoms, whereas 17 per cent presented more than a week after the onset of symptoms. The majority of patients (97 per cent) were general practitioner (GP) referrals and most (93 per cent) were operated on within 24 h of admission. Median (range) hospital stay was 4 (2–8) days. A total of 63 per cent were diagnosed as having acute appendicitis by the GP, and 22 per cent were referred by the GP as uncertain, non-specific abdominal pain (NSAP). On admission the diagnosis of acute or complicated appendicitis was made by the surgeon in 86 per cent of cases, offering NSAP for only 3 per cent. Surgical registrars performed the majority of these operations (69 per cent), whereas a minority of 17 per cent and 14 per cent were performed by senior house officers and consultants respectively. In 83 per cent the operative diagnosis agreed with the histology. False negatives were seen in 10 per cent and false positives in only 7 per cent. The histological findings were 69 per cent acute inflammation and 13 per cent normal appendix. Of patients, 91 per cent took antibiotics, with a median of 3 days cover; 18 per cent had only preoperative antibiotic cover, 21 per cent had only postoperative and 61 per cent had both preoperative and postoperative antibiotics. Anticoagulant therapy was given in 6 per cent. The postoperative complication rate was only 2 per cent.

In conclusion, the conventional care provided by district general hospitals offers a high standard of treatment with a very low complication rate, immediate surgical intervention, a high rate of accurate diagnosis and, on average, a short hospital stay.

Practical score to aid in decision making in doubtful cases of appendicitis

J.M. Ramirez and J. Deus, *Servicio de Cirugia 'A', Hospital Clinico Universitario, Zaragoza, Spain*

The diagnosis of appendicitis is not always easy and this is evidenced by the high negative laparotomy rate. During recent years different procedures have been utilized to assist in questionable cases; of these methods, few acceptable scoring systems remain.

The aim of the present study was to design a simple scoring system and to use it prospectively in order to evaluate its feasibility and real value as an aid in surgical decision making.

A total of 360 patients who had undergone appendicectomy were analysed to identify historical, clinical and laboratory findings that allowed differentiation between patients with acute appendicitis (81·4 per cent) and patients who had histologically non-inflamed appendices removed (18·4 per cent).

Seven single criteria were found to be significantly different (white blood cell count, percentage neutrophils, sex, location of first pain, diarrhoea, rebound tenderness and contracture). A weighting for each of the predictive factors was calculated using sensitivity, specificity and Bayesian probability. The scoring system was performed with the different weights and a cut-off point established the score that designated patients for observation and those for surgery.

The score was prospectively applied in 166 consecutive patients who had had appendicectomy, 134 (80·7 per cent) with acute appendicitis and 32 (19·3 per cent) without. The scoring system indicated intervention in 113 patients, six of whom had a normal appendix. Therefore, the use of this method could have decreased the negative laparotomy rate to around 5 per cent with a specificity of 0·81 and a sensitivity of 0·80. Scoring systems could become the ideal complementary method in diagnoses of appendicitis, being cheaper, easier and faster to use than any other approach.

Appendicectomy: laparoscopy *versus* McBurney

N. Rizk, G. Champault, J. Lauroy and P. Boutelier, *Department of Surgery, Hôpital J. Verdier, Bondy, France*

One hundred patients, 57 women and 43 men, with a mean age of 26·3 (range 15–71) years were admitted to the emergency room over a period of 9 months with a presentation of straightforward acute appendicitis. Fifty were treated by McBurney's surgical approach and 50 by laparoscopy. The distribution of the two groups was according to the availability of equipment and the experience of the on-call surgeon in laparoscopic surgery. Although non-randomized the two groups had comparable medical background, symptomatology, topographical and pathological distribution of the appendix. There was no mortality.

0007–1323/93/S004–02 © 1993 Butterworth-Heinemann Ltd

Patients operated on by laparoscopy had a significantly shorter return of gut transit (18·3 *versus* 29·4 h); they had less morbidity (1 *versus* 7 per cent, $P = 0.001$) especially for abdominal wall abscesses (0 *versus* 16 per cent, $P = 0.001$). The overall rate of conversion is 12 per cent, but this has progressively diminished with experience (from 22·2 to 6·2 per cent). Operative time was also higher (64·1 *versus* 39·3 min, $P = 0.02$) early in the study, becoming comparable at the end of the study. Finally, laparoscopy has reduced the rate of ablation of macroscopically normal appendices (from 10 to 2 per cent).

The laparoscopic approach to the appendix seems to be the method of choice because of its advantages in the obese, for the ablation of atypical location, for its low morbidity and the economic impact of the reduction of hospital stay and convalescence in non-specific abdominal pain in young women. It avoids 20 to 30 per cent unnecessary appendicectomies. Finally, it constitutes an ideal teaching model for laparoscopic surgery.

Fine-catheter peritoneal cytology for acute abdominal pain

B.R. Tulloh, D.C.R. Adams, J.M. Blazeby, S.W. Galloway, K.R. Poskitt and J.B. Bristol, *Cheltenham General Hospital, Cheltenham, UK*

For many abdominal emergencies, the diagnosis is unclear. In such cases fine-catheter peritoneal cytology (FCPC) is reported to be a useful diagnostic aid[1].

All abdominal emergencies have been allocated to a control or study group for 5 months, according to the admitting surgical consultant. The control group was managed conventionally, those under study were subdivided: group 1 comprised patients requiring operation on clinical grounds; group 2 included those considered not to require operation; and group 3 consisted of patients for whom the decision for operation was uncertain. Group 3 patients underwent FCPC unless dictated otherwise by conventional exclusion criteria. Men with a positive FCPC underwent mini-laparotomy, women diagnostic laparoscopy followed by laparotomy if indicated.

There were 151 controls and 171 under study. Fourteen of 15 patients in group 3 underwent FCPC; two were unsuccessful, there was one false-positive and one false-negative result, and one patient refused. FCPC reliably predicted the management in ten other patients. The patient with the false-positive result underwent unnecessary operation, as did a further five from group 1. Operation was delayed in the false-negative patient. There were seven unnecessary operations among controls.

FCPC has a useful but limited role in managing the acute abdomen.

1. Vipond MN, Paterson-Brown S, Tyrrell MR, Coleman D, Thompson JN, Dudley HAF. Evaluation of fine catheter peritoneal cytology of the peritoneum as an adjunct to decision making in the acute abdomen. *Br J Surg* 1990; **77**: 86–7.

Carcinoid tumours of the appendix

P. Vicq and J. L. Gouzi, *French Associations for Surgical Research, Hôpital du Val de Grâce, Paris, France*

The records of 181 patients with carcinoid tumour of the appendix seen during the 10-year period 1977–1987 were analysed retrospectively to determine the indications for right colectomy and the significance of intermediate histopathological forms of tumour. Appendicectomy was the only treatment in 146 cases. Right hemicolectomy was performed in 35 patients: initially in seven with one death after operation, and secondarily in 28 without mortality or morbidity. Colectomy was initially indicated in seven cases for bulky tumours of the base of the appendix invading the caecum or for associated carcinoma of the right colon. The 28 secondary colectomies were for tumours that were statistically larger and more invasive than those treated by simple appendicectomy and/or for intermediate forms (five cases). There were five cases of residual tumour in secondary hemicolectomy specimens. In 11 of the 181 carcinoid tumours (6 per cent), the intermediate type of tumour was associated with mucin production (seven adenocarcinoids and four carcinoids with mucocele). Of the seven patients with adenocarcinoid, there was one death at 2 years and one patient is alive with metastases.

Other than a size > 2 cm and basal localization, this study suggests that the presence of mucin-producing cells is a further indication for secondary right hemicolectomy.

Biliary

Haemobilia: a rare cause of acute cholecystitis

G. Altaca, E. Özdemir, K. Kiliç, N. Gülekon and R. Tokyay, *Bayindir Medical Centre, Ankara, Turkey*

Haemobilia is generally thought to be caused by trauma to the liver. Ruptured hepatic artery aneurysm, liver tumours, suppurative cholangitis, pyogenic and amoebic abscesses, and anticoagulation are also reported to result in haemobilia. A patient with haemobilia that caused acute cholecystitis is reported.

An 18-year-old man had right upper quadrant pain 8 days after mitral valve replacement (MVR). He had received anticoagulation after the operation. Ultrasonography and computed tomography revealed a distended gallbladder with a wall thickness of 10 mm, which contained inspissated bile showing a double contour. The common bile duct was found to be dilated. The patient was treated conservatively but the symptoms kept recurring and he was operated on 40 days after MVR. At operation, there was a reddish-brown haematoma combined with inspissated bile in the gallbladder and the common bile duct. Histopathological examination confirmed the diagnosis of haemobilia and acute cholecystitis. T tube cholangiography revealed cystic dilatations of the hepatic ducts at the confluence which were thought to be choledochal cysts of type IV. The patient had an intra-abdominal haemorrhage and haemobilia on the second day after surgery due to anticoagulation. He was treated conservatively, after which the T tube was removed and he was discharged. He is now being followed for the cystic dilatations of the bile ducts.

Although haemobilia resulting in acute cholecystitis but not jaundice and haemobilia associated with cystic dilatations of the bile ducts are extremely rare conditions, they should be considered in patients on anticoagulation therapy who have symptoms of acute cholecystitis.

Non-filling of the gallbladder during intravenous cholangiography is associated with conversion of laparoscopic to open cholecystectomy

T.H. Brown, D.A. Nicholson, G. Ingram, J. Bancewicz, M. Mughal and N.A. Scott, *Hope Hospital, Salford, UK*

Between August 1990 and February 1993, 96 patients considered suitable for laparoscopic cholecystectomy underwent preoperative intravenous cholangiography (IVC) to exclude asymptomatic stones in the common bile duct (CBD). As well as outlining the CBD, IVC demonstrated opacification of the gallbladder in 64 patients; in the remaining 32 patients, contrast did not enter the gallbladder.

Laparoscopic removal of the gallbladder was successfully accomplished in 84 patients. The remaining 12 (12 per cent) required conversion of the laparoscopic procedure to open cholecystectomy. Of the 64 patients whose gallbladder filled during preoperative IVC, only four (6 per cent) required a laparotomy. However, eight of the 32 patients in whom the gallbladder did not fill during cholangiography required conversion to open cholecystectomy ($\chi^2 = 5\cdot25$; $P = 0\cdot02$).

Non-filling of the gallbladder during preoperative IVC is associated with a fourfold increase in the incidence of abandoning laparoscopic and conversion to open cholecystectomy.

Effects of experimental external biliary drainage and extrahepatic cholestasis on bacterial translocation

M. Demirel, A. Isgor, A. Baykan, M. Uhri, O. Buyukbaba and T. Altug, *Sisli Etfal Hospital and University Experimental Research Centre, Istanbul, Turkey*

The effects of bile duct ligation and cessation of bile flow into the gut, by bile duct cannulation, on bacterial translocation were determined. Three groups each containing eight rats were studied: sham ligated, bile duct ligated and bile duct cannulated, in which external biliary drainage was performed, using a 0·45 × 25 mm catheter. The aim of the latter procedure was to determine whether cessation of bile flow into the gut, under conditions of normal liver cellular function, contributed to bacterial translocation. Rats were killed after 7 days. Serum glutamic–oxaloacetic transaminase, serum glutamic–pyruvic transaminase and alkaline phosphatase levels were determined. Liver, spleen, mesentery, ileum and caecum were studied microbiologically and histologically. Levels of liver enzymes were significantly raised ($P < 0\cdot05$) in rats with a ligated bile duct, compared with other groups. Bacterial translocation was 87·5 per cent whereas no translocation was detected in other groups. Histologically, the intestinal mucosal barrier was compromised with accompanying pericholangiitis and ductal proliferation in the liver. There was caecal bacterial overgrowth. By contrast, in rats with external biliary drainage the intestinal mucosal barrier and liver were completely normal and there was no bacterial overgrowth in the caecum. Thus cessation of bile flow into the gut, when the liver was not under stasis, did not promote bacterial translocation.

Treatment of postoperative bile duct stricture using vascularized jejunal patches

U. Eickhoff, K. Schäfer and V. Zumtobel, *St Josef Hospital, Bochum, Germany*

In six patients with a history of recurrent cholangitis, a stricture of the extrahepatic bile duct was diagnosed by endoscopic retrograde cholangiography (ERC) as the source of infection. The strictured duct was 3–5 cm long. Cholecystectomy in four patients and bilioenteric anastomoses in the other two caused the recurrent bile duct infections leading to the strictures. Because of the length of the strictures, a vascularized jejunal patch was used for reconstruction of the bile duct after splitting of the stricture. In the follow-up 5–15 years after operation, whereas four patients did not report any problems regarding their disease, two patients had recurrent infections twice a year. In all patients, the bile duct was visible at endoscopy. None of the patients had raised bilirubin levels, the bile flow was not disturbed and no fibrosis of the bile duct was seen.

Experience in these six patients suggests that reconstruction of strictured bile ducts after splitting using a jejunal patch is an effective method of treatment for strictures >2 cm long. The advantages of bilioenteric anastomosis are the possibility of visualizing the bile duct by ERC and of obtaining bile fluid for microbiological analysis in the case of cholangitis.

Selective cholangiography before laparoscopic cholecystectomy

S.W. Galloway, J.M. Blazeby, B. Tulloh and K.R. Poskitt, *Cheltenham General Hospital, Cheltenham, UK*

Common bile duct (CBD) stones occur in 8–20 per cent of patients with cholelithiasis. Preoperative detection allows endoscopic duct clearance before laparoscopic cholecystectomy. Criteria established in a previous study[1] were used to identify patients for selective cholangiography before laparoscopic cholecystectomy in 100 cases. Patients were categorized into three groups according to the risk of choledocholithiasis: group I (low risk): CBD < 7 mm, normal liver function tests (LFTs); group II (moderate risk): CBD ≥ 7 mm or mild derangement of LFTs; group III (high risk): clinical jaundice (bilirubin > $50\,\text{mmol l}^{-1}$) or stone seen in the CBD on ultrasonography.

Clinical and biochemical assessment was performed 12 months after surgery. Fifty-three patients (group I) had no further CBD imaging; 38 (group II) underwent intravenous cholangiography with 11 proceeding to endoscopic retrograde cholangiopancreatography (ERCP) and nine (group III) had primary ERCP. CBD stones were found in 11 cases. One patient required postoperative ERCP but no retained CBD stones were demonstrated in any patient.

The results from this study support the use of selective CBD imaging before laparoscopic cholecystectomy.

Critical assessment of 'biliary' symptoms

M. Harper, I. Bailey, S. Julious and C.D. Johnson, *University Surgical Unit and Department of Medical Statistics, Southampton, UK*

Many patients suffer persisting symptoms after cholecystectomy. A recent study showed that 43 per cent complained of pain or dyspepsia at > 1 year after operation. Several authors have failed to identify which symptoms are specific to gallbladder stones. A questionnaire survey was carried out on 164 patients referred for ultrasonography (US) for investigation of 'biliary' symptoms and 218 patients 1–2 years after open cholecystectomy for gallstones (184 of 218 patients (84 per cent) responded).

Multivariate analysis confirmed that stones were more likely if the pain was severe or followed by jaundice. Absence of stones was suggested by age < 60 years, reflux, sharp pain or pain not relieved by vomiting. A simple model allows rapid calculation of a score that predicts 90 per cent of patients without stones, with a certainty of 90 per cent.

Careful symptom assessment could reduce unnecessary requests for US. After cholecystectomy the most common symptoms were flatulence (48 per cent), pain (30 per cent), fullness (34 per cent) and bloating (28 per cent). Heartburn (21 per cent) and reflux (14 per cent) were also reported. Manning's criteria for irritable bowel syndrome (IBS) were satisfied in 47 per cent of patients with pain after cholecystectomy.

This study confirmed the high incidence of symptoms after cholecystectomy. IBS occurs in one-third of patients thought to have gallstones, and is more often after cholecystectomy. Careful analysis of symptoms may identify patients likely to benefit from cholecystectomy.

Management of choledochal cysts in adults

I. Karanikas, S. Dendrinos, S. Koundourakis, H. Panayoditis, M. Loizou and A. Papagrigoriadis, *2nd Surgical Department, General Hospital, Athens, Greece*

This study reports five cases of type I choledochal cysts (two men and three women, aged 20–84 years), operated on in this department during the period 1978–1991. Symptoms were recurrent upper abdominal pain in all patients, jaundice in two and ascending cholangitis in four. A palpable mass was present in one patient and gallstones were seen in two. Diagnosis was established by intravenous cholangiogram or ultrasonography, in one case during operation. The surgical procedure was Roux-en-Y choledochocystojejunostomy in three cases, cyst excision with Roux-en-Y hepaticojejunostomy in one, and choledochocystoduodenostomy in an elderly patient. Concurrent cholecystectomy was performed in two cases.

After operation, no major complications occurred apart from one case of respiratory failure in an elderly patient, treated successfully in the intensive care unit. During the follow-up period (2–15 years), one patient had recurrent episodes of ascending cholangitis within 2 years of cystoduodenostomy. Late results are very good in the other four patients (4–15 years after the operation). Cystojejunostomy or cyst excision with hepaticojejunostomy are the most frequently reported surgical procedures in the literature. The therapeutic actions in this study were in agreement with published recommendations for therapy.

Indications for and value of choledochoduodenostomy

J. Koufopoulos, M. Loizou, S. Papagrigoriadis, V. Kollias, Z. Gouvas and T. Liakakos, *Athens General Hospital, Athens, Greece*

The long-term effectiveness of choledochoduodenostomy was investigated in a retrospective analysis of 166 patients. From January 1971 to December 1989, 224 patients underwent side-to-side choledochoduodenostomy. Fourteen (6·2 per cent) died in the immediate postoperative period and another nine (4·0 per cent) from malignancy not previously detected. Thirty-five patients were lost to follow-up and the remaining 166 were followed for 3–14 years.

Choledocholithiasis, ampullary stenosis, echinococcosis, intrahepatic stones and postoperative stricture were the indications for choledochoduodenostomy. The diameter of the common bile duct (CBD) ranged from 18 to 43 mm. The overall morbidity rate was 24 per cent. The long-term follow-up revealed 15 (9 per cent) patients with symptoms 6 months to 11 years after choledochoduodenostomy. Two had mild attacks of pancreatitis and 13 had episodes of cholangitis. In four patients cholangitis resolved spontaneously and in three endoscopic retrograde cholangiopancreatography showed impacted stones which were treated by endoscopic sphincterotomy. At operation in six patients, two fibrous anastomotic strictures were demonstrated and the other four patients were believed to have a sump syndrome. Two transduodenal sphincteroplasties and four Roux-en-Y conversions were performed. One patient died and the others are symptom-free. These results show that choledochoduodenostomy is an effective long-term treatment for non-neoplastic obstructing lesions of the distal CBD.

Value of repeated reconstruction for recurrent benign biliary stricture

I. Kozicki, K. Bielecki, A. Kawalski and L. Królicki, *Department of General Surgery, Medical Centre of Postgraduate Education, Warsaw, Poland*

Since 1965, 101 operations for benign iatrogenic biliary duct stricture have been performed, including 61 Roux-en-Y hepaticojejunostomies. All operated patients are under permanent clinical observation, with a mean follow-up of 12·5 years. Restricture of previous anastomosis was an indication for reoperation in nine patients. In all patients, including those who underwent successful reoperation, the cumulative late patency rate evaluated clinically, biochemically and by HIDA scan was 90 per cent. In seven of nine reoperated patients, no abnormalities were found, with a follow-up period of up to 19 years. One patient has had four reoperations; the last operation was a Hepp's procedure and right duct anastomosis with stent into the jejunum.

Early reconstructive surgery for recurrent biliary stricture after hepaticojejunostomy is recommended to cure patients with iatrogenic benign lesions. Continued postoperative follow-up is required.

Intraoperative choledochoscopy: the most effective method for biliary tract exploration

R. Madjov and P. Chervenkov, *Department of Surgery, Medical University, Varna, Bulgaria*

A consecutive series of 453 common bile duct (CBD) explorations was studied to examine the efficacy of various methods of imaging the biliary tract. Patients were divided into two groups: group A comprised 335 patients before the advent of choledochoscopy and group B consisted of 118 patients treated after the introduction of intraoperative choledochoscopy in 1990.

Choledochoscopy was performed for the following clinical indications: current or previous obstructive jaundice, cholangitis, pancreatitis, stenosing papillitis, biochemical evidence of obstructive jaundice, ultrasonographic evidence of CBD dilatation or choledocholithiasis and endoscopic retrograde cholangiopancreatographic identification of multiple bile duct stones. Intraoperative indications included multiple and small gallstones and a dilated cystic duct, dilated CBD, and palpable stones.

The authors have performed 87 choledochoscopies using an Olympus choledochoscope. Nine patients had unsuspected bile duct stones that would have been missed without choledochoscopy.

Before the introduction of choledochoscopy, 11 patients in group A underwent reoperation for retained stones (3·3 per cent), while in group B there was no incidence of missed stones.

Postoperative trans T tube choledochoscopy was successfully performed in three patients. Complications were not seen. Flexible choledochoscopy is a safe and simple method of exploring the biliary tract. It significantly reduces the incidence of missed stones.

Role of bupivacaine in decreasing postoperative pain and pulmonary complications

M. Ozmen Mahir, S. Hengirmen, M. Cete and Y. Kadioglu, *Numune Hospital, Ankara, Turkey*

The effectiveness of bupivacaine was investigated for control of postoperative pain in 90 selected patients, who underwent elective cholecystectomy. Patients were randomized into three groups of 30 patients. In group 1, 50 ml 0·5 per cent bupivacaine was injected into the incision layers before closure. In group 2, a thin epidural catheter was inserted between the peritoneum and muscle layers. During the first postoperative 60 h 150 ml 0·5 per cent bupivacaine was given through an infusion pump. In group 3, 50 ml 0·9 per cent NaCl was injected into the incision before closure. The three groups were compared using postoperative visual analogue pain score, postoperative need for analgesia, respiratory function and duration of hospital stay. Bupivacaine was more effective than 0·9 per cent NaCl in reducing the need for postoperative pethidine in the first 24 h after surgery. The median (range) pethidine required was 60 (20–75) mg in group 1, 55 (25–60) mg in group 2 and 100 (25–150) mg in group 3. In the later postoperative period there was no significant difference. The amount of analgesia required was the same for injection or infusion of bupivacaine in the first 24 h ($P > 0{\cdot}05$). There were no significant differences between the three groups regarding respiratory function or duration of hospital stay. Bupivacaine administered into the wound reduced early postoperative pain but had no effect on postoperative recovery.

Obstructive jaundice: Wallstent metallic endoprosthesis

I. Pinto, A. Carabias, R. Tobio, M.A. Delgado and M. Moreno, *Hospital U. Getafe, Madrid, Spain*

Permanent prostheses in the bile duct provide good palliation for malignant biliary non-operable obstructive jaundice. Between April 1990 and August 1991, 25 Wallstent biliary prostheses were implanted in 20 patients with biliary obstruction. This new prosthesis has a large internal diameter and can be inserted percutaneously. Indications, morbidity and mortality were studied. The mean age of the 20 patients (11 men) was 68·2 (range 33–84) years. Nineteen had malignant lesions: ten cholangiocarcinoma, five pancreatic cancer and four metastatic nodes near the ampulla of Vater. One obstruction was benign in a patient with two stenoses of an enterobiliary bypass. Early complications (< 72 h) (biliary sepsis, pancreatitis and subcapsular haematoma) occurred in 30 per cent of the cases. Late complications were cholangitis without obstruction of the prosthesis (20 per cent) and prothesis obstruction (30 per cent). Eleven patients (55 per cent) died, two from cholangitis, one from intestinal bleeding, four from progression of carcinoma and four from other causes.

Predicting the need for cholangiography during laparoscopic cholecystectomy: selective *versus* routine

M.V. Planells Roig, R. García Espinosa, A. Moya Sanz, P. García and D. Rodero, *'La Fe' Hospital, Valencia, Spain*

The aim of this study was to assess the feasibility of a policy of selective cholangiography using a simple method for predicting the need for cholangiography during laparoscopic cholecystectomy.

The study comprised three different analyses: retrospective analysis (discriminant analysis) of factors associated with common bile duct (CBD) stones in a subpopulation of patients ($n = 204$) submitted for elective open cholecystectomy (control group 1); prospective evaluation of the same factors in patients ($n = 177$) submitted for elective open cholecystectomy (control group 2); and prospective evaluation of these factors in a consecutive group of patients submitted for elective laparoscopic cholecystectomy.

Results are expressed in terms of the diagnostic properties of the prediction obtained from the discriminant analysis of each subgroup of patients.

	Control group 1	Control group 2	Laparoscopic cholecystectomy group
Sensitivity	74·7	76·9	40·0
Specificity	69·9	82·6	94·1
Accuracy	71·9	81·4	92·6
Undetected stones	10·7	5·1	1·7
Unnecessary peroperative cholangiography	17·3	13·6	5·7

Values are percentages

In conclusion, the present study demonstrates the feasibility of a policy of selective cholangiography for patients submitted for open and laparoscopic cholecystectomy using an equation that accurately predicts which patients are at risk of harbouring CBD stones. Using this system the need for peroperative cholangiography can be routinely assessed for each patient. Only asymptomatic CBD stones are not detected by the system (1–7 per cent of unsuspected stones in patients submitted for laparoscopic cholecystectomy) although this figure compares favourably with false-negative and false-positive rates obtained in patients undergoing routine peroperative cholangiography.

Biliary peritonitis after T tube removal: experimental study of pathogenic factors (latex *versus* silicone with systemic corticosteroid administration)

P. Ramirez, A. Piñero, J. Sanchez, J.M. Ruiz, A. Moreno, R.S. Robles, F.S. Bueno and P. Parrilla, *Department de Cirugia, Hospital Universitario V. Arrixaca, Murcia, Spain*

The aims of the present study were to compare the degree of postoperative peritoneal adhesion (PPA) conditioned by two different materials (latex and silicone) and to analyse the influence of corticosteroids on PPA.

Forty Wistar rats were divided into four groups: group I ($n = 10$) were a latex control group; group II ($n = 10$) had latex and corticosteroids; group III ($n = 10$) were a silicone control group; and group IV ($n = 10$) had silicone and corticosteroids. A 2-cm midline mini-laparotomy to position a 2-cm segment of T tube in the subhepatic space was performed. In groups I and II the tube was latex, and in groups III and IV silicone. Corticosteroids were administered to the rats in groups II and IV, 30 mg kg^{-1} day^{-1} of intramuscular methylprednisolone for 30 days. The rats were killed after 30 days, and the PPAs were measured using a point scale which considered: (1) mobilization of the tube; (2) percentage of surface covered outside the tube; (3) percentage of lumen occupied inside the tube; (4) degree of tenacity; and (5) existence of vascularization. The maximum score possible for each rat was 10 points and minimum 0. The non-parametric Kruskal–Wallis and Mann–Whitney tests were used to analyse the results. The overall scores of the rats in each group were: group I (latex), 82 points; group II (latex, corticosteroids), 46 points; group III (silicone), 33 points; and group IV (silicone, corticosteroids), 18 points. Silicone caused fewer PPAs than latex ($P < 0{\cdot}001$). Corticoid administration significantly reduced the PPA rate in both the latex ($P < 0{\cdot}001$) and silicone groups. Silicone conditions PPAs to a lesser extent than latex and corticosteroids reduce the PPA rate with both latex and silicone.

Agenesis of the gallbladder in adult patients: a diagnostic problem

M. Raule, C.M. Bagni, M. Marinoni, M. Meroni, G. Perazzoli and G. Trivellini, *Istituto di Patologia Speciale Chirurgica, Milan, Italy*

Agenesis of the gallbladder without extrahepatic biliary atresia is a rare congenital disorder. The incidental finding during surgery of two cases of gallbladder agenesis over the past 15 years at this institution prompted a review of the diagnostic problem. Both patients were symptomatic, ultrasonography showed false-positive gallstones and the gallbladder was not visualized using cholangiography. The first patient underwent an open laparotomy and the second a laparoscopic operation. In spite of modern diagnostic methods such as ultrasonography and cholangiography, gallbladder agenesis cannot be diagnosed before surgery. Diagnosis is possible by intraoperative cholangiography or at autopsy. The incidence of this anomaly in the authors' experience is reported.

Place of routine cholangiography at laparoscopic cholecystectomy: a prospective study

C. Rey, S. Msika and J.M. Molassoko*, *Services de Chirurgie Digestive, Clinique Sainte Marie, Vernon and *Centre Hospitalier Henri IV, Meulan, France*

The development of laparoscopic cholecystectomy has reduced the proportion of patients undergoing routine operative cholangiography because of the technical problems. The necessity of obtaining a cholangiogram should not be influenced by the procedure of cholecystectomy. The aim of this study was to assess the feasibility and performance of laparoscopic cholangiography (LC) during the treatment of symptomatic gallstones.

Between January and December 1992, 100 patients with symptomatic gallstones eligible for laparoscopic cholecystectomy were studied prospectively. Of these, acute cholecystitis was present in 26 patients. There were two conversions to open cholecystectomy. LC was attempted in 87 of the 100 cases, but was not attempted in 13 because of iodine allergy or a previous endoscopic sphincterotomy. Cholangiography was successful in 72 patients (83 per cent). The 15 failures were because of a narrow cystic duct in ten and cystic duct valves in five. According to preoperative clinical, biological, ultrasonographic and cholangiographic findings, 68 of 72 cholangiograms were normal. In the four abnormal peroperative cholangiograms there was abnormal biliary anatomy (no cystic duct) in one case, a common bile duct stone in one case and cystic duct stones in two. In the two former cases conversion to open cholecystectomy was performed. In the two latter cases, laparoscopic cholecystectomy was performed after removal of the cystic duct stones.

In conclusion, LC permits detection of: (1) abnormalities of biliary anatomy, usually unsuspected on routine preoperative investigations, avoiding severe bile duct injuries; (2) cystic duct stones, whose laparoscopic treatment is generally easy; and (3) common bile duct stones, usually suspected before operation.

LC can be carried out simply and effectively in most cases, but failures are unpredictable. Other methods of preoperative bile duct evaluation (endoscopic retrograde cholangiopancreatography, endoscopic ultrasonography) have to be evaluated.

Caroli's disease: therapeutic procedures and late results

K. Ridwelski, T. Benhidjeb, B. Münster*, K. Gellert, H. Lippert and B. Rudolph†, *Surgical Clinic, *Radiological and †Pathological Institute (Charité), Berlin, Germany*

Caroli's disease is a rare condition characterized by multiple segmental cystic dilatations of the intrahepatic bile ducts. The existence of the ectasia is usually recognized through the resulting complications, such as cholelithiasis, abscess of the liver, septicaemia, cirrhosis and portal hypertension. The risk of malignant degeneration is approximately 10 per cent. For this reason, radical resection is considered the ideal therapy, although it is possible only when a single liver lobe is affected. Experience in the treatment of 16 patients with Caroli's syndrome is reported. The group consisted of nine men and seven women (mean age 42 years). Twelve patients had cholangiolithiasis, and in five secondary biliary cirrhosis had developed, which in three cases resulted in portal hypertension with liver failure. Eight of the patients had previously undergone cholecystectomy elsewhere. A 17-year-old patient also underwent a portocaval shunt. Surgical revisions were performed on seven patients. In six cases, a choledocholithotomy was carried out with extrahepatic and intrahepatic stone extraction. This was combined with cholecystectomy in three patients and with papillotomy in two. Partial hepatectomy was possible only in two cases. Ten patients had endoscopic procedures, nine had papillotomy, eight underwent extrahepatic and intrahepatic stone extraction and internal drains were inserted in six. In a follow-up period of 12 years less than 25 per cent of the patients were asymptomatic. Among these were both patients who underwent partial hepatectomy. In all other patients, recurrent cholangitis, sometimes with cholangiolithiasis, was the main complaint. This led to a requirement for repeated palliative and endoscopic drainage procedures. The mortality rate at 12-year follow-up was 26 per cent, which indicates the poor prognosis in this condition.

Cholecystectomy by microlaparotomy and minilaparotomy

I. Rozsos and T. Rozsos, *Moritz Kaposi Medical Centre, Kaposvár, Hungary*

A total of 412 consecutive microlaparotomy and minilaparotomy cholecystectomies were performed between 13 December 1990 and 31 January 1993. These minimally invasive cholecystectomy procedures were developed as alternatives to laparoscopic and conventional cholecystectomy. Microlaparotomy surgical removal of the gallbladder was done through a 2–3-cm vertical midline incision between the xiphoid and umbilicus. This technique was used for 296 operations (71·8 per cent). Minilaparotomy cholecystectomy with a 3–4-cm vertical incision was performed in 93 patients (22·3 per cent) and with a 4–6-cm vertical midline incision in 23 (5·6 per cent) patients of whom 17 had choledocholithiasis, four had accessory bile ducts and three had abscess formation around the gallbladder. There was one death (0·3 per cent), three early reoperations (0·7 per cent) and four late reoperations (1·0 per cent). Of the 296 patients with a 2–3-cm incision, 294 were discharged between 1 and 3 days after surgery. Except for those requiring early reoperation and some very elderly patients, all patients were discharged by the fifth day. All patients with diseased gallbladders are potential candidates for these procedures.

Management of obstructive cholecystitis with minilaparotomy

I. Rozsos and T. Rozsos, *Moritz Kaposi Medical Centre, Kaposvár, Hungary*

A total of 412 modern minilaparotomy cholecystectomies were performed between 13 December 1990 and 31 January 1993; 99 patients (24 per cent) had acute or chronic obstructive cholecystitis. These cases were divided into three groups. Group 1 comprised 27 patients who presented within 10 days of the acute attack. There were four cases of acute Mirizzi syndrome with jaundice and seven of necrosis of the gallbladder wall. There was no morbidity. These patients were discharged 2 or 3 days after surgery. In group 2, 34 patients presented between 10 days and 6 weeks of the acute attack. In nine cases, there was abscess formation around the gallbladder; in one of these, there was bile leakage and subhepatic bile collection from Luschka's duct. This patient required reoperation 2 days after surgery. Two cases of wound suppuration and four of common bile duct stones were encountered. The 38 patients in group 3 presented with a history longer than 6 weeks, with one or more episodes of acute attack. There was one death. In one instance, Schloffer's tumour compressed the hepatic and common bile ducts. Three instances of spontaneous biliary–enteric fistula, six of common bile duct stones and three of wound suppuration were encountered.

Bile culture of 366 patients undergoing biliary surgery

A.K. Samy and G. MacBain, *Surgical Unit, Southern General Hospital, Glasgow, UK*

This study of bile samples from 366 patients taken during biliary surgery performed in the Southern General Hospital, Glasgow, during the 5-year period from January 1985 to December 1989 was carried out to establish the incidence of positive bile cultures and the prevalence and frequency of cultured organisms therefrom. The relationship between positive culture, age of patients and magnitude of the surgery was also explored.

The results showed 17 different organisms in a variety of combinations. Culture was positive in 19·9 per cent of cases, of which 69·9 per cent grew one type of organism, 23·3 per cent grew two types and 6·8 per cent grew more than two. Organisms were grown in the following order of frequency: *Escherichia coli* (45·2 per cent), streptococci (16·4 per cent), *Clostridium*, mainly *C. perfringens* (15·1 per cent), *Klebsiella* (9·6 per cent) and *Bacteroides* (8·2 per cent). The number of positive cultures increased in relationship to the magnitude of the surgical procedure undertaken. Cultures were positive in 17·5 per cent of patients undergoing simple cholecystectomy, in 23·6 per cent undergoing cholecystectomy and cholangiography, and in 44·4 per cent undergoing cholecystectomy with exploration of the common bile duct. The incidence of positive cultures increased with increasing age with a steep rise in those >60 years which was maintained to a level of 75 per cent in patients aged >80 years.

Management of cholangitis: retrospective study of 160 cases

C.L. Thiry, S. Rohr, N. de Manzini, O. Firtion and Ch. Meyer, *Service de Chirurgie Générale et Digestive, CHU Strasbourg-Hautepierre, France*

Between 1 January 1970 and 20 January 1992, 160 patients (107 women and 53 men, mean age 67 (range 28–94) years) were treated for cholangitis. Of these, 147 had a simple form (SC) and 13 an acute suppurative form (ASC). Six patients (4 per cent) did not undergo surgery (medical treatment in two cases, endoscopic sphincterotomy (ES) in four). The remaining 154 patients were operated on, 26 of them (17 per cent) after preoperative ES. Common bile duct (CBD) exploration was carried out through a choledochotomy in 147 cases (95 per cent) and via the cystic duct in three cases; in four cases, peroperative cholangiography confirmed CBD evacuation after ES. External biliary drainage (EBD) was performed in 127 cases (82 per cent) and biliary–enteric anastomosis (BEA) in 22 (14 per cent); in five cases (3 per cent), only the cystic duct was ligated. EBD and BEA rates (respectively 75 and 25 per cent before 1980) became 87 and 8 per cent from 1980 (P not significant). The overall mortality rate was 12·5 per cent, being 22 per cent in 1970–1979, 8 per cent in 1980–1989 and 0 per cent since 1990 ($P < 0\cdot05$). The mortality rate was 7 per cent (ten of 147) in SC and 77 per cent (ten of 13) in ASC ($P < 0\cdot01$). ASC mortality rate decreased from 100 per cent (seven of seven) in the first decade to 50 per cent (three of six) in the second. Mortality rate was higher after BEA (23 per cent (five of 22)) than after EBD (12 per cent (15 of 127)) ($P < 0\cdot05$). It was 7 per cent (two of 30) when preoperative ES was performed against 14 per cent (18 of 130) without it ($P < 0\cdot05$). The morbidity rate was 27 per cent (43 cases), being 34 per cent (20 of 58) in the first decade, 21 per cent (18 of 84) in the second and 28 per cent (five of 18) in the last 2 years ($P < 0\cdot05$). It was 31 per cent after EBD and 14 per cent after BEA ($P < 0\cdot01$). Cholangitis is a serious complication of CBD stones. The prognosis has improved over the past decade and preoperative ES appears to improve the outcome.

Surgical management of injuries to the extrahepatic biliary system

Z. Wajda, Z. Gruca and R. Marczewski, *Medical Academy of Gdańsk, Poland*

Fifty-four patients operated on between 1950 and 1990 were divided into three groups according to the injury, time to diagnosis and time to corrective procedure. The first group consisted of 18 patients in whom reconstruction of the bile ducts was performed during the primary operation. The second group comprised nine patients in whom injury was diagnosed in the early postoperative period. The third group of 27 patients had restenoses after reconstruction performed in other hospitals. The primary operation, localization of the injury, diagnostic procedures and operative treatment of the bile duct injuries were analysed in each group. Thirty-two patients reviewed at least 2 years after corrective surgery were studied as a long-term follow-up group. According to clinical examination, laboratory tests, radiography and biliary scintigraphy, long-term results were satisfactory in 24 patients. The authors believe hepaticojejunostomy Roux-en-Y to be the procedure of choice in the majority of cases.

Targeted delivery of antibiotic in biliary surgery

Zh.Sh. Zhumadilov, E.A. Taygulov and D.R. Musinov, *Medical Institute, Semipalatinsk, Kazakhstan*

A new method has been developed experimentally and applied clinically that targets delivery of antibiotic to the liver and biliary system by means of autologous erythrocyte ghosts. Intravenous infusion of erythrocyte ghosts containing a single dose of antibiotic is performed twice a day.

The clinical trial consisted of three treatment groups. Group 1 comprised 190 patients with acute cholecystitis and with a high risk of needing urgent operation. Group 2 comprised 17 patients with intrahepatic biliary abscesses. Group 3 comprised 33 patients with acute cholangitis. The effect of the new method was also studied on the immune status of patients and the pharmacokinetics of antibiotics in the bile.

The results have shown greater effectiveness of a targeted delivery method in comparison with conventional methods of antibiotic infusion. The new method creates a high and prolonged antibiotic concentration in the bile, and reduces the recovery time of patients with acute cholecystitis. All patients with intrahepatic abscesses and with acute cholangitis were treated successfully without operation.

Breast

Ultrasonographic localization of impalpable breast tumours after screening

A.H. Davies, A. Cowan, P. Jones, R.M. Watkins and
C. Teasdale, *Derriford Hospital, Plymouth, UK*

Accurate localization of a tumour is imperative before excision biopsy for impalpable breast lesions seen on screening mammography. Ultrasonographic localization has the advantages of being simple, quick and non-invasive.

In a 3-year period from September 1989, 26 953 women have been screened for breast carcinoma. Of these, 185 have required localization before biopsy; 159 (86 per cent) were performed using a wire localization technique and 26 (14 per cent) were performed using ultrasonography alone. These latter 26 women were of mean age 57 (range 50–64) years. The location of these tumours were: 13 upper inner quadrant, nine upper outer quadrant, one lower outer quadrant, two lower inner quadrant and one lower mid-breast. Twenty-two of the 26 were malignant; the four benign lesions were two sclerosing lesions and two fibroadenomas. The mean (95 per cent confidence interval) maximum diameter of tumour diagnosed by ultrasonography compared with the histological specimen was 10·6 (8·5–12·7) *versus* 11·1 (8·9–13·3) mm with a correlation (r_s) of 0·87. In the malignant cases the mean maximum diameter of tissue excised was 63·0 (95 per cent confidence interval 57·2–65·9) mm. Complete excision was obtained in 21 of the 22 patients with malignant disease by a single operation. One patient with two foci identified on ultrasonography required subsequent mastectomy.

Ultrasonography alone has been used successfully as a means of preoperative localization in selected cases before excision biopsy of a breast tumour.

Non-palpable breast lesions: correlation between radiology findings and histological features

M.A. Delgado, A. Carabias, C. Cerquella, J.L. Letamendia,
A. Polo, J. Coba, M. Martin, J. Bajo and M. Moreno, *Hospital Universitario de Getafe, Madrid, Spain*

Non-palpable breast lesions are very non-specific and require biopsy, usually with mammographic needle localization, to provide histopathological confirmation of their nature.

Over a period of 19 months 52 biopsies of non-palpable breast lesions were performed, with 22 carcinomas (42 per cent) and 30 benign tumours (58 per cent). Correlations between mammographic lesions and histopathological features were: (1) 26 (50 per cent) had microcalcifications (seven carcinomas and 19 benign lesions); (2) six (12 per cent) had mammographic nodules (three carcinomas and three benign lesions); (3) 12 (23 per cent) images showed nodules with microcalcification (eight carcinomas and four benign lesions); (4) three (6 per cent) images demonstrated architectural abnormality (one carcinoma and two benign lesions); (5) two (4 per cent) images showed architectural abnormality with microcalcifications (one carcinoma and one benign lesion); and (6) three (6 per cent) normal mammographies revealed carcinoma (subsequently diagnosed by cytology).

This study showed a higher malignancy rate in non-palpable breast lesions compared with the reported literature. The highest incidence of malignancy was in non-palpable mammographic nodules.

Perioperative blood transfusion and prognosis after operation for breast cancer

J.H. Eickhoff, J. Andersen and C. Laybourn, *Department of Surgery, Gentofte Hospital, University of Copenhagen and Danish Breast Cancer Cooperative Group Secretariat, Finsen Institute, Copenhagen, Denmark*

The Danish Breast Cancer Cooperative Group collects data on all patients operated on for breast cancer. These prospective data were used with retrospectively collected transfusion data to test the hypothesis that perioperative blood transfusion increases the rates of recurrence and death after mastectomy. In the period 1977–1982, 1599 patients in Copenhagen underwent mastectomy. Of 228 patients who received perioperative transfusion, the disease recurred in 110 (48 per cent), compared with 647 (47 per cent) of 1371 patients not having transfusion ($P = 0·85$). The 5-year recurrence-free survival rate was 54 per cent in the transfused group *versus* 60 per cent in the non-transfused group ($P = 0·44$). For overall and cancer-specific survival the rates were 67 *versus* 73 per cent ($P = 0·24$) and 69 *versus* 76 per cent ($P = 0·12$). The patients having transfusion had a higher prevalence of risk factors. When the effects of these risk factors were accounted for using Cox multiple regression analysis, the effect of blood transfusion on recurrence and death was eliminated. This study does not support the hypothesis that perioperative blood transfusion increases the risk of recurrence and death after mastectomy for breast cancer.

Diagnostic reliability of a combined approach of physical examination, mammography and fine-needle aspiration biopsy in patients with breast cancer

Y. Erhan, A. Eldem, M. Akyildiz, M. Kapkaç, S. Aldemir,
N. Özdemir, M.R. Yilmaz, O. Özbal and Yildiz Erhan,
Ege University Medical School, Bornova-İzmir, Turkey

Breast cancer is a common malignancy in women. Physical examination is the first step and the most widely used diagnostic method. Mammography, an important adjunct for proving the diagnosis of breast cancer, has a low accuracy rate in detecting small masses. Recently fine-needle aspiration biopsy (FNAB) has gained acceptance as an adjuvant diagnostic procedure to physical examination and mammography for the evaluation of breast masses. Various accuracy rates have been reported for these three methods.

In this study the accuracy of a combination of physical examination, mammography and FNAB in diagnosing breast tumours in a consecutive, unselected series of women referred to the department for breast lesions was assessed. During the study period, 184 women with breast cancer were examined. Physical examination performed by the specialist surgeons was graded as malignant, suspected malignant and benign. Mammography results were classified as in the physical examination. The results of FNAB were reported as unsatisfactory, benign, non-diagnostic, malignant and suspicious. The results obtained were compared with the histopathological examination results of the specimens.

Using physical examination 92·9 per cent of the lesions were evaluated as malignant or suspicious. The false-negative diagnosis rate was 7·1 per cent. Mammography showed 94·9 per cent of the lesions as malignant or suspicious and its false-negative rate was 5·1 per cent. By FNAB, 94·8 per cent of the breast lesions were diagnosed as malignant or suspicious and the false-negative rate was 5·2 per cent. The accuracy rate of the combination of three diagnostic methods was 100 per cent. As a result, when these three methods were used in combination, diagnosis of the breast cancer was made accurately.

Psychological treatments for anxiety in breast cancer: initial findings

W.P. Fox, J. Gray, S. Lewis, R. Elliott*, R.A.J. Spence*,
K. Harrison*, A. Wilkinson and W. Odling-Smee, *The Queen's University of Belfast and *Belfast City Hospital, Belfast, UK*

Initial results are presented that form part of an ongoing longitudinal study measuring the degree of anxiety experienced by women after breast cancer has first been diagnosed. A number of psychological interventions aimed at reducing this anxiety have been initiated. Patients are randomized on a weekly basis to one of three treatment groups: relaxation, taught by volunteers; befriending, by psychotherapists; and a control group from which the current level of care can be assessed. Each patient is asked to complete a series of questionnaires before surgery and at regular intervals afterwards.

Initial findings suggest that there are no significant differences between groups with respect to anxiety. The Mental Adjustment to Cancer scale appears to be more sensitive and reveals some modest group differences. However, the small number of patients per group precludes making any

0007–1323/93/S011–03 © 1993 Butterworth-Heinemann Ltd

firm conclusions. For approximately one-third of patients, waiting for breast cancer surgery and the pathological results of that surgery can be very stressful. However, such levels of anxiety gradually diminish with time.

Investigation and treatment of breast cancer in England and Wales

S.A. Harries, R.N. Lawrence, R. Scrivener, N. Fieldman,
J.H. Scurr and M.W. Kissin*, *University College Hospital, London and *The Royal Surrey County Hospital, Guildford, UK*

The treatment of breast cancer is controversial. To ascertain how surgeons in England and Wales treat this disease a questionnaire was sent to all consultant general surgeons listed in the Medical Directory in 1992. A total of 985 questionnaires were sent and 592 replies were received, a response rate of 60 per cent. Regarding the treatment of a premenopausal woman with a 2-cm carcinoma in the upper outer quadrant, 78 per cent indicated that they would treat this conservatively, 17 per cent would offer the patient the choice of conservation or mastectomy and only 5 per cent indicated that they would advise mastectomy. Regarding the treatment of the axilla, a full axillary dissection was recommended by 41 per cent and axillary sampling by 36 per cent. Surgeons were more than twice as likely to leave the axilla untreated in postmenopausal (8 per cent) than in premenopausal (3 per cent) patients. A total of 37 per cent of surgeons would treat an elderly patient with breast cancer by lumpectomy and tamoxifen compared with 34 per cent who would use tamoxifen alone. Mastectomy would be recommended by 69 per cent for a patient who developed local recurrence after conservative treatment for breast cancer. Finally, 91 per cent of surgeons believe that outpatient follow-up is worthwhile, but 70 per cent would not perform any regular staging investigations apart from mammography if the patient remained asymptomatic. This study provides an important insight into the current treatment of this common disease.

Breast-conserving therapy in 832 patients

U. Laffer, F. Harder, A.C. Almendral, J. Torhorst and R. Hünig,
Department of Surgery, University of Basel, Basel, Switzerland

Between 1977 and 1990, 832 breast-conserving treatments in 814 patients with breast cancer (median age 49·4 years) have been carried out according to a prospective controlled trial in the region of Basel. Although the surgical procedures were done by a number of surgeons, the radiotherapeutic treatment and histopathological review were limited to one centre and one pathologist respectively.

Of the patients 46·4 per cent had stage pT_1pN_0 disease, 18·2 per cent pT_1pN_1, 16·0 per cent pT_2pN_0 and 13·9 per cent pT_2pN_1 respectively (5·5 per cent carcinoma *in situ*).

At a median follow-up of 3·4 years, according to the Kaplan–Meier method the estimated 5-year survival rate was 91 per cent for all patients and reached 88 per cent for those with invasive ductal cancer, 96 per cent for those with invasive lobular cancer, and 95 per cent for those with medullary cancer. The overall local recurrence-free survival rate is 94 per cent at 5 years. The corresponding figures are 97 per cent for node-negative, 89 per cent for node-positive, 96 per cent for pT_1 and 91 per cent for pT_2 patients. Of the patients 84·5 per cent are distant disease-free at 5 years (91 per cent pN_0, 70 per cent pN_1).

In this analysis, tumour-free margins of the specimen were found to be statistically significant in local recurrence-free survival (P = 0·00008). Overall, in 43 of 832 patients a local failure occurred after breast-conserving treatment. After salvage therapy, the 5-year survival rate reached 63 per cent for this group of patients.

Smooth *versus* textured breast implants: a rodent study

C.M. Malata, I.L. Naylor and M.J. Timmons, *Bradford University, UK*

The withdrawal of polyurethane foam-covered breast prostheses has intensified the search for an alternative implant with a low capsular contracture (CC) rate. Preliminary clinical studies comparing CC around smooth and textured implants suggest that surface texturing reduces the incidence of contracture. Animal studies are contradictory.

This study was designed to investigate the contractility of capsules formed around smooth and textured surface silicone gel prostheses in an animal model of CC. The prostheses (15 mm × 5 mm) were implanted subcutaneously in female Hooded Lister rats (mean(s.d.) 250(25) g) and the capsules harvested after 7 or 28 days. The capsules were analysed histologically (Masson's trichrome stain) and functionally (contractility response to a myofibroblast stimulant).

The capsules around textured surface prostheses were more adherent, thinner (P < 0·05), and structurally less organized than those around smooth prostheses. Their reactivities (mg tension) to 4 mg mepyramine are shown in the table.

Day	Smooth (n = 8)	Textured (n = 8)	Mann–Whitney *U* test	
			P	U
7	7·9 (3·1–9·7)	1·8 (0·9–1·9)	0·01	10
28	2·0 (1·5–2·1)	1·1 (0·0–1·6)	0·03	14

Values are mean (range)

Textured surface implants induced significantly less reactive capsules. These results support the preferential use of textured surface prostheses.

Immunomodulatory potential of *Mycobacteria phlei* in primary breast cancer

J.M. O'Donoghue, C. Curran, D. O'Hanlon, D. Maher and
H.F. Given, *National Breast Cancer Research Institute, University College Hospital, Galway, Ireland*

Mycobacteria are known to have immunomodulatory effects. A purified cell wall extract of *Mycobacteria phlei* (MCWE) may circumvent the problems associated with live whole-cell preparations. A pilot study investigated the potential of MCWE to modulate the *in vitro* immune response of patients with primary breast cancer. A dose–response curve was first established to determine the optimum dose of MCWE to be used. Peripheral lymphocytes and monocytes were separated over Ficoll from ten volunteers. The lymphocyte blastogenic response to phytohaemagglutin (PHA) and concanavalin A (Con A) was measured by counting the cells after pulsing them with tritiated thymidine. MCWE was added to the cells in 96-well microtitre plates in concentrations ranging from 0·1 to 200 µg ml^{-1}. Maximum blastogenesis was observed at 5 µg ml^{-1}. The blastogenic response was reduced significantly (P < 0·0001) at doses above 50 µg ml^{-1}, suggesting toxicity at high doses. Similar responses were not seen with lipopolysaccharide (LPS). The same experiment was repeated in six patients with primary breast cancer and two controls. MCWE and LPS were used at a concentration of 5 µg ml^{-1}. Two patients were significantly immunosuppressed to the mitogens PHA and Con A (P<0·05) when compared to the controls. These two patients had a significantly better blastogenic response than the four immunocompetent patients (P < 0·05) in response to MCWE. This suggests that a purified cell wall extract of *Mycobacteria phlei* has potential as an immunotherapeutic agent and may have an adjunctive role to play in the management of immunosuppressed patients with breast cancer.

Conservative surgery in breast carcinoma: experience over 13 years

F. Orvalho, P. Dias, R. Alves, N. Abecasis, C. C. Moniz and C. S. Costa, *Instituto Português de Oncologia, Lisbon, Portugal*

Conservative surgery represents an important step forward in the treatment of breast carcinoma, providing the same level of disease control as traditional surgical therapies but reducing the deformity and mutilation to which patients are subjected. This consequently increases their acceptance of the disease and its treatment. Application implies, in our experience, observing three principles: (1) tumour excision with an acceptable safety margin; (2) complete axillary dissection, preferably by a separate incision; and (3) adjunctive radiotherapy of the remaining breast.

From 1979 to 1992, 183 patients in our service received conservative surgery for breast carcinoma. Eligibility criteria were T_1 N_0 M_0 clinically staged tumours, excluding those located centrally. Analysed were age distribution, laterality, quadrant distribution in the breast, risk factor assessment (family history of breast cancer, premenopausal/postmenopausal status, length of fertile period up to the appearance of the tumour, parity), histological classification of the tumours, lymph node metastases and hormonal receptor status. Finally presented are actuarial survival rates at 10 years for the global series: 82·4 per cent overall, 71·3 per cent without evidence of disease and 90·5 per cent without local recurrence. Actuarial survival according to lymph node status is also presented.

Patient satisfaction with breast reconstruction after cancer surgery

S. Shrotria and M.W. Ghilchik, *St Mary's and St Charles' Hospitals, London, UK*

Breast reconstruction after cancer surgery has evolved from reconstruction of the entire breast after mastectomy to the more recent techniques of restoration of shape and symmetry after conservative breast surgery. These procedures with variation in the extent, duration and timing of surgery influence patient satisfaction. A total of 54 patients underwent reconstructive surgery with prosthetic replacement (18 patients), reduction mammoplasty (25) or myocutaneous flap reconstruction (11). The main reason for requesting reconstruction was to improve body image. Satisfaction was assessed on a scale from 1 (very satisfied) to 5 (very dissatisfied) in relation to the shape, size and scarring after reconstruction. Overall outcome of the procedures was compared in the three groups. The mean period of stay in hospital was 2·7 days for the reduction group, 3·8 days for the replacement group and 9·8 days for the flap reconstruction group. The mean overall satisfaction score was 1·6 in the reduction group, 2·0 in the flap reconstruction group, and 2·2 in the replacement group. The incidence of complications was highest in the replacement group (15 per cent) with infection and extrusion of the prostheses being the main problems. It is concluded that reconstruction by reduction mammoplasty after conservative surgery provides a more satisfactory outcome than replacement mammoplasty.

Breast-conserving therapy for ductal carcinoma *in situ*

M. Zuber, U. Laffer, J. Torhorst, R. Hünig and F. Harder, *Department of Surgery, University of Basel, Basel, Switzerland*

As the use of breast cancer screening programmes has grown there has been a marked increase in the detection of ductal and lobular carcinoma *in situ*. This study asked what influence tumour excision, axillary dissection and consecutive irradiation as treatment for ductal carcinoma *in situ* (DCIS) has on the incidence and localization of non-invasive and invasive recurrence. From 1977 to 1990, 893 breast-conserving procedures were performed for breast cancer. In 55 patients (6·2 per cent) the histological diagnosis was carcinoma *in situ* (50 DCIS). The median follow-up is 3·5 (range 0·4–13·4) years. In the group of 50 DCIS five local recurrences (10 per cent; three non-invasive, two invasive) occurred. Two patients developed carcinoma in the contralateral breast. There were two deaths (disease-free at autopsy) in this group. Breast conservative therapy is a treatment option for DCIS. The local recurrence rate is not low, therefore careful follow-up by clinical examination and mammography is mandatory.

Cardiovascular

En bloc transplantation of the heart and entire thoracic aorta

M. D'Silva, O. Achilleos, A.D. Mayer and P. McMaster,
The Liver Unit, Queen Elizabeth Hospital, Birmingham, UK

Rat cardiac and aortic transplantation have been useful tools to study rejection and tolerance. However, thus far, these techniques have been used separately as allograft models. The purpose of this study was to develop an *en bloc* 'heart–entire thoracic aorta' (H–TAO) transplant model to study immunological phenomena in both organs, in the same animal. This model was developed and based on 15 transplants in DA and Lewis (DA × Lew) rats.

The H–TAO was harvested after thoracotomy as follows: (1) division of the TAO at the diaphragm and clamping of the thoracic inferior vena cava; (2) ligature and division of the superior vena cava; (3) dissection and division of the left branch of the pulmonary artery; (4) perfusion of the heart–lungs with 4°C Ringer's solution (2–3 ml); (5) excision of the lungs; and (6) separation of the entire TAO by ligature and division of its branches. After the TAO had been flushed, the H–TAO unit was transplanted to the recipient's abdominal vessels in a conventional microsurgical manner. Before the abdominal vascular clamps were released, a vascular clamp was placed on the TAO, allowing for controlled perfusion of the heart without blood loss, by permitting ligature of hitherto unseen lumbar arteries.

Donor and recipient operations lasted for a maximum of 15 and 30 min respectively. There was no technique-related mortality. While the hearts of unmodified recipients were rejected at 6 days, the TAO did not reveal grossly the rejection features seen in the cardiac counterpart. Strikingly, the lumen of these TAOs remained free from thrombus and debris. Also noted was a shortening of the initial aortic length at the time of cardiac rejection.

Immunosuppressed recipients are under observation for the development of chronic rejection. This model will help further to define immune-mediated events occurring in the two organs in one recipient.

Ejection fraction *versus* clinical index for predicting cardiac problems after infrarenal aortic reconstruction

R.B. Galland, K. Luxton, J.A. Bell, A. Whyman and
C. Verghese, *Royal Berkshire Hospital, Reading, UK*

Following infrarenal aortic reconstruction, the cardiac morbidity and mortality rates are high. A prospective comparison of a clinical risk index and ejection fraction measurement for predicting postoperative cardiac events has been carried out.

Forty-eight consecutive patients were assessed by the Detsky modification of the Goldman risk index. Ejection fractions were also measured using both echocardiography and ^{99m}technetium. There were 31 patients with abdominal aortic aneurysms and 17 with occlusive disease. Within 30 days, three patients (6 per cent) experienced four major cardiac events (three left ventricular failures and one fatal myocardial infarction). In addition, 14 patients (29 per cent) experienced 15 minor cardiac events (11 arrhythmia and four ST segment depression). As the cardiac risk index rose, so did the likelihood of cardiac events ($P < 0{\cdot}01$, multiple regression analysis). Ejection fraction, determined by either method, failed to correlate with subsequent cardiac events.

In conclusion, the clinical cardiac risk index predicts postoperative cardiac events in patients undergoing aortic reconstruction whereas calculation of the ejection fraction is unhelpful.

Metabolic and haemodynamic determination of left ventricular function in isolated pig hearts during sustained cold chemical cardioplegia and storage

P. Helligsø, H.H. Kimose, F. Randsbæk, S.B. Hansen,
B.T. Jensen, H.E. Bøtker, J.P. Bagger and T.T. Nielsen,
Departments of Cardiovascular Surgery and Cardiology, and Institute of Experimental Clinical Research, Skejby Sygehus, University Hospital of Århus, Denmark

Left ventricular function was evaluated during sustained cold chemical cardioplegia and hypothermic storage.

Forty-eight Danish Landrace pigs, weighing 70–80 kg, were used. Seven groups of pig hearts were evaluated. Group 1 hearts excised from slaughterhouse pigs were subjected to 9 min of warm ischaemia before induction of 171 min cold chemical cardioplegia. Group 2–7 hearts were excised from pigs under general anaesthesia. After induction of intracellular-type cold chemical cardioplegia, using a single infusion, the hearts were stored hypothermically at 4°C for 30 ($n = 8$), 90 ($n = 8$), 180 ($n = 8$), 270 ($n = 7$), 360 ($n = 6$) and 1080 ($n = 3$) min in groups 2–7 respectively. Bretschneider no. 3 cardioplegic solution was used. The hearts were thereafter mounted in a modified Langendorff model and reperfused for 120 min. The reperfusion medium was a 1:1 mixture of blood and Ringer's chloride. Functional parameters measured were: contractility (+dP/dt), relaxation (−dP/dt), developed left ventricular pressure, left ventricular systolic pressure, left ventricular end-diastolic pressure, coronary blood flow, heart rate and heart work. Metabolic parameters measured were: adenosine 5'-triphosphate (ATP) and glycogen content, lactate extraction and myocardial oxygen uptake. The frequency of DC-conversion and of pacing were also determined.

The functional and metabolic recovery during the reperfusion period were the same for hearts in groups 2–5. However, the functional recovery and myocardial oxygen uptake in hearts from groups 1, 6 and 7 were significantly lower than in hearts from groups 2–5. The myocardial release of lactate from hearts in groups 1 and 7 was significantly higher during reperfusion than that from hearts in groups 2–5. The most sensitive functional parameters were +dP/dt and −dP/dt. Tissue glycogen was significantly lower in groups 4–7 than in group 2 hearts (a 70 per cent decrease in glycogen was observed after 18 h, $P < 0{\cdot}01$). Tissue glycogen declined linearly with time of ischaemia. The ATP content of group 7 hearts was significantly lower than in group 2 hearts.

In conclusion, cold chemical cardioplegia and hypothermic storage with Bretschneider's solution containing procaine is safe for periods of up to 4·5 h.

Interatrial pressure reversal measured in patients after coronary artery bypass surgery

R. Hes, B.A. Cambier, L. Missault, M. Kockx, P. Stabel and
P. Van Cauwelaert, *Middelheim Hospital, Antwerp and University Hospital, Ghent, Belgium*

Reports on patency of the open foramen ovale resulting from an increased pulmonary resistance are common. These shunts can lead to a decrease in partial pressure of oxygen, which cannot be corrected with a higher fraction of inspired oxygen. Other clinical studies stress that patients with an open foramen ovale are at risk of paradoxical emboli and decompression sickness. As it is currently believed that the foramen is functionally closed during the cardiac cycle, and that the lung can filter venous emboli, no satisfactory explanation can be found in the literature to justify the paradoxical nature of emboli through a patent foramen.

To analyse the haemodynamic basis for interatrial shunts, right and left atrial pressures were measured simultaneously after coronary artery bypass grafting in 17 patients with sinus rhythm and normal left ventricular function, using catheters placed during operation. Recordings were made both during spontaneous breathing and positive-pressure ventilation.

A cyclical pressure reversal, in which right atrial pressure exceeded left atrial pressure, was reproducibly recorded. It started a mean(s.e.m.) 215(5) ms after the onset of the electrocardiographic P wave, lasted 179(14) ms and had a maximal amplitude of 4·1(0·3) mmHg. During the expiration phase of spontaneous breathing and the inspiration phase of positive-pressure ventilation, the onset of the pressure reversal occurred later; its duration was shorter and its amplitude smaller.

These observations demonstrate the presence of a cyclical interatrial pressure reversal and show that the breathing mode affects the time course and amplitude of this reversal.

Transfusion after coronary artery bypass surgery

J. McCarthy, M. Bowen, D. Manion, M. McCarroll and E. McGovern, *Departments of Cardiac Surgery and Anaesthesia, Mater Hospital, Dublin, Ireland*

Risks associated with homologous blood transfusion are well documented. The incidence of homologous blood transfusion and the effects on

0007–1323/93/S014–02 © 1993 Butterworth-Heinemann Ltd

haematological parameters in a cardiothoracic unit where three different transfusion policies exist were investigated. In group A, patients were transfused at a haemoglobin level of $7\,g\,dl^{-1}$ or less, group B at $8\,g\,dl^{-1}$, and group C at $9\,g\,dl^{-1}$. A prospective study was made of 120 patients. Intraoperative and postoperative blood loss, preoperative haematocrit, immediate and 4-day postoperative haematocrit, and the need for fresh autologous and homologous blood transfusion were recorded. Intraoperative and postoperative blood losses were similar in all three groups. Group A had a significantly decreased incidence (6·2 per cent) of homologous blood transfusion compared with the other groups ($P < 0·01$) and group B (40 per cent) had significantly fewer transfusions than group C (75 per cent; $P < 0·01$). Despite this there was no difference in the preoperative or postoperative haematocrits between the three groups. Patients who received autologous blood transfusion but who did not require homologous blood transfusion had significantly less postoperative blood loss ($P < 0·05$) and significantly higher postoperative haematocrits ($P < 0·01$). The overall amount of blood transfused (1·08 units) was less than previously reported. However, the results suggest that the institution of a predetermined blood transfusion policy and the use of autologous blood could further reduce the incidence of homologous blood transfusion without affecting haematological parameters.

Aprotinin and thrombolytic therapy in cardiac surgery

A. Romano and G. Tundo, *Cardiochirurgia Ospedale Civico, Palermo, Italy*

Despite better testing of donors, allogenic transfusions still imply risks for patients. A case of intraoperative thrombosis of an aortocoronary saphenous vein graft on the left anterior descending artery, occurring in a patient treated with an aprotinin protocol (2×10^6 KI units in the priming volume and 5×10^5 KI units every hour of cardiopulmonary bypass) is detailed. Thrombectomy of the left anterior descending artery using a 2-Fr Fogarty catheter and revision of the anastomosis with a new segment of vein was performed. Then 1 mg recombinant tissue plasminogen activator diluted in 10 ml was injected selectively into the graft. Balloon-pump counterpulsation was used to wean off the extracorporeal circulation. The patient had an uneventful recovery and there were neither electrocardiographic signs nor cardiac enzyme modifications indicative of myocardial infarction.

It is strongly believed that this episode of thrombosis of the coronary artery was related to the use of aprotinin. The authors now use low-dose aprotinin (2×10^6 KI units in the priming volume) in patients with a high risk of perioperative bleeding.

A 10-year review of the stability of Carpentier's mitral valvuloplasty in 150 patients with mitral insufficiency

A.E. Wood, K. Subbaraeddy, J. McCarthy and J. Hurley, *Mater Hospital, Dublin, Ireland*

Mitral valve reconstruction resulting in conservation is now considered to preserve left ventricular function better than mitral valve replacement. Reconstruction techniques are complex and difficult to acquire. Over a 10-year period from 1 January 1983 to 31 December 1992, 150 mitral valve reconstructions were performed by one self-taught surgeon. All patients had dominant mitral regurgitation. There were 69 men and 81 women of mean age 62 (range 24–72) years. The aetiology of valve disease was rheumatic (72 patients), degenerative (69), endocarditis (four), ischaemic (three) and hypereosinophilia (two). Operation was performed using cardiopulmonary bypass with moderate hypothermia (28°C) and crystalloid cardioplegia throughout. Annuloplasty was performed in 148 patients using a Carpentier ring (142 patients), DeVega (three), Duran (two) and St Jude Medical (one). Fifty-two patients had some form of leaflet resection; there were 50 posterior leaflet resections. Associated procedures were performed in 47 patients: vein graft (23 patients), aortic valve replacement (12), atrial septal defect repair (five) and tricuspid valve repair (five).

The 30-day hospital mortality rate was 2·0 per cent (three patients). Isolated mitral Carpentier annuloplasty (102 patients) carried a mortality rate of 1·0 per cent (one patient). Two patients (1·3 per cent) required immediate valve replacement at first operation. Actuarial 1- and 5-year survival rates were 98·0 and 96·8 per cent respectively. Six late valve replacements (4·2 per cent) were performed, four within the first 2 years. The valve reoperation-free rate was 92 per cent at 5 years and 89 per cent at 8 years. Progression of rheumatic valve disease was the main cause (90 per cent) of late failure. Mitral reconstruction combined with prosthetic ring annuloplasty gives a stable and durable repair with a very low operative mortality and reoperation rate for valve failure. Failure is more likely to occur where there is rheumatic valve disease and is unrelated to the initial learning phase.

Colon and rectum

Diverticular disease in patients under 50 years of age

D.N. Anderson, P. Halliday, C. Driver, A.I. Davidson, Z.H. Krukowski and R.A. Keenan, *Department of Colorectal Surgery, Aberdeen Royal Infirmary, Aberdeen, UK*

Seventy-seven patients under 50 years of age were admitted with acute diverticular problems. The total number of admissions was similar for each year. The mean(s.d.) age at admission was 41·7(6·3) years and there was no significant sex difference. Some 25 per cent of patients had previously been admitted with diverticular disease.

At presentation, 79 per cent had abdominal pain, 22 per cent a change in bowel habit, 21 per cent rectal bleeding, and 30 per cent were on a high-fibre diet, but only 3 per cent had taken non-steroidal anti-inflammatory drugs. The mean(s.d.) white cell count was $11{\cdot}3(5{\cdot}4) \times 10^{9}\,\mathrm{l}^{-1}$ for the whole group, but was significantly higher in 18 patients who required surgery ($13{\cdot}7(7{\cdot}8) \times 10^{9}\,\mathrm{l}^{-1}$) than in the rest ($10{\cdot}6(4{\cdot}3) \times 10^{9}\,\mathrm{l}^{-1}$), $P < 0{\cdot}05$. Radiological assessment was by plain radiography (66 per cent), contrast enema (79 per cent), ultrasonography (29 per cent) and computed tomography (1 per cent). Colonoscopy was performed on 21 per cent of individuals. By a combination of clinical and radiological review, diagnosis was made in 98 per cent of patients.

Surgical intervention for control of the disease process was required in 23 per cent of patients; 61 per cent of these had had one or more previous admissions for an acute diverticular episode. The indications were: overwhelming peritonitis (67 per cent), bowel obstruction (11 per cent) and troublesome fistulas (17 per cent). Early postoperative mortality (30 days) was zero. The majority of patients (78 per cent) had resection of the diseased colon as Hartmann's procedure (44 per cent) or resection and primary anastomosis (34 per cent). Only 16 per cent were treated by peritoneal irrigation and drainage of the septic focus.

Diverticular disease in young people runs an aggressive course, and early surgery is advised.

Intraoperative colonic irrigation in the treatment of left-sided large bowel obstruction

J.P. Arnaud, C. Casa and V. Serra-Maudet, *Department of Visceral Surgery, CHU Angers, Angers, France*

The surgical treatment of acute left colonic obstruction continues to be controversial. Since the introduction of intraoperative colonic irrigation, resection and primary anastomosis has become an acceptable method in the treatment of obstructing lesions of the left colon. This paper reports the use of such intraoperative antegrade colonic irrigation in the management of left-sided large bowel conditions requiring emergency surgery.

During the 2-year period from 1990 to 1992, 30 consecutive patients (17 women and 13 men) with a mean age of 72·8 (range 45–89) years underwent emergency operation for obstructing lesions of the left colon. All patients were managed by intraoperative colonic irrigation. A Foley catheter was inserted into the caecum through either a caecostomy or the appendix stump; the colon was rapidly washed out with 3–5 litres of warm saline until the effluvium was clear. In all cases, a colonic resection and primary anastomosis without colostomy was performed. The site of the large bowel obstruction was sigmoid in 14, descending colon in four and rectum in two patients, and the cause of the obstruction was large bowel carcinoma in 23, diverticulitis in five and volvulus in two. There were two postoperative deaths (7 per cent): one myocardial infarction and one inhalation pneumonia. No postoperative fistula was observed. Mean hospital stay was 195 (range 9–35) days.

The results of this study suggest that intraoperative colonic irrigation is an effective method, enabling the surgeon to perform a primary anastomosis with reasonable safety after emergency resection of selected distal colonic lesions.

First impressions with the biofragmentable anastomosis ring: report of 15 cases

J.C. Bernal-Sprekelsen, F. Puchades, J. Garcia-Romero, F. Ripoll, F. Villalba and R. Trullenque, *Hopital General Universitario de Valencia, Spain*

Fifteen patients underwent large bowel resection with anastomosis using the biofragmentable anastomosis ring (BAR) between May and December 1992; eight men and seven women, with a median (range) age of 64 (22–83) years. Fourteen patients had neoplasms and one colonic angiodysplasia. Tumour location was sigmoid in seven, right colon in four, splenic flexure in one, descending colon in one and rectosigmoid in one. Preoperative antegrade intestinal lavage was carried out in 14 patients and intraoperative lavage in one patient with intestinal obstruction. Seven sigmoidectomies, four right hemicolectomies, two left hemicolectomies, one subtotal colectomy and one anterior resection were performed. Anastomosis was made with BAR size 28 in nine cases, size 31 in five cases and size 25 in one case. Postoperative ileus lasted a median of 3·7 days with expulsion of the BAR occurring a median (range) of 22 (15–28) days after operation. There were three anastomotic leaks with one death caused by the leakage.

Use of the BAR is easy and time sparing, but does not avoid complications.

Total abdominal colectomy, mucosal proctectomy and J pouch–anal anastomosis

S. Bozoklu, T. Coskun, A. Özdemir, A. Özenc and Z. Öner, *Faculty of Medicine, Department of General Surgery, University of Hacettepe, Ankara, Turkey*

Total abdominal colectomy, mucosal proctectomy and ileal J pouch–anal anastomosis is the most suitable and radical treatment of diseases that are precancerous and affect only the mucosa, such as familial adenomatous polyposis (FAP) and ulcerative colitis. Of seven patients (four male, three female, mean age 33 years), four were operated on for FAP and three for ulcerative colitis using this technique. In five patients diverting ileostomy was performed and closed between 35 and 56 (mean 46) days. Postoperative complications were one wound infection, one retrograde ejaculation and one intestinal obstruction. (Intestinal obstruction occurred in one of the two patients without ileostomy.) There was no mortality. All patients except one with retrograde ejaculation are currently well, with no disturbance of urinary or sexual function. The follow-up period was between 6 and 36 (mean 15) months. Continence of faeces was complete in all during the day and night. Average frequency of evacuation was 5–7 times in 24 h. All patients tolerated a full diet and only two used medication to reduce stool frequency.

Role of retinal and endoscopic examination, and DNA analysis in screening for familial adenomatous polyposis

W.J. Campbell, N.C. Nevin, R.A.J. Spence and T.G. Parks, *University Department of Surgery, Belfast, UK*

Increasing awareness of the genetic abnormalities and extracolonic manifestations associated with familial adenomatous polyposis (FAP) has resulted in a multidisciplinary approach to screening for the disease.

Sigmoidoscopy, retinal examination to detect congenital hypertrophy of the retinal pigment epithelium and DNA analysis have been used to adjust the risks for those people in the region born with a prior risk of 0·5. Using Bayes' theorem, risks have been increased in two individuals from 0·5 to 0·998 and reduced in a further 19 individuals to values ranging from 0·0025 to 0·000023. The use of sigmoidoscopy and DNA analysis alone achieved a significant alteration in all but one individual. In this patient, findings on retinal examination reduced the risk from 0·018 to 0·004.

Retinal examination in combination with sigmoidoscopy does not reduce risks sufficiently to alter current screening practice. However, given a favourable DNA result, linkage analysis combined with endoscopy is sufficient to alter risks to such levels that screening practice may be altered.

0007-1323/93/S016-04 © 1993 Butterworth-Heinemann Ltd

Retinal examination is advisable in families in which risks cannot be reduced sufficiently by DNA and endoscopic findings alone, but need not necessarily be performed routinely in all families carrying the FAP gene.

Closing a colostomy with the biofragmentable anastomosis ring

G. Char, J. Benichou, M. Ascorbe* and J.M. Hoang, *Department of Surgery, Hospital Avicenne, Bobigny, France and *Department of Surgery, Pamplune, Spain*

Twelve patients have been studied; all had a diverting lateral colostomy. There were five cancers of the rectum, one sigmoid injury, one ischaemic colon and five cases of sigmoid diverticulosis. Colostomy closure was performed 8 weeks after the original procedure. There was no technical problem using the recommended technique, which included good dissection and resection of the distal end on each side and application of 2/0 Maxon sutures to fix the colon on the ring on each side. Operating time was 1 h; the postoperative course was uneventful. All patients were able to leave hospital in 4 days.

Anastomotic stenosis after colorectal surgery

D. De Giorgi and G. Carrozzo, *Department of Emergency Surgery, Digestive Endoscopy Hospital, Copertino, Italy*

Stenosis arising after colorectal anastomosis is a late complication. The anatomy is uncertain, its frequency is underestimated and its pathogenesis is poorly understood. Reported is experience of the risk factors and endoscopic conservative treatments. A total of 178 colorectal anastomoses were performed from 1989 to 1992: the EEA autostapling device was used in 158 patients (48 using the Knight–Griffen technique, 36 of whom underwent emergency procedures); at follow-up two patients had a small leak, five patients a subclinical pelvic infection. Colonoscopy was performed every 6 months. In all, 71 patients were excluded (49 for pelvic recurrence and were 22 were lost to follow-up). A total of 19 anastomotic stenoses were analysed: 17 were stapled (six with the Knight–Griffen technique) and two were hand-sewn; 18 were located in the extraperitoneal side between 1 and 12 cm. Complications were as follows: anastomotic leakage in two, pelvic infection in two, irradiation in one, obesity in seven, urgent operation in four. Endoscopic treatment was accomplished (five settings on average) using a Hegar thrusting sigmoidoscope, a Foley catheter, balloon dilators, a Savary probe and a papillotomy knife. The results were satisfactory in 14 cases, adequate in three and transient or inadequate in two.

Some risk factors can be minimized by careful technique and new methods of anastomosis; dilatation, using endoscopic treatment, is the safest and easiest technique, and gives the least blood loss.

Effect of parenteral and enteral nutrition on the healing of colonic anastomoses in rats

M. Düren, Y. Bükey, O. Alver and E. Düren, *Department of Surgery, Cerrahpasa Medical Faculty, Turkey*

The effect of parenteral and enteral nutrition enriched with pectin on the healing of colonic anastomoses in rats was studied. The rate of healing was assessed by bursting pressure and hydroxyproline measurements on the fourth and tenth days after operation following a colonic transection and primary anastomosis. Rats of group 1 were given only water after operation, group 2 received parenteral dextrose and saline solution, group 3 was fed with total parenteral nutrition and group 4 with regular enteral diet. Group 5 received regular enteral diet plus pectin at a low perfusion rate, group 6 received the same diet at a higher perfusion rate (0·2 and $0{\cdot}8\,\mathrm{ml\,min^{-1}}$ respectively). On the fourth day after operation groups 4, 5 and 6 differed significantly from groups 1, 2 and 3 ($P < 0{\cdot}001$). On the tenth day after operation group 6 differed significantly from groups 1–5 ($P < 0{\cdot}001$).

The present data suggest that enteral solutions enriched with pectin perfused at a rate of $0{\cdot}8\,\mathrm{ml\,min^{-1}}$ serve to increase the absorptive surface area for enteral nutrition agents, leading to a higher rate of colonic anastomotic healing.

Emergency intestinal anastomosis in peritonitis

U. Ginanneschi, M. Rizzi, G. Fanti, L. Scevola, L. Tenze and P. Fabiani, *Semeiotica Chirurgica Ospedale di Cattinara, Trieste, Italy*

To evaluate the results of primary intestinal resection and anastomosis performed in patients presenting with peritonitis, 15 patients with a mean age of 59 (range 37–69) years have been studied retrospectively. All patients had emergency operations. Ten patients had localized peritonitis and five had generalized peritonitis that was purulent in three, faecal in one and barium peritonitis in the other. Five sigmoid resections, three ileocaecal resections, three ileal resections, two right hemicolectomies, one left hemicolectomy and one transverse colonic resection were performed. The mean total time of operation was 4 (range 2–7) h. There were no postoperative anastomotic complications. One patient with generalized faecal peritonitis caused by a ruptured caecum died on the first postoperative day from septicaemia.

Three of four patients who had major postoperative complications had generalized peritonitis. The overall mortality rate was 7 per cent and the morbidity rate 27 per cent.

We believe that primary resection and anastomosis in patients with peritonitis is a safe technique.

Hand-sewn *versus* stapled colonic anastomosis

J.S. Leite, M.G. Jorge, P. Pinto, F.A. Pontes, C.R. Oliveira and F. Castro Sousa, *Serviço de Cirurgia III, Hospital da Universidade, Coimbra, Portugal*

Conflicting results have been published concerning the advantages of hand-sewn over stapled anastomosis. This study aimed to compare mechanical, biochemical and histological parameters of healing in hand-sewn *versus* stapled anastomosis.

In 24 mongrel dogs a segment of colon was resected and randomized to undergo one-layer hand-sewn or stapled anastomosis. The largest stapler that the bowel could accommodate was used. Six animals, three from each group, were killed at 1, 4, 7 and 28 days after operation. The anastomoses were evaluated for radiological index, bursting pressure, hydroxyproline content and histological appearance. The radiological index was calculated as the ratio of the diameter of the anastomosis to that of the adjacent bowel. Data were compared using the Mann–Whitney *U* test.

	Time after operation (days)			
	1	4	7	28
Radiological index				
Hand-sewn	0·72(0·07)	0·68(0·07)	0·55(0·04)*	0·83(0·08)
Stapled	0·79(0·06)	0·69(0·04)	0·69(0·01)*	0·85(0·08)
Bursting pressure (mmHg)				
Hand-sewn	115(36)	182(12)	243(29)	383(9)
Stapled	153(40)	150(30)	192(9)	360(6)
Hydroxyproline content (µg per mg dry weight)				
Hand-sewn	7·9(1·9)	13·3(1·8)	10·5(0·3)	9·4(2·5)
Stapled	9·3(1·9)	15·2(0·8)	10·7(1·5)	14·2(1·9)

Values are mean(s.e.m.). * $P = 0{\cdot}05$

Mean(s.e.m.) hydroxyproline content in the resected colon of the hand-sewn group was $10{\cdot}3(0{\cdot}9)\,\mu\mathrm{g\,mg^{-1}}$ and $12{\cdot}3(1{\cdot}0)\,\mu\mathrm{g\,mg^{-1}}$ for those undergoing stapling. Histological examination showed no differences in the grade of epithelialization and in the extent of inflammatory reaction in both techniques. These results suggest no significant advantage for hand-sewn or stapled anastomosis concerning the risks of stenosis or leakage.

Definitive one-stage emergency management of acute uncomplicated left colonic obstruction

J.A. Paraskevopoulos, J.V. Psaila and R.J. Cuschieri, *Doncaster Royal Infirmary, Doncaster, UK*

The management and outcome of acute uncomplicated large bowel obstruction has been reviewed in a district general hospital over a 2-year period.

A total of 19 patients (11 women and eight men) with a mean age of 69 (range 41–92) years were treated under the care of two consultant surgeons. Most of the operations (n = 13) were performed by registrars. The site of the obstruction (without any perforation or peritonitis) was the splenic flexure in two, descending colon in six, sigmoid colon in eight and rectum in two. The underlying pathology included carcinoma in 17 patients, stricture due to diverticular disease and pseudo-obstruction in the remaining two patients. A variety of procedures was carried out: colonic resection/bowel lavage/primary anastomosis in 12, extended right hemicolectomy in two, Hartmann's procedure in two, palliative bypass in two and caecostomy in one. One elderly patient (80 years) died within 30 days of operation because of fulminant bronchopneumonia. There was no perioperative morbidity, including the reversal of the two Hartmann's procedures.

Routine colostomy is no longer indicated in the treatment of left-sided large bowel obstruction. It is clear that resection and primary anastomosis should be the rule, and colostomy should be reserved for exceptional circumstances.

Clinical appraisal of solitary rectal ulceration

T.G. Parks and E.J. Mackle, *University Department of Surgery, Belfast, UK*

This paper describes 89 patients with histologically proven solitary rectal ulceration. The mean age at onset of symptoms in men (n = 27) was 27 (range 13–61) years and in women (n = 62) 39 (range 15–82) years. The incidence was 3·1 new cases per million per year.

Typical symptoms included rectal bleeding in 92 per cent, passage of mucus (91 per cent), tenesmus (73 per cent), constipation (54 per cent), abdominal discomfort (64 per cent) and rectal discomfort (44 per cent). Attempts at defaecation averaged 3·3 times per day; 64 per cent of patients resorted to digitation to aid evacuation. Complete rectal prolapse featured in 25 per cent, intussusception to the anal verge in 14 per cent, occult rectal prolapse in 14 per cent and anterior mucosal prolapse in 20 per cent. Ulcers were solitary in 37 per cent and multiple in 20 per cent. Hyperaemic granular mucosa was demonstrated in 34 per cent and polypoid lesions in 9 per cent. The pathological lesions were situated between 4 and 14 cm (mean 7·6 cm) from the anal verge. Mean perineal descent on straining as recorded by perineometer was 2·7 (range 0·75–6·0) cm. Difficulty with balloon expulsion from the rectum was noted in 65 per cent.

Advice regarding symptomatic management and reassurance helped many patients. Two-thirds of patients benefited from a high-fibre diet. Abdominal rectopexy gave good results in patients with coexisting complete rectal prolapse but was less effective for mid-rectal intussusception.

Comparison between different faecal occult blood tests in neoplastic and inflammatory diseases of large bowel

C. Ratto, F. Forni*, L. Sofo, P. Nucera, M. Ippoliti, M. Bossola, R. Bellantone, G.B. Doglietto and F. Crucitti, *First Clinica Chirurgica and *Chimica Clinica, Catholic University, Rome, Italy*

The preliminary results of a study in progress comparing three different faecal occult blood tests in patients with neoplastic or inflammatory bowel diseases or without any intestinal disease are presented.

A total of 65 patients with the following diagnoses entered the study: cancer (32), benign neoplasms (seven) chronic inflammatory diseases of the large bowel (seven), and control individuals (19). The patient's history and clinicopathological data were collected on admission. The diagnosis was confirmed by histological examination of colorectal tissue samples taken endoscopically or from the surgical specimen. After a meat-free diet for 3 days, three faecal samples were collected, frozen at −80°C and analysed by three different faecal occult blood tests: guaiac test (test on guaiac-impregnated paper); anti-Hb test (immunological test with monoclonal antihuman-Hb antibodies); and anti-Hb+anti-Tf test (immunological test with monoclonal antihuman-Hb and antihuman-transferrin antibodies). The sensitivity, specificity and predictive values of the three tests used were calculated.

In patients with cancer, the sensitivity rate was lower in the guaiac test than the anti-Hb or anti-Hb+anti-Tf tests; a high rate of false-negative results was observed in the guaiac test (40·6 per cent) as well as in the anti-Hb (21·9 per cent) and anti-Hb+anti-Tf (25 per cent) tests. In tumours staged early (within the muscle layer in six cases) the sensitivity was low (guaiac test 33·3 per cent; anti-Hb test 66·7 per cent; anti-Hb+anti-Tf test 50 per cent); in advanced tumours (beyond the muscle layer in 26 cases) the sensitivity was higher (guaiac test 65·4 per cent; anti-Hb test 80·8 per cent; anti-Hb+anti-Tf test 80·8 per cent), but gave a large number of misdiagnosed neoplasms (guaiac test, nine cases; anti-Hb test, five cases; anti-Hb+anti-Tf test, five cases). In patients with polyps and inflammatory disease, the sensitivity was very low in all three tests; in the control group, false-positive results were detected in only one, two and two cases by the guaiac, anti-Hb and anti-Hb+anti-Tf tests respectively. The specificity was high for all tests (guaiac test, 4·7 per cent; anti-Hb test, 89·5 per cent; anti-Hb+anti-Tf test, 89·5 per cent). The predictive value for overall disease was 95·8, 93·9, and 93·5 per cent for the guaiac test, anti-Hb test and anti-Hb+anti-Tf tests respectively. However, it was higher in the tumour group than in the polyp or inflammatory disease groups.

The large number of false-negative results in patients with tumour, polyps and inflammatory disease decreased the sensitivity for all tests used in the present study, particularly for tumours staged early. However, the specificity and predictive values of the tests were very high. The higher costs of the anti-Hb and anti-Hb+anti-Tf tests (six times more expensive) in comparison with the guaiac test suggest that, despite its limited sensitivity, the guaiac test is likely to remain the test of choice for mass screening because of its good specificity for tumours.

Skin-stapled colonic anastomosis: a workshop study

C. Royle, *Chemical and Biological Defence Establishment, Salisbury, UK*

The use of disposable skin staples for intestinal anastomosis was first described by Fackler during the Vietnam War. Animal studies have proved the technique to be fast and effective for small bowel anastomosis. If skin-stapled colonic anastomosis can be shown to be suitable for use under arduous battlefield conditions it would allow military surgeons to determine whether there are any indications for primary colonic repair in war.

A craft workshop study has been devised to determine the level of surgical skill required to perform an effective skin-stapled colonic anastomosis, having been introduced to the technique for the first time. This video presentation is the standardized teaching method of the craft workshop study. After a short introduction the author performs an unedited skin-stapled anastomosis on pig colon.

Preliminary results (n = 44) suggest skin-stapled colonic anastomosis is easily mastered by surgeons of all grades.

Ulcerative colitis: prospective surveillance and flow cytometric DNA analysis in an unselected population

J. Rutegård, B. Jonsson, L. Åhsgren, L.-O. Andersson and R. Stenling, *Departments of Surgery and Medicine, Örnsköldsvik Hospital and Departments of Surgery and Pathology, Umeå University, Sweden*

Between 1977 and 31 December 1991, 135 patients (of whom 57 had had total colitis for >10 years) were followed by clinical surveillance including colonoscopy with biopsies. DNA analysis was performed from 1984. A total of 38 patients left the study: nine died (one had colitis, one colonic carcinoma), 15 left because of radical operation and 14 for other reasons. Some 631 colonoscopies were performed. Four patients had colorectal carcinoma diagnosed. High-grade dysplasia was detected in five patients. Only two of these underwent operation because of dysplasia. Flow cytometric DNA analysis was performed in 102 patients with colitis for >6 years. DNA status was aneuploid in 17 patients, of whom 16 had total colitis. The results were reproducible at consecutive examinations and correlated well with dysplasia.

The risk of cancer or high-grade dysplasia was low, but surveillance was no guarantee against cancer or cancer death. Few operations were performed for imminent cancer, and the cost–benefit of the programme must be questioned. However, the follow-up provided reassurance and continuity, and gave possibilities to assess new cancer-predictive markers. DNA aneuploidy correlated well with other cancer risk factors, but its independent value as a cancer predictor remains to be established.

Ileal pouch–anal anastomosis for ulcerative colitis and familial adenomatous polyposis: requirement for endoanal mucosectomy

Cl. Soravia, A. Kartheuser, J. Haot, T. Ayala, R. Detry,
P. Hoang, R. Fiasse, R. Vanheuverzwijn and P.T. Kestens,
St-Luc Hospital, UCL, Brussels, Belgium

Restorative proctocolectomy with ileal pouch–anal anastomosis (IPAA) is now an established surgical procedure for ulcerative colitis (UC) and familial adenomatous polyposis (FAP). However, whether to preserve the anal mucosa to enhance continence remains controversial. The aims of this study were to assess the clinical outcome after IPAA with mucosectomy for UC or FAP and to characterize the histology of the stripped anorectal mucosa.

From June 1986 to November 1992, 28 patients underwent IPAA with mucosectomy, 16 for UC (group 1) (nine men and seven women, mean age 30 years) and 12 for FAP (group 2) (eight men and four women, mean age 27 years). There were no intraoperative complications in group 1, but mucosectomy was difficult in ten patients and anastomosis performed under some degree of tension in ten. In group 2, there was a direct injury of the internal sphincter by a posterior tear during mucosal stripping in one case. Mucosectomy was easy to perform in eight patients and ten anastomoses were performed under tension. There were no postoperative complications directly related to the mucosectomy or anastomosis in either group.

Functional results were good, with normal continence in 80 per cent of patients with UC and 92 per cent of those with FAP. Histological examination of sections of the stripped anal mucosa in group 1 showed chronic active UC in eight patients, chronic non-active UC in four and quiescent UC in four. There was only one case of mild dysplasia in a patient with a Dukes' A carcinoma of the large bowel. In group 2, the anal mucosa showed micropolyps in all cases with mild dysplasia in three and moderate dysplasia in nine.

In conclusion, a careful mucosectomy does not affect the surgical outcome and functional results. Since removal of the diseased tissue is more complete, the anal mucosa should always be removed down to the level of the dentate line in restorative proctocolectomy for UC or FAP.

Colorectal cancer

Colorectal cancer in under 45-year-olds: prognostic factors and survival

J.S. Bagley, S.D. Heys, A. Sherif, C. Smart, J. Brittenden and O. Eremin, *Aberdeen Royal Infirmary, Aberdeen, UK*

Over 1800 patients die each year in the Grampian region from colorectal cancer, 3 per cent of whom are in the under-45 years age group.

The records of 92 patients under 45 years with colorectal cancer were reviewed from the period 1970 to 1990. Ninety-one patients (44 men and 47 women) presenting with 35 rectal and 56 colonic tumours were evaluated. They were staged using tumour node metastasis (TNM), Dukes' and Jass classifications, and examined with reference to disease-free survival and overall survival. Formalin-fixed wax-embedded material (tumour and regional nodes) was examined microscopically for evidence of perineural, intramural and extramural vascular invasion. Univariate and multivariate Cox multiple hazard statistical analyses were performed to determine risk factors.

The overall 5-year and 10-year survival for all groups was 61 and 59 per cent respectively. Dukes' stage provided the best single measure of risk in all three outcome groups, outperforming the Jass classification (exponential coefficient (EC) 2·95, $P < 0\cdot0001$ Duke's *versus* EC 2·14, $P < 0\cdot0001$ Jass). Mucinous tumours were significantly more likely to recur locally (EC 4·92, $P = 0\cdot03$). M, N and presence of perineural tumour invasion were independently predictive of metastatic recurrence while T, N, M and extramural vascular invasion were predictive of overall survival. There was no evidence that requirement for emergency surgery influenced survival.

Few studies have provided detailed analysis of colorectal cancer in the under-45 group and these data furnish useful information on the risk factors and prognosis in this important subgroup.

Combined multimodality treatment of primary or recurrent locally advanced rectal cancer

R. Bellantone, M. Bossola, C. Ratto, D. Borzomati, M. Ippoliti, P. Nucera, G.B. Doglietto, L. Sofo and F. Crucitti, *First Clinica Chirurgica, Catholic University, Rome, Italy*

After surgery alone, locally advanced rectal cancer has a poor prognosis as the extent of local disease makes it impossible to perform a resection without leaving gross or microscopic residual disease. From January 1990, ten patients with primary (group 1, five cases) or recurrent (group 2, five cases) locally advanced rectal cancer, without evidence of distant metastases, underwent combined multimodality treatment of preoperative chemoradiotherapy (FUMIR; 24 Gy × 2), surgical resection, intraoperative radiotherapy (IORT) and postoperative chemotherapy (FUL × 9).

Surgery consisted of anterior resection in two patients, abdomino-perineal resection in seven, and resection of the recurrence *en bloc* with coccyx and sacrum (S4–S5 vertebrae) in one. IORT fields encompassed tumour bed (nine) or microscopic residual disease (one). Areas irradiated were the sacrum (five) or the sacrum and the lateral pelvis wall (five). The most frequently used cone sizes were 5 and 6·5 cm. IORT doses were 10 Gy (eight) and 15 Gy (two).

There were no postoperative mortalities or major complications. Two wound infections occurred. In group 1 after a mean follow-up of 10 (range 2–19) months all patients are alive and disease-free. In group 2 two patients are alive with lung metastases (without evidence of local failure) at 34 and 24 months; three patients are alive and disease free (at 24, 12 and 2 months respectively).

IORT, combined with external radiotherapy, in primary and locally recurrent advanced rectal cancer appears safe, tolerable and may result in good local control of disease.

Growth pattern of colorectal cancer: comparison of *in vitro* and *in vivo* carcinoembryonic antigen expression

J.-M. Calmes, L. Suardet* and J.-Cl. Givel, *Service de Chirurgie, CHUV Lausanne, Switzerland and * Laboratory of Radiobiology, Harvard School of Public Health, Boston, Massachusetts, USA*

Carcinoembryonic antigen (CEA) has been used for monitoring early recurrence of colorectal cancer; however, it is not known whether sequential CEA determination may be a reliable indicator of tumour growth.

A cancer cell line (FA-18) of a hepatic metastasis was established from a 43-year-old woman who, 24 months earlier, underwent right hemicolectomy followed by 5-fluorouracil plus levamisole chemotherapy for Dukes' B cancer of the caecum. Clinical follow-up and CEA blood level tests were performed every 45 days until hepatic metastases were detected. The cancer cell line was maintained in standard culture conditions and growth curves (t_2 44 h, clonogenicity 0·6 per cent) were carried out for 15 days. Every 2 days, cells were counted and the CEA level determined in concomitant supernatant by the same method used for blood samples. *In vivo* and *in vitro* CEA levels and cell counts were plotted as ln (x) graphs. The slope of linear regression and the coefficient of correlation (R^2) were established for each graph using Statview 512^+ software. The slope of linear regression of the FA-18 growth curve and concomitant CEA expression curve were 0·3 and 0·4 respectively. The R^2 values of linear regression were >0·95. CEA blood level regression was linear with R^2 0·99 and slope 0·012.

Both cell growth and CEA expression curves of the FA-18 cell line were exponential and near parallel according to their regression slope and R^2 values. The CEA blood level curve was also exponential but the slope reduced compared with *in vitro* measurements. These results from a single tumour are of interest and merit investigation in larger series.

Oncoscint-Cyt 103 is helpful in the localization of primary and secondary colorectal carcinoma

N.P.J. Cripps and R.F. Dale, *Royal Navy Hospital Haslar, Gosport, UK*

Oncoscint-Cyt 103 is an indium-111-labelled radiopharmaceutical agent employing the immunoglobulin G murine monoclonal antibody B72.3 raised against the TAG-72 antigen expressed on 95 per cent of colorectal cancer cells. Experience is reported with the first 20 scans of patients who were screened after the diagnosis of colorectal carcinoma was made, who were scanned because of a high suspicion of the disease or who were scanned in follow-up after treatment of colorectal cancer. Analysis of results indicates that the method has a sensitivity of 69 per cent with a specificity of 86 per cent (mixed primary and secondary disease). The scan is useful even when the TAG-72 antigen is not measured and other tumour markers can be assayed to select patients for scanning. Primary tumours of each Dukes' stage can be detected. Whole-body scans can be acquired without increasing radiation dose, which may be helpful in selecting patients for re-resection (by excluding extra-abdominal disease). Although experience with the scan is at an early stage, the potential for detection of disease is shown. In particular, the scan may be helpful in detection of disease in the pelvis, where diagnosis by conventional techniques has been problematical.

Excision of rectal tumours using transanal endoscopic microsurgery

F. Curran, M. Brett and M.J. Hershman, *Royal Liverpool University Hospital, Liverpool, UK*

Upper rectal tumours are traditionally excised by low anterior, presacral or trans-sphincteric resection. Transanal endoscopic microsurgery (TEM) is a minimally invasive technique utilizing three-dimensional optics and an operating proctoscope. Insufflation, irrigation and suction are provided by an endosurgical unit connected to ports in the proctoscope. Either full-thickness or submucosal resection can be performed using a high-frequency knife. The wound is then sutured with silver clips instead of knots. Seven patients (two men, five women) have so far undergone TEM for upper rectal tumours. The mean age of the patients was 67 years and the mean distance of the tumour from the anal margin 12 cm. Of the tumours, six were tubular villous adenomas and one was a carcinoma (T_1). All were completely excised with a mean resection margin of 0·75 cm. The median diameter of the lesions was 3·2 cm. The mean operating time was 80 min and the mean postoperative hospital stay 4 days. These data suggest that TEM provides a safe, minimally invasive alternative technique for the treatment of upper rectal tumours.

Interleukin 2 therapy of colorectal carcinoma: prediction of response and survival

O. Eremin*, W.G. Simpson†, J. Broom*, P.H. Whiting* and S.D. Heys, *Departments of *Clinical Biochemistry and †Surgery, Aberdeen Royal Hospitals NHS Trust, Aberdeen, UK*

The response and natural history of 24 patients with metastatic colorectal cancer was studied following treatment with recombinant interleukin 2 (rIL-2). rIL-2 was given by continuous intravenous infusion (750 kIU m^{-2} h^{-1} for 120 h), followed by injections of 5-fluorouracil (600 mg m^{-2}) and leucovorin (folinic acid; 25 mg m^{-2}) at weekly intervals for 3 weeks. Patients were stratified by the basal serum levels of acute-phase proteins (C-reactive protein (CRP), α_1-antitrypsin, retinol-binding protein (RBP), transferrin (TF), albumin) and tumour markers (carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA 19-9)). Numbers of responders *versus* non-responders and of those surviving more than *versus* less than 1 year were compared by Fisher's exact test (two-tailed). Failure of response to treatment occurred when CRP was < 10 mg l^{-1} ($P < 0\cdot0003$), albumin < 37 g l^{-1} ($P < 0\cdot01$) and CEA > 30 ng ml^{-1} ($P < 0\cdot003$). Reduced survival (< 1 year) following treatment occurred when CRP was > 10 mg l^{-1} ($P < 0\cdot05$), α_1-antitrypsin > 2·2 g l^{-1} ($P < 0\cdot005$), albumin < 37 g l^{-1} ($P < 0\cdot01$) and CEA > 30 ng ml^{-1} ($P < 0\cdot05$).

These results suggest that abnormal acute phase and tumour markers before treatment are associated with a low response rate and poorer overall survival.

Primary squamous cell carcinoma of the colon and rectum: report of two cases

L. Frikart, H. Tevaearai*, J. Preitner* and J.-Cl. Givel, *Service de Chirurgie, CHUV, Lausanne and *Service de Chirurgie, Hôpital Régional, Monthey, Switzerland*

Squamous cell carcinoma represents the most frequent malignant tumour of the anal canal but accounts for only about 0·1 per cent of all primary malignancies of the colon and rectum. To date, only 72 squamous cell or adenosquamous carcinomas have been reported at this site. Over the past 15 years, the authors have observed two patients with this condition. Neither had had a previous cancer. In one patient the tumour was localized in the ascending colon with simultaneous hepatic metastases. The patient underwent right hemicolectomy followed by chemotherapy, but died 5 months later from hepatic failure. In the second patient the tumour was localized in the rectum without evidence of metastases. This patient was operated on recently and is currently undergoing radiotherapy. The diagnosis of primary squamous cell carcinoma of the colon and rectum is valid if another primary site or continuity with the stratum germinativum epidermidis (Malpighii) have been excluded. The prognosis compared with colorectal adenocarcinoma appears to be worse.

Low-dose preoperative radiotherapy for rectal cancer: a prospective randomized trial

P.A. Goldberg, R.J. Nicholls, J.E. Grimsey and N.H. Porter for the Rectal Cancer Group (Imperial Cancer Research Fund), *St Mark's Hospital, London, UK*

A prospective randomized trial of preoperative radiotherapy (three 50 cGy fractions over 5 days) followed by surgery (group 1) within 2 days *versus* surgery alone (group 2) was carried out in patients with rectal cancer 12 cm from the anal verge. A total of 27 surgeons from 15 centres in England entered patients who were followed to death or for a minimum of 5 years. Local recurrence was documented.

Of the 478 patients randomized between 1980 and 1984, 468 (mean age 66 (range 31–94) years, 273 men, 195 women) met the entry criteria (group 1, 228; group 2, 239). Of the 410 (group 1, 196; group 2, 214) who had all the primary disease excised, 310 (group 1, 154; group 2, 156) had curative operations. In all, 31 patients (7 per cent) died in the perioperative period (group 1, 21 (9 per cent); group 2, ten (4 per cent); $P < 0\cdot05$). Cardiovascular and thromboembolic complications were more common in group 1 (group 1, 30 *versus* group 2, eight; $P < 0\cdot005$). Of the patients who had curative operations, 157 (50 per cent) (group 1, 76 (49 per cent) *versus* group 2, 80 (51 per cent); P not significant) survived 5 years. Local treatment failure was documented at follow-up in 82 patients (group 1, 31 *versus* group 2, 51; log rank test $\chi^2 = 4\cdot37$, $P < 0\cdot05$). After curative resections, 70 patients developed recurrent disease that in 33 was due to local treatment failure (group 1, 11 *versus* group 2, 22; log rank $\chi^2 = 3\cdot59$, $P = 0\cdot058$).

Low-dose preoperative radiotherapy did not influence 5-year survival but resulted in a decrease in local treatment failure, and an increase in perioperative morbidity and mortality rates.

Accuracy of endosonography in the staging of rectal cancer before and after preoperative radiotherapy

G. Houvenaeghel, J.R. Delpero, M. Giovannini, P. Orsoni, J.F. Seitz, R. Rosello, M. Resbeut, G. Monges and G. Guerinel, *Institut J. Paoli-I. Calmettes, Marseille, France*

Between January 1988 and August 1992, 55 patients with rectal cancer were evaluated by clinical staging and endorectal sonography before (52 patients) and after (50) preoperative radiotherapy. Two criteria were correlated with histological findings: confinement to the rectal wall or spread beyond and uT stage; and the presence of mesorectal lymph node involvement.

The 52 patients who underwent endorectal sonography before radiotherapy were staged as uT$_2$ (seven patients), uT$_3$ (41) and uT$_4$ (four). At 15 days after irradiation, endorectal sonography showed a regression of the tumour in all patients; the uT stage was different in 19 patients and the uN stage was different in ten. Comparison of the preoperative and postoperative sonographic assessment of local invasion beyond the rectal wall with postoperative histopathology revealed a correlation with endorectal sonography before irradiation in 31 of the 52 staged tumours (60 per cent), and with sonography after irradiation in 34 of the 50 staged tumours (68 per cent). The presence of mesorectal lymph node involvement determined by histological examination correlated with the results of endorectal sonography after radiotherapy for 33 of the 49 staged tumours (67 per cent).

Endorectal sonography provides a good assessment of tumour stage before irradiation. Radiotherapy altered endosonographic staging of rectal cancer and downstaging occurred in 22 per cent of patients.

Carcinoma of the rectum: role of mesorectectomy in the early postoperative course

D. Kecmanovi, D. Stevovic, Z. Krivokapic, D. Askovic, P. Bulajic and P. Kovacevic, *University Clinical Centre, Clinic for Digestive Surgery, Belgrade, Serbia*

A total of 573 patients with rectal carcinoma were operated on from January 1985 to December 1991. The age range was 17–86 years. There were 42 per cent women and 58 per cent men. Mesorectectomy was performed in 376 patients. There were no statistically significant differences in age, sex and tumour characteristics between groups of patients that did or did not undergo mesorectectomy. Mesorectectomy did not extend the operating time or cause greater perioperative blood loss. The postoperative specific morbidity rate in patients who underwent mesorectectomy was 6·7 per cent (25 patients). The most frequent complication was postoperative fistula, which affected 15 (4·0 per cent) patients. Seven (1·9 per cent) patients had peritonitis, one testicular necrosis, one sepsis and one postoperative bleeding. The postoperative non-specific morbidity rate was 4·5 per cent (17 patients). Nine patients had urinary infection and five myocardial infarction; testicular necrosis, sepsis, postoperative bleeding, stroke and pulmonary embolism were seen as single complications. The mortality rate was 4·3 per cent. The mean hospital stay was 20·2 (median 18) days. There were no statistically significant differences in mortality, morbidity and hospital stay between the groups of patients that did or did not undergo mesorectectomy. It is concluded that operative procedures that include mesorectectomy do not have negative effects on the early postoperative course.

Venous invasion in colorectal carcinoma

M. Moutinho-Ribeiro and M. Sobrinho-Simões, *Faculty of Medicine, Porto, Portugal*

The presence of venous invasion in colorectal carcinoma is known to be associated with poor survival. In an attempt to clarify the mechanisms underlying this prognostic influence a systematic study was undertaken of venous invasion in 294 cases of colorectal carcinoma of a series of 353 cases submitted for resection from 1960 to 1991. Venous invasion was detected in the histological sections of 212 cases (72·1 per cent) using haematoxylin–eosin and orcein stain for elastic tissues. A significant association of venous invasion was found with right colon localization ($P = 0{\cdot}026$), ulcerative and/or infiltrative growth ($P = 0{\cdot}007$), poor differentiation ($P = 0{\cdot}0001$), lymphatic permeation ($P = 0{\cdot}001$) and stage C of Dukes' classification ($P = 0{\cdot}0001$). Preoperative carcinoembryonic antigen levels were found to be significantly higher in patients with carcinoma displaying venous invasion. No correlation was observed between the presence of venous invasion and sex or age of patients, intestinal obstruction and size of tumours.

It is concluded that the prognostic influence of venous invasion cannot be properly evaluated without taking into consideration the other biological parameters that are closely associated with the aggressiveness of neoplastic cells.

Cancer of the sigmoid colon and rectum: stapling techniques for anastomosis below the peritoneal reflection

A. Navarro-Pomares, R. González-Cajigal, A. Badia, A. Payno, R. Banet and C.M. González-Bueno, *Fundación Jiménez Diaz, Universidad Autónoma de Madrid, Spain*

Two stapling techniques used in colorectal surgery were compared. Anastomosis was perfomed in all cases below the peritoneal reflection.

A total of 31 patients suffering from cancer of the rectum or sigmoid colon were operated on in the past 18 months. Some surgeons perfomed the anastomosis by means of circular stapling (CS) and others selected the Roticulator (R) plus CS. Because of an obstructing tumour or a narrow pelvis, defunctioning colostomy was performed in some cases.

	CS (n = 12)	R plus CS (n = 19)
Mean(s.d.) age (years)	70·4(5·5)	67·7(12·6)
Mean(s.d.) hospital stay (days)	12·2(4·0)	12·1(5·0)
Rectum	9 (75)	15 (79)
Sigmoid colon	3 (25)	6 (32)
Dukes' stage		
A	3 (25)	4 (21)
B	4 (33)	7 (37)
C	4 (33)	8 (42)
'D'	1 (8)	0 (0)
Distance*		
<1 cm	0 (0)	2 (11)
1–2 cm	3 (25)	5 (26)
>2 cm	9 (75)	12 (63)
Lateral colostomy	3 (25)	6 (32)
Infection	1 (8)	1 (5)
Leak	0 (0)	1 (5)
Mortality	0 (0)	0 (0)

Values in parentheses are percentages. *Distance from tumour to resection line. *P* not significant for all parameters

In conclusion, both techniques are safe and have similar postoperative results. The distance between the tumour and line of resection was similar with the CS or CS plus Roticulator technique.

Audit of rectal cancer surgery: outcome in a defined population over 23 years

E. Nilsson, *Motala Hospital, Motala, Sweden*

All patients with carcinoma of the rectum or rectosigmoid junction who at the time of diagnosis lived within the catchment area of Motala hospital (87 000 inhabitants) were studied. Data were checked with the population register and the regional cancer register. Data of patient history, operation, histopathology and follow-up were collected retrospectively from 1 January 1970 to 31 December 1983, and prospectively thereafter. Actuarial methods were used for calculation of crude mortality rate, mortality rate with cancer (systemic and/or local) and mortality rate with local recurrence. Nine patients received preoperative radiotherapy within the framework of a nationwide controlled study. Since January 1990 all patients with low and mid-rectal tumours were treated by total mesorectal excision (TME).

Between 1970 and 1989, 332 patients were treated, 216 (65 per cent) with curative intent. Of those patients who underwent abdominal tumour resection, 21 per cent had anterior resection (AR) in the period 1970–1979, and 51 per cent in the period 1980–1989. For curative resections the mortality rate from generalized cancer after 5 and 10 years was 41 per cent and 50 per cent, respectively, and mortality rate from local recurrence was 33 per cent and 41 per cent. There was no difference in mortality rates between the two decades. Inadvertent opening of the rectum during the operation doubled the local recurrence rate. From 1 January 1990 to 31 December 1992, 46 patients were treated, 33 with curative intent. Of 33 patients with abdominal tumour resection, 24 underwent AR. Three curatively treated patients have died with manifestations of cancer, two with cerebral metastases and one with a local recurrence.

In conclusion, these results show that local recurrence rate during the pre-TME period (1970–1989) was high. Initial results with TME are promising. Audit is necessary for rectal cancer surgery.

Risk factors for local recurrence after radical surgery for rectal carcinoma: a prospective multicentre study

J. Norstein, A. Bergan and F. Langmark*, *Department of Surgery B, Rikshospitalet and *The Norwegian Cancer Registry, Oslo, Norway*

Local recurrence after radical surgery for rectal carcinoma is highly debilitating and, in most cases, fatal. Recurrence rates vary widely in published studies. To identify risk factors for local recurrence in an unselected population and to evaluate methods for identification of local recurrence at a resectable stage, a multicentre prospective study comprising 41 Norwegian hospitals was arranged by The Norwegian Cancer Registry.

During a 2-year period ending in August 1988, 284 patients aged less than 75 years with radically resected rectal carcinoma were entered into the study. Patients were followed at 3-monthly intervals for 2 years, and later at 6-monthly intervals. Follow-up included clinical examination, ultrasonography of the liver, and determination of serum levels of carcinoembryonic antigen. At predetermined intervals patients were examined by colonoscopy and chest radiography.

At a median observation time of 60 (range 48–72) months, complete data were available on 275 patients. Local recurrence was diagnosed in 81 patients (29 per cent), including 69 with no evidence of distant metastases. Radical re-resections were performed in 26 patients (38 per cent) without distant spread. Possible risk factors for local recurrence were studied in a multivariate analysis (logistic regression): age, sex, Dukes' stage, type of hospital (local, district, university), tumour distance from the anal verge, divided in three groups (lower, 0–5 cm; middle, 5–10 cm; upper, ≥11 cm), and resection method (local excision, abdominoperineal resection (APR), anterior resection). Only distance from the anal verge ($P = 0{\cdot}02$) and resection method ($P < 0{\cdot}02$) were significant risk factors for local recurrence. Tumours in the middle and lower part of the rectum recurred more frequently (middle, 32 of 86, 37 per cent; lower, 25 of 81, 31 per cent) than in the upper rectum (23 of 108, 21 per cent), irrespective of Dukes' stage. When compared with tumours removed by local resection, cancers treated with anterior resection had fewer recurrences (odds ratio 0·52 (95 per cent confidence interval 0·35–0·76)). APR carried the lowest risk of recurrence (odds ratio 0·36 (95 per cent confidence interval 0·25–0·52)).

A high local recurrence rate in the lower two-thirds of the rectum, irrespective of tumour stage, may indicate that technical factors related to the surgical procedure are more important than tumour stage.

Patterns of recurrence following surgery for carcinoma of the colon and rectum

E. Pellicer, P. Parrilla, J. Aguilar, B. Andrés, S. Ortiz and J.M. Ruiz, *Department of Surgery, Hospital Virgen de la Arrixaca, El Palmar, Murcia, Spain*

Factors influencing recurrence in colorectal cancer remain under debate. To investigate which factors were related to locoregional or distant recurrence of colorectal carcinoma, a series of 408 patients with colorectal carcinoma who underwent surgical resection for cure between 1979 and 1988 was studied. The median (range) follow-up period was 7·6 (4–14) years. Recurrence was diagnosed by clinical, radiological, endoscopic and/or histological features in 186 patients (45·6 per cent), while 222 (54·4 per cent) remained free from disease at the end of the follow-up period. Locoregional recurrence was seen in 137 patients (33·6 per cent of the global series), and distant recurrence in 99 patients (24·3 per cent). Fifty patients showed both types of recurrence simultaneously.

The following factors were found to be statistically related to locoregional recurrence: rectal location, level of invasion of the intestinal wall, lymph node involvement and blood transfusion. Distant recurrence was related to complete circumferential involvement of the colonic wall, level of invasion of the intestinal wall, lymph node involvement and blood transfusion. Age, sex, tumour size, duration of symptoms, surgical technique in the left colon (segmented colectomy *versus* standard hemicolectomy) and in the rectum (anterior resection *versus* Miles' operation), and surgical margins in rectal cancer had no influence on patterns of recurrence.

Multivariant analysis of prognostic factors in colorectal carcinoma: an approach to a new prognostic classification

E. Pellicer, P. Parrilla, J. Aguilar, B. Andrés, S. Ortiz and J.M. Ruiz, *Departamento de Cirugía, Hospital Virgen de la Arrixaca, El Palmar, Murcia, Spain*

Dukes' classification is of widespread use in the prognostic evaluation of patients with colorectal cancer. Nevertheless this classification has some limitations, basically when classifying just a small group of patients as 'good prognosis'.

Factors influencing survival were studied in a series of 410 patients who underwent surgical resection for cure from a global group of 689 patients with colorectal cancer treated from 1979 to 1988. Analysis was by means of a multivariate Cox regression model using 14 clinical, analytical and histological variables. It was found that localization of the tumour, presence of obstruction or perforation, level of invasion of intestinal wall, lymphatic involvement, grade of cellular differentiation and timing of blood transfusion were statistically related to prognosis.

With these variables a classification into three groups with different prognoses could be established: group 1 ($n = 135$), 5-year survival rate 84 per cent; group 2 ($n = 124$), 5-year survival rate 50 per cent; and group 3 ($n = 151$), 5-year survival rate 20 per cent.

In a second phase of the study, this classification was used prospectively in a series of 70 patients who underwent surgical treatment of colorectal cancer in 1989 (follow-up 4 years) and showed a good correlation between expected and actual prognosis. From these results, it is believed that a more accurate prognosis can be made in surgically treated colorectal carcinoma by considering variables other than those used in Dukes' classification alone.

Results of extended resection for colonic cancer adherent to other organs

J. Pimentel, L. Silveira, J. Botelho, J.P. Soares and L.J. Raposo, *Hospitais da Universidade de Coimbra, Coimbra, Portugal*

Carcinoma of the colon can occasionally adhere to other organs. In this situation it has been policy, whenever possible, to perform an extended resection with curative intent. The aims of this study were to evaluate whether this surgical procedure is justified, in terms of the postoperative morbidity and mortality rates.

From 1985 to 1990, 172 patients with colonic cancer were operated on. The mean age was 62 (range 38–82) years. In 38 patients (22 per cent) the tumour was adherent to other organs; of these, 23 were treated by an extended *en bloc* resection with curative intent, the other 15 undergoing palliative surgery. The postoperative morbidity and mortality rates in the *en bloc* resection group were 30 per cent (seven cases) and 9 per cent (two cases) respectively. The 5-year survival rate was 28 per cent; the mean survival of the palliative group was 7 months. Results of this study suggest that colonic cancer involving adjacent structures should not preclude a surgical procedure with curative intent.

Effect of essential fatty acids on natural cytotoxicity in patients with colorectal cancer

P. Purasiri, J. Ashby, S.D. Heys and O. Eremin, *University Medical School, Aberdeen, UK*

Essential fatty acids (EFAs) have been shown to modulate lymphocyte reactivity and destroy tumour cells *in vitro*. Natural cytotoxicity, mediated by natural killer (NK) and lymphokine-activated killer (LAK) cells, is believed to have an important anticancer role *in vivo*. The effect of EFAs, given orally, on NK and LAK cell activity in patients with both localized (seven cases) and advanced (11) colorectal cancer, was studied.

Activity of effector cells was expressed as lytic units, using *in vitro* ^{51}Cr release assays: NK (K562), LAK (DAUDI). NK cell activity was unchanged after 15 days' treatment with EFAs in both groups, but was significantly reduced after 1 ($P < 0{\cdot}05$) and 2 ($P < 0{\cdot}01$) months' supplementation (advanced group). LAK cell responses showed no alteration after 15 days' treatment with EFAs (both groups) but the cytolytic activity on prolonged intake (1 and 2 months) showed an overall reduction (not statistically significant). Cell surface marker analysis revealed reduced absolute numbers of CD16$^+$ and CD57$^+$ lymphocytes in the localized group. Prolonged supplementation with high doses of EFAs may have detrimental effects on natural cytotoxic mechanisms.

Modulation of cytokine production by dietary essential fatty acids in patients with colorectal cancer

P. Purasiri, A. Murray, S. Richardson, S.D. Heys and O. Eremin, *University Medical School, Aberdeen, UK*

Cytokines play a key role in the inter-relationships between nutrition, host defences and diseases. The effects of the essential fatty acids (EFAs) γ-linolenic acid (GLA), eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), 4·8 g day^{-1}, given in combination as dietary supplementation, on cytokine production was investigated in patients with colorectal cancer. Total levels of serum cytokines – interleukins (IL-1β, IL-2, IL-4, IL-6), tumour necrosis factor (TNF) α and interferon-γ (IFN-γ) – were analysed using the enzyme-linked immunosorbent assay (ELISA) technique at different time intervals during the course of treatment.

Fatty acid uptake and patient compliance were confirmed by a significant increase in levels of GLA, EPA and DHA in all the three fractions (triglyceride, cholesterol and phospholipid). There was no significant alteration of total serum cytokine production in the first 2 months of EFA ingestion in both the localized and advanced groups, but the levels of serum cytokines steadily declined after 2 months and continued to fall, reaching minimum levels at 6 months, after EFA supplementation. EFAs at the doses used in this study reduced total IL-1β synthesis by 61 per cent ($P = 0{\cdot}044$), IL-2 by 63 per cent ($P = 0{\cdot}05$), IL-4 by 69 per cent ($P = 0{\cdot}025$), IL-6 by 83 per cent ($P = 0{\cdot}03$), TNF-α by 73 per cent ($P = 0{\cdot}04$) and IFN-γ by 67 per cent ($P = 0{\cdot}05$).

The present study has shown that long term n-3 and n-6 EFA treatment reduced cytokine production. Although their induced reduction may have beneficial anti-inflammatory effects, the suppression of IL-1β, IL-2 and IFN-γ production may not be desirable in malignant disease.

Variation in receptor status between primary colorectal cancer and liver metastases

J.-P. Puts, G. Verhoeven and J.A. Gruwez, *Catholic University Hospitals, Leuven, Belgium*

Measurement of oestrogen receptor (ER) and progesterone receptor (PR) levels in the cytosol fraction of tumour homogenates is a routine procedure in evaluation of breast cancer treatment. The receptor status of primary colorectal cancer has also been investigated. However, there is no information on changes in receptor level and status during the clinical course of colorectal cancer. A prospective follow-up study was carried out including 61 patients over a 3-year period, to detect any influence of hormonal status on prognosis and metastatic pattern of colorectal cancer. ER and PR levels were measured in 60 colorectal cancers, giving mean(s.e.m.) values of 12·5(24·9) and 0·7(3·6) fmol per mg protein respectively. Of the colorectal cancers 60 per cent are ER-positive and 5 per cent are PR-positive. Fifteen liver metastases were also resected or biopsied during the study. ER and PR levels were measured, giving respectively a mean(s.e.m.) value of 21(19) and 202(221) fmol per mg protein. Of the metastases 73 per cent are ER-positive and 80 per cent are PR-positive. The statistical significance is low for ER ($P < 0{\cdot}10$) but very high for PR level and status ($P < 10^{-7}$), when comparing colorectal cancer and metastases. For comparison, the ER and PR levels in liver metastases of colorectal cancer are respectively 17 and 172 per cent of the levels found in primary breast cancer treated during the same period of time. The presence of PR in liver metastases of colorectal cancer and not in primary colorectal cancer may be a marker of the clone of cancer cells that are able to produce metastatic deposits in the liver. It may also be induced by an autocrine or paracrine effect between the metastatic cells ('seed') and the liver ('soil'). It is suggested that there should be a European trial with adjuvant hormonal manipulation of PR in patients with colorectal cancer.

Management of colorectal cancer

I. Rodriguez, J. Lombardia, E. Morales, C. Ugena and J. Vera, *Garcia Hospital 'Virgen de la Salud', Toledo, Spain*

From January 1985 to December 1990, 591 patients underwent operation for colorectal cancer. There were 325 men and 266 women. The average age was 70 (range 33–93) years. The more important symptoms were abdominal pain (35 per cent) and diarrhoea (30 per cent). Diagnosis used blood (carcinoembryonic antigen) and urine analysis, enema and colonoscopy with biopsy. The rectum is the commonest site of these tumours (212). Elective surgery was performed in 458 patients. Preoperative preparations included oral solutions (polyethylene glycol), enemas, antibiotics and anticoagulation prophylaxis. In emergency surgery on 133 patients, antibiotics and, in 35 cases, anterograde lavage were employed. Mechanical sutures were used in more than 90 per cent of anastomoses.

Resection was performed in 537 patients, with anastomoses in 389 cases, and without in 148. The techniques used most often were anterior resection (155 patients), right hemicolectomy (90), sigmoidectomy (88) and Hartmann's (84). Overall, 188 patients had postoperative complications, with the majority after emergency surgery. Local complications were more frequent than general, with wound abscess (88 patients) and anastomotic leak (36). Reoperation was performed in 35 patients, in ten cases for leakage. The mortality rate was 35 patients, 24 after emergency surgery.

Sequential anterior–posterior resection with coloanal anastomosis for distal rectal tumours

W.E.W. Roediger, *University of Adelaide, Adelaide, South Australia*

Sequential anterior–posterior resection of the rectum was developed: (1) for resection of tumours in the distal third of the rectum and; (2) to improve in-continuity resection of perirectal fat in its inferior and lateral extent into which spread of tumour may occur.

Between 1988 and 1992, 15 patients were selected for operation. Preoperative evaluation included endoscopy, computed tomography of the pelvis and carcinoembryonic antigen evaluation. Initial low anterior dissection was followed by a posterior transcoccygeal (Kocher) approach to the distal rectum. Transection of the external but not the internal anal sphincter aided dissection in the intersphincteric plane and tissues circumferentially to the rectum. The intact internal sphincter facilitated the creation of a coloanal anastomosis.

Twelve patients had carcinoma of the rectum and three giant or recurrent villous adenoma. Two patients had tumour recurrence at 6 and 14 months that required abdominoperineal resection. Two other patients had terminal pulmonary metastases but no liver or local recurrence. Two patients developed strictures which responded to dilatation. All patients are continent with 0–5 motions per day. Eleven patients who would otherwise have had an abdominoperineal resection are now well without a colostomy.

It is concluded that the operation is an appropriate treatment in certain cases of tumour of the distal rectum and avoids a permanent colostomy.

Role of conservative treatment for low rectal cancer

G. Romano, G. Rotondano, M. Santangelo, C. Sassaroli and P. Giordano, *Department of General Surgery and Transplants, University of Naples School of Medicine, Naples, Italy*

Transanal excision of low rectal cancer has long been reserved for patients unfit for major surgery. The development of preoperative diagnostic tools such as endorectal ultrasonography, which provides a precise assessment of depth of the intramural invasion of the tumour, together with the progress of pelvic and endocavitary radiotherapy, which allows a good local control of the residual disease, has recently changed the indications for conservative treatment of low rectal cancer.

From 1987 to 1990, eight patients with non-high-grade invasive rectal cancer were treated by full-thickness transanal excision as a curative procedure. Three patients had T_1 and five had T_2 cancers (four T_{2a} and one T_{2b}, i.e. infiltrating the muscularis propria). T_1 cancers were only excised, whereas T_2 cancers were treated by local excision and radiotherapy. Resection margins were disease-free. Mean follow-up was 2 years. All patients are alive with no sign of local recurrence.

Low, well or moderately well differentiated tumours, with no distant spread, extending no deeper than superficial layers of muscularis propria can be managed conservatively, providing that strict endoscopic and endosonographic postoperative surveillance is undertaken. Radiotherapy for T_1 cancers is still debated.

Conservative treatment by local excision and radiotherapy might have a role in the treatment of T_1 and T_2 low rectal cancer.

Monoclonal antibody imaging in surgical management of colorectal carcinoma

T. Rubeš, V. Hlaváčková, Z. Procházková, J. Faltýn, J. Masopust and K. Michalová, *Departments of Surgery and Nuclear Medicine, 3rd Medical Faculty, Charles University and Department of Nuclear Medicine, Hospital 'Na Homolce', Prague, Czech Republic*

Experience with the introduction of a new diagnostic method in oncosurgery is presented. Immunoscintigraphic use of radiolabelled monoclonal antibodies specifically targets tumour-associated antigens and seeks recurrent foci, metastases and primary tumours of colorectal carcinoma, facilitating their detection.

A commercial kit containing monoclonal antibodies radiolabelled with technetium-99 and indium-111 was used. Scintigrams were obtained by planar or single photon emission computed tomography scanning at two time intervals after administration of the radiolabelled drug. Since 1991, 50 immunoscintigraphic examinations of patients with colorectal carcinoma undergoing surgery were performed. The sensitivity attained was 84 per cent.

Immunoscintigraphy is a valuable complementary examination; it is a safe, non-invasive test that can be used for detection and presurgical staging of colorectal carcinoma and may play a significant role in follow-up in oncosurgery.

Intra-arterial chemotherapy for colorectal liver metastases using a totally implantable pump

G. Samori, C. Beati, A. Ferrandi, G. Pancera*, R. Labianca*, M. Altieri and P. Tozzi, *Departments of Surgery and *Oncology, San Carlo Hospital, Milan, Italy*

Intra-arterial chemotherapy shows significantly higher response rates than systemic chemotherapy, but the impact on survival and extrahepatic disease is unclear. In this trial, the possibility of increasing the response rate in patients with irresectable liver metastases but no extrahepatic disease was analysed. Patients were treated with intra-arterial floxuridine

0·25 mg kg^{-1} over 14 days via a totally implanted infusion pump with the addition of systemic folinic acid (100 mg m^{-2} day^{-1} over 4 days) and 5-fluorouracil (5-FU) 400 mg m^{-2} day^{-1} over 4 days. There were no postoperative complications. Fifteen of 18 patients have been evaluated; the median extent of liver involvement was 30 per cent. A complete response was achieved in seven patients, a partial response in three and no change in four. The overall response rate was thus 66 per cent; 57 per cent of patients are alive at 2 years. Thirteen of 17 patients developed chemically reversible hepatitis and four diarrhoea; there was neither biliary sclerosis nor gastric ulcer. Patient acceptance was excellent. These preliminary data suggest that a combination of intra-arterial floxuridine via an implanted pump and systemic 5-FU and folinic acid may reduce extrahepatic progressive disease without unacceptable toxicity.

Preoperative and postoperative penile rigidity in patients suffering from colorectal neoplasia

M.S. Saviano, A. Carriero, E. Ricchi, R. Lonardi and A.R.M. Granata*, **Department of Endocrinology and Institute of Surgical Pathology, Modena, Italy*

Nocturnal penile tumescence and rigidity monitoring (NPTRM) is currently used to study patients who complain of sexual dysfunction. NPTRM is performed by computerized devices and helps to differentiate between organic and psychogenic impotence. This technique has been used to study 51 patients who underwent operation for colorectal cancer. NPTRM was performed for 2 consecutive nights before and after the surgical treatment. All subjects who complained of postsurgical sexual dysfunction underwent a multidisciplinary evaluation that included a sexual questionnaire. NPTRM, real-time monitoring of penile response to intracavernous injection of 20 µg prostaglandin E_1 and both vascular functional and neurological studies were undertaken. All these parameters were studied to determine whether NPTRM is a useful method of distinguishing postsurgical psychogenic impotence from that of post-operative organic causes.

Epidemiological and clinical considerations on right colonic cancer

G. Zografos, A. Papachristodoulou, C. Fotiades, M. Safioleas, V. Papadimas, J. Gogas and M. Sechas, *Athens University, Laikon Hospital, Greece*

This retrospective study included 389 consecutive patients treated at this institution from 1983 to 1991. Of these, 81 patients had right colonic cancer: 36 (44 per cent) men and 45 (56 per cent) women, mean age (range) 67·6 (35–92) years. Right hemicolectomy and ileotransverse anastomosis was performed in almost all patients, whereas palliative bypass was performed in only one. Simultaneous cholecystectomy was performed in 13 cases (16 per cent). Operative mortality rate was 5 per cent. Clinical anastomotic leakage occurred in two patients (2 per cent). Patients treated as emergencies had similar morbidity and mortality rates to elective cases. The mean hospital stay was 10 days. Right colonic cancer had a higher incidence in women (55 per cent) than left colonic (47 per cent) or rectal (47 per cent) cancer. The incidence of right colonic cancer was greater in this series (1983–1991) (26·2 per cent) than in 1968–1982 (21·7 per cent). Coexistence of gallstones was noticed in only 4 per cent of patients with sigmoid and rectal cancer. Further epidemiological studies could document any trends in age, sex and anatomical distribution of colonic cancer.

Duodenum and small bowel

Indications for the Roux-en-Y jejunal loop in intestinal surgery

N. Angelescu, N. Jitea, T. Burcos, D. Cristian, A. Juncu and V. Vidu, *Coltea Hospital, Bucharest, Romania*

This study aims to present the advantages of diversion or reconstruction using a Y loop in digestive and biliary surgery. A series is reported of 33 patients (20 men and 13 women, aged 27–80 years), operated on during the past 9 years. A Y jejunal loop was used in 19 patients for the following indications: conversion of anastomosis in patients with gastroduodenal or gastrojejunal anastomotic fistula (three cases); after gastric resection in patients with duodenal ulcer and duodenal diverticula (three); after exclusion of a postbulbar bleeding ulcer with *in situ* haemostasis (one); after excision of ulcer with precarious duodenal closure (three); closure of high-flow duodenal fistula (two); in patients with penetrating, bleeding duodenal ulcers with isolation of the papilla and bile duct after duodenal closure (two); for biliary obstruction by carcinoma of the liver and bile duct (two); and in complex biliodigestive fistula (three).

The advantages of this method include avoidance of reflux and stasis in afferent loops due to intestinal peristalsis, and preservation of a good anastomosis due to rich jejunal vascularization.

The results were good, with only one death after surgery in a patient with postoperative pancreatitis.

In conclusion, it is considered that the Roux-en-Y jejunal loop has a role in preventing some postoperative complications of gastroduodenal surgery.

Captopril increases endothelin release after small intestine ischaemia–reperfusion injury in the rat

O. Büyükgebiz, A.Ö. Aktan, C. Yeğen, S. Yalçin, S. Ercan and R. Yalin, *Marmara University Hospital, Istanbul, Turkey*

Captopril, unlike other angiotensin-converting enzyme (ACE) inhibitors, contains a sulphydryl group and can act as a free radical scavenger. Iloprost (ZK 36374) is a synthetic analogue of prostacyclin. This study was undertaken to investigate the effects of iloprost and captopril on small intestinal ischaemia–reperfusion injury in the rat. Experimental groups consisted of sham ($n = 6$), control ($n = 7$), iloprost ($n = 7$), captopril ($n = 8$), and captopril plus iloprost ($n = 8$). Superior mesenteric occlusion for 30 min was followed by 90 min reperfusion; portal venous blood was obtained for endothelin assay and ileal tissue samples were obtained for malonyldialdehyde (MDA), PGE_2 and leukotriene C_4 (LTC_4) determinations. MDA levels were reduced in rats receiving iloprost, captopril or both, indicating the inhibition of lipid peroxidation. Endothelin levels increased in the control group and this increase was reversed with iloprost. In the captopril group, endothelin levels were significantly increased and this was not reversed with the addition of iloprost ($t = 44·4$, $P = 0·000001$ and $t = 46·7$, $P = 0·000001$). LTC_4 levels were unchanged and PGE_2 levels were significantly reduced in the iloprost group. This study reveals that captopril increases the release of endothelin after small intestinal ischaemia–reperfusion injury and that this increase is unrelated to the arachidonic acid cascade.

Skin stapler intestinal anastomosis: a safe and efficient method in humans

I. Fraser, *Warwick Hospital, Warwick, UK*

A reliable method of anastomosis of human intestine using an economical skin stapling gun has been used in 22 humans with various pathological conditions. The method is learned quickly and easily, is efficient in time (less than 10 min) and is inexpensive (£10).

Twenty-two patients with conditions including intestinal obstruction, neoplasia, chronic inflammatory disease, soiling and sepsis have demonstrated no contraindication to the method after resection of the diseased bowel. There have been no complications. Gross discrepancy in bowel size and contracted bowel in patients with epidural anaesthesia militate against the method.

This simple method now applied to human disease may be transferrable to laparoscopic intraperitoneal intestinal anastomosis.

Primary adenocarcinoma of the small intestine: 80 cases

French Association for Surgical Research and A. Fingerhut, M. Veyrieres, J.-M. Hay and H. Levard, *Bois Colombes, France*

Primary adenocarcinoma of the small intestine is rare, occurring in 0·5–5 per 1000 tumours of the intestinal tract. During the past 10 years 80 patients from 72 institutions have been studied retrospectively to analyse diagnostic, pathological and prognostic data. Intestinal obstruction was the single most common presentation (50 per cent of patients), followed by declining general health (45 per cent), abdominal pain (43 per cent), and anaemia (41 per cent). Nearly 33 per cent of patients were operated on as an emergency; 16 per cent of tumours were discovered only at exploratory laparotomy. Loss of weight, pain and anaemia were more common when the tumour was located in the proximal intestine. Intestinal obstruction was more common when the tumour was ileal.

Barium follow-through was the essential preoperative diagnostic tool, being positive in 82 per cent of patients. Some 92 per cent patients had a single tumour, 11 per cent had metastatic deposits and nearly 20 per cent had spread to adjacent organs at the time of surgery. The resectability rate of the tumours was 95 per cent; colonic resection was necessary in one-fifth of cases.

Operative mortality and morbidity rates were 13 and 33 per cent, respectively. Mortality and morbidity rates were significantly higher ($P < 0·01$) when the tumour was ileal and operated on as an emergency. Serosal involvement (80 per cent), lymph node involvement (52 per cent), and undifferentiated tumours (40 per cent) were associated with a poorer prognosis (P not significant). Villous adenoma (one case), colonic polyps (five), Crohn's disease (three) and carcinoma (ten) were associated in 15 per cent of patients. The overall cumulative survival rate was 35 per cent at 5 years. The survival rate was >50 per cent in the absence of serosal or lymph node involvement.

In conclusion, the prognosis in primary adenocarcinoma of the small intestine is not always poor. The essential need is to improve diagnostic awareness and to perform a barium follow-through examination in patients with undiagnosed gastrointestinal symptoms.

Surgery for primary neoplasia of the small intestine

C. Kelm, W. Padberg, T. Zimmermann and J. Stahl, *Klinik für Allgemein und Thoraxchirurgie, JLU Gießen, Gießen, Germany*

In a retrospective analysis, 25 patients with malignant small bowel tumour were studied. There were nine patients with carcinoid tumour, seven with leiomyosarcoma, seven with adenocarcinoma, one with malignant schwannoma and one with lymphoma. Definitive diagnoses were made by ultrasonography and contrast study of the gastrointestinal tract. Nevertheless, months or even years elapsed before diagnosis was established. In only 14 patients could curative resection be accomplished. In the remaining patients, hepatic metastases were found or the tumour could not be resected further because of its size. In six patients, adjuvant regional intra-arterial chemotherapy of the liver was carried out. The mean survival time for the whole patient group was 19 months. Patients who had undergone complete resection of the tumour had a significantly longer survival time (mean 25 months) than patients who had undergone a palliative operative procedure (mean 14 months). The mean survival time for patients with leiomyosarcoma was 38 months, adenocarcinoma 14 months and carcinoid tumours 22 months. Because of difficulties in establishing the diagnosis, a tumour of the small intestine should be considered in any patient complaining of abdominal pain.

Effect of somatostatin on experimental intestinal obstruction and tumour necrosis factor

J.I. Landa, M. Grau, K. Llanos, J.A Sanchez, J. Alcalde, I. De Gaspar and J.L. Balibrea, *Centro de Ivestigación, Universitario Complutense, Madrid, Spain*

Intestinal obstruction is a very common surgical problem with a high morbidity and mortality. Recently, clinical improvement and histological changes of intestinal mucosa have been reported with intravenous

0007–1323/93/S026–02 © 1993 Butterworth-Heinemann Ltd

perfusion of somatostatin-14. The objective of this work is to establish whether histological changes obtained with somatostatin are correlated with changes in the intraluminal production of tumour necrosis factor (TNF).

Thirty Wistar rats of mean(s.d.) weight 340(15) g were used. In each, a 10-cm closed-loop obstruction was created with ligatures in the ileum for 24 h. Half of the animals were infused with intravenous physiological serum ($0{\cdot}1\ \mathrm{ml\,h^{-1}}$) for 24 h (PS), the other group with somatostatin $2\ \mathrm{ng\,h^{-1}}$ and every rat was killed for histological study (presence or absence of inflammatory infiltrate, haemorrhage and mucosal necrosis), and measurement of TNF in intraluminal liquid between ligatures (mouse TNF ELISA kit). The histological results were expressed with a score (0, normal; 3, maximal) and TNF values as mean(s.d.) and were analysed with a statistical test.

The microscopic pathological scores from closed-loop segments in PS rats were 2·6(0·2) *versus* 0·4(0·2) in somatostatin rats ($P<0{\cdot}05$). The values of TNF were 407·2(49·98) in PS *versus* 147·4(50·31) in somatostatin rats ($P<0{\cdot}001$). In this model, somatostatin gives less histological intestinal damage and decreases TNF values inside the intestinal loop.

Foreign material in postoperative adhesions in man

R.W. Luijendijk, C.C.A.P. Wauters*, M.H.J. Voormolen, W.C.J. Hop† and J. Jeekel, *Departments of General Surgery, *Pathology and †Biostatistics, University Hospital Rotterdam–Dijkzigt, Rotterdam, The Netherlands*

Postoperative adhesion formation is potentiated by the introduction of foreign materials, as is proved by animal experiments. Such adhesions often contain foreign body granulomas. Since little is known about this in humans, a study of 119 patients scheduled for relaparotomy was performed. The presence, distribution and quality of adhesions was scored during the operative period, and adhesion samples were taken for microscopic examination.

Adhesions were present in 94 per cent of the patients. Most frequently these were attached to small bowel (89 per cent) and omentum (83 per cent), followed by abdominal wall (66 per cent), colon (55 per cent), liver (53 per cent), stomach (33 per cent), female reproductive organs (19 per cent), retroperitoneum (15 per cent) and spleen (14 per cent). Significantly fewer adhesions were found in patients with a history of only one minor operation, compared with those with one major or multiple laparotomies ($P<0{\cdot}05$). Foreign body granulomas were found in 22 per cent of patients. These were caused by suture (16 per cent), starch glove powder (3 per cent) or a combination of the two (3 per cent). When granulomas were present, the median interval between the present and most recent laparotomy was 4 months. When granulomas were absent, this interval was significantly longer ($P = 0{\cdot}001$, Mann–Whitney test), namely 36 months. In other words, foreign body granulomas were more often found in patients recently operated on. For instance, in patients operated on no longer than 6 months before, granulomas were present in 71 per cent. In patients who had had a laparotomy performed more than 6 months before, granulomas were present in 13 per cent.

In conclusion, following laparotomy adhesion formation nearly always occurs. In recent adhesions foreign body granulomas occur in large percentages. This strongly suggests that the intra-abdominal presence of foreign material is an important cause of adhesion formation. Intra-abdominal contamination with suture and glove powder should therefore be avoided.

Prognostic factors in villous tumours of the duodenum

D. Pezet, N. Rotman, J. Chipponi and P.L. Fagniez, *CHU Clermont Fd and Hôpital Mondor Creteil, France*

A multicentre, retrospective study to evaluate the prognostic factors influencing survival of patients with villous tumours of the duodenum was carried out by the French Surgical Associations from November 1974 to January 1991. There were 20 women and 18 men (mean(s.d.) age 60(11·5) (range 38–81) years). Associated diseases were cancer of the gastrointestinal tract ($n = 4$), duodenal ulcer ($n = 3$), polyposis coli ($n = 1$) and Gardner's syndrome ($n = 1$). Symptoms were epigastric pain ($n = 17$), jaundice ($n = 12$), vomiting ($n = 9$), diarrhoea ($n = 8$), acute gastrointestinal haemorrhage ($n = 3$) and ten patients were symptom-free. Cholestasis was diagnosed in 13 patients and anaemia in four.

Gastrointestinal barium series ($n = 32$) had a sensitivity of 84 per cent and endoscopy ($n = 35$) a sensitivity of 100 per cent for the diagnosis of villous tumours. The location of the villous tumours was in the first part of the duodenum in two patients, the second part in 31, third part in three and fourth part in one. Survival curves were established according to Kaplan–Meier and compared with the log rank test. The median follow-up was 75 months.

Treatment involved limited resection of the duodenal wall ($n = 15$), a pancreatoduodenectomy ($n = 12$), limited resection with reconstruction of the biliary and pancreatic ducts ($n = 6$) and a palliative procedure in five patients. The histological data were: villous ($n = 18$), tubulovillous ($n = 7$) and villous tumours with a malignant component ($n = 10$). The sensitivity and specificity of preoperative biopsy to detect a malignant component in villous tumours was 50 per cent.

Overall survival rate was 81·2 per cent at 2 years and 47·4 per cent at 5 years. Survival and recurrence rates were not affected by the existence of a malignant component to' the villous tumours. Limited resection and reconstruction of the biliary and pancreatic ducts was associated with a statistically higher recurrence and mortality rate, compared with the two other curative treatments ($P < 0{\cdot}05$).

This series shows that limited resection of villous tumours located near the papilla of Vater carries a high risk of recurrence. It seems necessary to perform pancreatoduodenectomy.

Statistics concerning 80 cases of Meckel's diverticulum

P. Tătaru, M. Aronescu, R. Popescu, V. Ion, M. Carpen and Th. Drăgan, *Departmental Hospital, Buzău, Romania*

Eighty patients with Meckel's diverticulum seen over a 40-year period are reported.

In this series, the incidence of finding Meckel's diverticulum was 2 per cent of the total number of patients undergoing laparotomy, the highest incidence being in patients who were less than 20 years of age (48 cases) or more than 50 years old (13 cases).

Clinical diagnosis is rather difficult. Meckel's diverticulum may produce haemorrhage, inflammation, and obstruction in children and young adults. Alternatively, it may present as obstruction of the small intestine in a patient with fever but who had had a previous appendicectomy. In the present series Meckel's diverticulum caused inflammation in 38 patients, obstruction in 23, and haemorrhage in three.

The surgical treatment was removal of Meckel's diverticulum by local excision in 55 patients or by segmental resection of the small intestine in 34; two deaths occurred.

Effects of the somatostatin analogue octreotide in experimental small bowel obstruction

S. Yamaner, T. Bulut, Y. Büyükuncu, D. Bugra, A. Akyuz and N. Söküců, *Department of Surgery, Istanbul Medical School, Istanbul, Turkey*

Two groups of 20 Wistar rats were subjected to total obstruction of the jejunum. Octreotide administration $0{\cdot}35\ \mu\mathrm{g\,kg^{-1}}$ twice daily was instituted in the first group and saline in the second (control) group. Some 2 days later, all rats underwent operation for measurement of diameter of the bowel, determination of luminal loss of sodium and potassium, and for resection and anastomosis of the obstruction. At intervals, the animals were killed and bursting pressures, tissue hydroxyproline levels and histopathological evaluation of the anastomoses carried out. Distension of the ligated bowel was found to be significantly lower in the first group (0·74 *versus* 1·05 mm; $P < 0{\cdot}05$). The luminal losses of sodium and potassium were 0·03 *versus* $0{\cdot}06\ \mathrm{mmol\,ml^{-1}}$ and 0·0016 *versus* $0{\cdot}0024\ \mathrm{mmol\,ml^{-1}}$ ($P < 0{\cdot}01$). Anastomotic bursting pressures were significantly higher in the first group on the seventh day ($P < 0{\cdot}05$). Tissue hydroxyproline concentration showed no significant difference, but ischaemic changes were significantly less in the first group ($P < 0{\cdot}05$). It has been concluded that octreotide administration after small bowel obstruction enhances the distension of bowel, the loss of intraluminal water, sodium and potassium, and ischaemic changes in the bowel wall.

Endocrine

Subtotal thyroidectomy in euthyroid and hyperthyroid goitre

G. Balbo, B. Lasagna, P. De Paolis and A. Resegotti, *Department of Surgery B, S. Giovanni Hospital, Turin, Italy*

A series of 268 patients operated on for euthyroid and hyperthyroid goitre over 10 years is reported. In the first 7 years unilateral subtotal lobectomy (USL) was performed if the contralateral lobe was normal and bilateral subtotal thyroidectomy (BST) if the goitre was bilateral; in the last 3 years BST was performed electively in every case. Patients were discharged without hormone replacement, thyroid function was assessed at 2 months and thyroid hormone was given only in cases of subclinical or clinical hypothyroidism.

The recurrence rate (three of 135; 2·2 per cent) and complication rate (four of 135; 3·0 per cent) were low; thus, total thyroidectomy for benign goitre is not warranted. As recurrence rates are higher after USL than after BST (two of 36 *versus* one of 99), and USL reduces but does not abolish subclinical hypothyroidism (seven of 36), BST is now considered to be the method of choice.

Surgery for secondary hyperparathyroidism

R. Casadei, L. D'Alessandro, M. Taffurelli, S. Lumia, A. Leone, A. Ceccarini and D. Marrano, *Istituto di 1° Clinica Chirurgica Generale dell'Università di Bologna, Italy*

A series of 231 patients with hyperparathyroidism is reported. In all, 78 cases of primary hyperparathyroidism, 137 cases of secondary hyperparathyroidism with chronic renal failure and 16 cases of tertiary hyperparathyroidism were treated between 1975 and 1992. In secondary hyperparathyroidism two forms of therapy were prevalent: subtotal parathyroidectomy and total parathyroidectomy with autotransplantation.

Subtotal parathyroidectomy, which was performed in 35 cases (25·5 per cent), must leave adequate vascularization of the residual hemiparathyroid. Total parathyroidectomy was performed in 102 cases (74·5 per cent). A parathyroid implant into a muscular pouch of the forearm is required. The implant consists of thin slices of parathyroid that have been sectioned under the microscope so that they are more adequately nourished and, therefore, more functional. The results obtained, compared with the literature, show that there are no radical differences between these two methods: recurrence of hyperparathyroidism is 7·4 per cent for subtotal parathyroidectomy and 4 per cent for total parathyroidectomy with autotransplantation; persistent hypoparathyroidism is present in 3·7 per cent *versus* 4 per cent.

The authors concluded that subtotal or total parathyroidectomy with autotransplantation are both good methods if correctly performed; total parathyroidectomy with autotransplantation has been performed more frequently because it permits an easier follow-up of patients and, in cases of recurrent hyperparathyroidism, an easier resection of the hyperplastic parathyroid of the forearm.

Primary hyperparathyroidism: experience with 59 patients undergoing operation

K. Gellert, J. Rudolph, T. Benhidjeb and K. Ridwelski, *Surgical Clinic (Charité), Berlin, Germany*

Fifty-nine patients (44 women, 15 men) underwent surgery for primary hyperparathyroidism (pHPT) at the authors' institution between 1981 and 1991. The main diagnostic indications were nephrolithiasis in 59 per cent and skeletal complaints in 12 per cent. The most common complaints of the patients were related to the gastrointestinal tract (46 per cent) and the skeleton (39 per cent). Three patients had no symptoms.

The most useful diagnostic procedures were ultrasonography and computed tomography with a sensitivity of 40 and 20 per cent respectively. Histological examination of the parathyroid gland tissue showed adenoma in 68 per cent, hyperplasia in 29 per cent and carcinoma in 4 per cent. Forty-three patients were followed at a mean of 58·8 months. The success rate of the primary operation was 70 per cent. Persistence and recurrence of pHPT was observed in 16 and 12 per cent respectively. A high recurrence rate of 75 per cent was seen in patients with MEN I syndrome (four cases). The success rate in patients with adenoma (79 per cent) was higher than that in patients with hyperplasia (50 per cent). The two patients with carcinoma both showed normal calcium levels after 17 and 125 months. Permanent hypoparathyroidism was observed in only one patient.

Subtotal thyroidectomy for Graves' disease: a review of 100 cases

E.M. Gemar Antúnez, *Snat Quirze del Vallés, Barcelona, Spain*

The use of radioiodine for definitive treatment of Graves' disease has been increasing. However, there is a high incidence of hypothyroidism which requires a long-term follow-up, even in euthyroid patients. Surgery also has a high incidence of hypothyroidism, but this usually occurs early after thyroidectomy. Experience has been reviewed in the surgical treatment of 100 patients diagnosed with Graves' disease.

A group of 16 men and 84 women, mean(s.d.) age 31·9(11·8) years, diagnosed as having Graves' disease underwent subtotal thyroidectomy because of recurrence of hyperthyroidism after 1 year of antithyroid drug therapy or resistance to medical treatment. Patients were divided into three groups according to goitre size (1, only palpable; 2, visible; 3, very large). Surgical outcome was analysed to define a better-prognosis group. Statistical evaluation was with Student's *t* test.

Two patients (2 per cent) became hypoparathyroid, one of group 1 and one of group 2. They both require treatment with calcitriol. Five patients remained hyperthyroid after surgery and were treated with radioiodine (three of group 2 and two of group 3). They all thereafter became hypothyroid. Of the 95 successfully treated patients, 55 (58 per cent) became hypothyroid (thyroid-stimulating hormone level $> 5\ \text{mU ml}^{-1}$) at 12 months after surgery. The incidence of hypothyroidism is 73 per cent for group 1, 61 per cent for group 2 and 37 per cent for group 3.

When euthyroid and hypothyroid patients were compared, they showed significantly different mean(s.d.) goitre weights (60·9(28·7) g for hypothyroid and 81·5(44·7) g for euthyroid, P = 0·007).

Surgery is an effective treatment for hyperthyroid Graves' disease. A lower thyroid weight is associated with a higher incidence of postsurgical hypothyroidism. In patients with a larger goitre, subtotal thyroidectomy should be considered as a treatment of choice, as hypothyroidism is much less frequent.

Thyroid cancer: a study of 250 case reports

A. Granado-Tiagonce and A. Granado, *Modesto Lafuente, Madrid, Spain*

Although thyroid cancer represents only 25 new cases per million population per year and has a mortality rate of 10–15 cases per million population per year, it is of clinical significance. A total of 250 case reports of patients with thyroid cancer were studied: patients were predominantly women (n = 215), with a mean (range) age of 44 (12–81) years. The tumour was located in the right lobe of the gland in 43 per cent of cases. Pathological distribution was papillary in 131, anaplastic in 13, follicular in 76, medullary in eight, and in Hürthle cells in 22 cases.

Total thyroidectomy was performed in 47 per cent of patients and hemithyroidectomy in 43 per cent. The morbidity and mortality rates were 12·4 and 4·5 per cent respectively.

Thyroid cancer was found to be more frequent in women, except when there was an intrathoracic location. Papillary cancer appeared in younger patients, while anaplastic pathology was more prevalent in older patients. Hyperthyroidism and multinodularity did not result in a lower risk of thyroid cancer. Of these patients, 78 per cent had a cold nodule on scintigraphy, but hot nodules were also seen. Metastasis was more frequent in the follicular type and recurrence was more frequent in patients with Hürthle cell tumours.

0007–1323/93/S028–04 © 1993 Butterworth-Heinemann Ltd

Hürthle cell adenoma of the thyroid gland

S. Guadagni, A. Agnifili, G. Carducci, E. Mancini, M. Marino, P. Gola, F. Gianfelice, R. Verzaro, G. Turco, I. Ibi, D. Ranalletta, D. Centi, M. Di Renzo, A. Sawaid and G. De Bernardinis, *Department of Surgery, University of L'Aquila, L'Aquila, Italy*

Hürthle cell neoplasms of the thyroid gland are uncommon but potentially lethal lesions whose treatment is controversial because of a lack of information about their biological and clinical behaviour. Based on histological criteria Hürthle cell tumours cannot always be accurately divided into benign and malignant. Unexpected late recurrences of an adenoma previously labelled as benign have been reported.

From a total of 502 primary thyroid epithelial tumours (1981–1991), after accurate analysis 35 (6·9 per cent) Hürthle cell adenomas were found. The selection of cases was made by evaluating multiple capsular blocks. Patients with lesions characterized by the coexistence of cellular atypia, frequent mitoses and invasive features (vascular, capsular or stromal) were excluded, as were those with only a Hürthle cell component in a papillary or follicular adenoma. Histology and electron microscopy were used to evaluate surgical specimens.

The following operations were performed: 29 hemithyroidectomies and six subtotal thyroidectomies. Based on the presence of multicentricity or coexisting carcinoma, five patients were reoperated on with complete excision of the remnant thyroid lobe. No operative death was recorded. The duration of follow-up after surgery ranged from 8 months to 9 years (mean(s.d.) 2·4(1·4) years). Two patients previously submitted to hemithyroidectomy developed a Hürthle cell carcinoma in the remnant lobe, after 3 and 6 years. In these two cases total excision of the thyroid gland was performed. In one of these, a radical neck dissection because of involved lymph nodes was necessary. After 3 years, the two patients are alive without distant recurrence.

The results suggest that total thyroidectomy is not always necessary and that electron microscopic criteria are useful to understand the nature and predict the biological behaviour of Hürthle cell adenomas.

Thyroperoxidase immunodetection in the diagnosis of malignancy of thyroid nodules using fine-needle aspiration

J.-F. Henry, A. Porcelli, A. Denizot, S. Garcia and C. De Micco, *Department of Endocrine Surgery, University Hospital Timone, Marseille, France*

The aim of this study was to investigate the value of thyroperoxidase (TPO) immunodetection in the diagnosis of malignancy of thyroid nodules using fine-needle aspiration (FNA). A total of 300 representative preoperative samples were examined. Slides were air-dried and stained with anti-TPO monoclonal antibody 47. According to the percentage of TPO-positive epithelial cells, patients were divided into two groups: benign (≥ 80 per cent) and malignant (< 80 per cent).

In 279 cases, additional slides were available for Giemsa stain and conventional cytology. Patients were divided into two groups: benign, and suspect or malignant. All patients underwent surgery and the final histological diagnosis was recorded as benign in 248 cases and malignant in 52 (44 papillary and eight follicular carcinomas).

	Cytology			TPO immunodetection		
	No.	Benign	Suspect/ malignant	No.	Benign	Malignant
Histology						
Benign ($n = 248$)	231	183	48	248	215	33
Malignant ($n = 52$)	48	4	44	52	0	52

The sensitivity of TPO immunodetection in the diagnosis of malignancy is 100 per cent and that of cytology 91·6 per cent; their specificity is 86·7 and 79·2 per cent respectively.

It is concluded that TPO immunodetection is a highly sensitive and specific method of detecting malignancy in FNA of thyroid nodules. It should become an essential adjunct in the preoperative cytological examination of such nodules.

Successful allotransplantation of microencapsulated parathyroids in rats

C. Hasse, J. Schrezenmeier, B. Stinner, C. Schark, P.K. Wagner, K. Neumann and M. Rothmund, *Department of Surgery and Pathology, Philipps-University of Marburg and Medical Hospital, Johannes-Gutenberg-University, Mainz, Germany*

The various roles of parathyroid hormone in metabolism make drug therapy for persistent hypoparathyroidism difficult. However, this does not justify parathyroid allograft with subsequent immunosuppression. Reduction of the immunogenicity of tissue using culture passages is rarely successful. Thus, the authors tried to protect the parathyroid transplants against an immunological response while maintaining the function of the glands using microencapsulation.

Parathyroidectomy was performed on 28 Lewis and 14 DA rats. After passage in tissue culture for 6 days, half of the parathyroid glands of the Lewis rats were microencapsulated, and 10:1 (donor:recipient) isotransplanted ($n = 7$) and allotransplanted ($n = 7$). The other half was treated similarly, except for the microencapsulation ($n = 7$ each). Serum calcium levels were tested on the day before parathyroidectomy and 7 and 14 days afterwards in the donors, and, additionally, every week in the recipients. A successful transplantation was defined as an increase of a serum calcium level from <1·6 mmol l^{-1} to >1·9 mmol l^{-1}. At 3 months after implantation, a histological examination was performed of the region of the transplant.

Before the study, all animals were normocalcaemic. After parathyroidectomy, all became hypocalcaemic with a mean serum calcium level of 1·55 mmol l^{-1}. Six weeks after transplantation all isotransplanted and one of seven allotransplanted rats without microencapsulation were normocalcaemic, and four of seven isotransplanted and zero of seven allotransplanted after 12 weeks. In the group with microencapsulated transplants, all seven isotransplanted and six of seven allotransplanted rats became normocalcaemic; after 4 months the numbers were four and five respectively. The histological examination of functionally successful transplantations revealed intact glands; if transplant was not successful there was only a fibrotic remnant of glands. There was no difference in pericapsular lymphocytic and fibroblastic infiltration between isotransplanted and allotransplanted animals.

In an animal experiment, microencapsulated parathyroid tissue both isografted and allografted can survive and function in a host. The microcapsule protects the transplant successfully from a foreign-body reaction by the recipient.

Salivary laser lithotripsy with spectroscopic feedback

M. McGurk, Z.X. Giang, T.A. King and N.M. Girdler, *Maxillofacial Surgery Department, Guy's Hospital, London, UK*

Endoscopic laser lithotripsy has provided a less traumatic alternative to electrohydraulic and electromagnetic lithotripsy in the treatment of urinary and biliary calculi. However, the small diameter of the ductal systems of salivary glands precludes the use of such endoscopic techniques in the treatment of sialolithiasis. An alternative method of directing the laser photon beam can be achieved by a technique known as spectroscopic feedback analysis. This technique was used on 13 salivary stones *in vitro*. It was also performed on two submandibular calculi in freshly excised submandibular glands. The glands and ducts were examined histologically for damage after treatment. The results indicated that the laser fragmented all the calculi treated *in vitro*. There was no evidence of damage to the duct or gland from the laser beam. This technique offers a non-invasive method of removing salivary calculi while retaining the function of the gland.

Cytokines in thyroid autoimmune infiltrate

P. Miccoli, P. Iacconi, S. Mariotti, G.F. Del Prete, P. Caturegli, G. Barbesino, M. Marino and A. Pinchera, *Università di Pisa, Pisa, Italy*

T lymphocytes are regulated by a complex network of soluble polypeptides called cytokines, which are involved in the development and perpetuation of autoimmune diseases. Thyroid autoimmune infiltrate shows an unusual pattern of cytokine production, but until now all studies have been performed *in vitro*. The aim of the present study was to assess cytokine production *in vivo*. Ten patients with Graves' disease and two with goitrous Hashimoto's thyroiditis underwent subtotal thyroidectomy. Three patients with toxic and eight with non-toxic nodular goitre were included as controls. Venous blood (5 ml) was drawn during surgery, either from one of the major epithyroidal veins or from a forearm vein. All blood samples were immediately centrifuged and frozen. The assayed cytokines, all by immunoenzymatic methods, included interleukin (IL) 1β, IL-2, IL-6, interferon γ and tumour necrosis factor α. Serum concentration was in the normal range for all cytokines, both in the thyroidal and peripheral venous blood, with no significant difference between the autoimmune and non-autoimmune patients. No cytokine showed a difference between thyroidal and peripheral blood. The failure to detect significant local cytokine production could be for several reasons: all patients with Graves' disease were receiving antithyroid drugs; locally produced cytokines could have a half-life so short that they disappeared before reaching the epithyroidal veins; only two patients with Hashimoto's thyroiditis, the condition expected to display the highest activation of the thyroid destructive autoimmune effector mechanisms, were included in the study. Interestingly, one of the two patients with Hashimoto's thyroiditis showed a clear positive gradient between thyroidal and peripheral blood for IL-2 and IL-6. IL-2 production is consistent with the presence of an active autoimmune infiltrate. From previous studies *in vitro*, it may be suggested that IL-6 production derives not only from infiltrating lymphocytes but also from direct thyrocyte secretion. This is believed to be the first study to assess cytokine production *in vivo*.

Diagnostic procedures for thyroid nodules

T. Okamoto, T. Yamashita, A. Harasawa, M. Kawakami, M. Aiba, Y. Ito and T. Obara, *Departments of Endocrine Surgery, Radiology and Surgical Pathology, Tokyo Women's Medical College, Tokyo, Japan*

Although the management of thyroid nodules is a common problem, it remains controversial. One of the reasons for this is uncertainty about the reliability of diagnostic procedures. A study to clarify the reliability of physical examination, ultrasonography (US) and fine-needle aspiration cytology (FNAC) for the diagnosis of thyroid nodules was therefore conducted.

A total of 252 patients with thyroid nodules who underwent thyroid surgery at Tokyo Women's Medical College during 1987–1991 were studied. The patients comprised 126 with benign lesions (adenoma or adenomatous goitre), 114 with papillary carcinoma and 12 with follicular carcinoma. Preoperative diagnoses (negative or positive for carcinoma) made by physical examination, US and FNAC were checked from the patients' medical records, and the sensitivity and specificity of each diagnostic procedure calculated.

The specificity of physical examination, US and FNAC was 98 per cent (123 of 126), 90 per cent (113 of 126) and 98 per cent (124 of 126) respectively. The sensitivity of physical examination, US and FNAC for all carcinomas was 63 per cent (80 of 126), 78 per cent (98 of 126) and 80 per cent (101 of 126), respectively. However, after taking account of the histological categories of carcinoma, the sensitivity of physical examination, US and FNAC was 68 per cent (77 of 114), 83 per cent (95 of 114), 88 per cent (100 of 114) for papillary carcinoma and 25 per cent (three of 12), 25 per cent (three of 12) and 8 per cent (one of 12) for follicular carcinoma respectively. When all the test results were negative, the likelihood ratio favouring papillary carcinoma was 0·008 whereas that of follicular carcinoma was 0·6.

The histological category of a carcinoma should be considered when evaluating the reliability of diagnostic procedures for thyroid nodules, as the overall sensitivity of the diagnostic information depends on the frequencies of the categories in the sample. These investigations are unable to exclude follicular carcinoma, either individually or in combination.

Review of 7 years' experience with fine-needle aspiration biopsy of the thyroid

N. Palestini, R. Durando, M. Papotti and M.A. Fortunato, *II Clinica Chirurgica, Università di Torino, Italy*

In the past 7 years, 1936 fine-needle aspiration biopsy (FNAB) procedures of the thyroid were performed on 1881 subjects with one or more thyroid cold nodules, either solitary or in the setting of an adenomatous goitre. Adequate material was obtained from 1862 FNAB procedures (96·2 per cent) and the diagnosis was negative for cancer in 88·5 per cent, suspicious in 8·4 per cent and positive for cancer in 3·1 per cent. Histological evidence after surgery in 311 cases (16·7 per cent) showed malignancy in 3·2 per cent of the 'negative' cases, in 21·1 per cent of 'suspicious' and in 93·8 per cent of patients positive for cancer on FNAB. A cytological diagnosis negative for cancer was usually followed by clinical observation, and only 187 patients had resection. A malignant tumour was found after surgery in six patients. Surgery was always recommended after suspicious FNAB and a malignant tumour was found in 16 of 76 cases. A positive diagnosis was an absolute indication for prompt surgery. Histological confirmation was obtained in 48 patients, five patients had an inoperable tumour and four refused. Analysis showed a false-negative rate of 2·6 per cent, false-positive rate of 1·3 per cent, sensitivity of 88 per cent, specificity of 98 per cent, positive predictive value of 94 per cent, negative predictive value of 97 per cent and accuracy of 96 per cent. Addition of the suspicious cases to the positive increases the sensitivity to 91 per cent.

These findings offer further evidence of the reliability of FNAB in the evaluation of thyroid nodules, especially when the procedure is performed by skilful operators and close cooperation established between clinician and pathologist.

Zollinger–Ellison syndrome: surgical treatment for 'cure' or long-term palliation

C. Pasquali, C. Sperti, D. Miotto*, A. Alfano D'Andrea, C. Filipponi and S. Pedrazzoli, *Semeiotica Chirurgica and †Radiology, University of Padua, Italy*

Since 1970, 51 patients with Zollinger–Ellison syndrome have been observed; 11 had a MEN type I with two or more endocrine glands involved; 24 had a portal venous sampling (PVS) before surgery for tumour localization and evaluation of resectability.

Twenty-eight patients underwent surgery; 11 had only a total gastrectomy because the tumour was not found. Seventeen patients underwent resection, 13 having a PVS performed before surgery that in eight showed only a single source of gastrin. All eight cases became normogastrinaemic after operation (follow-up 5–16 years). Only one of the five patients in which PVS did not localize a single tumour was cured by surgery. Only one of the four patients who underwent surgery without prior PVS was made normogastrinaemic by resection. Thus gastrin fell to normal in ten of 28 patients surgically treated, but in two patients a late recurrence of hypergastrinaemia was found after 5 and 14 years. Patients in whom gastrin did not fall to normal were treated with antisecretory drugs. Of the 26 patients who had medical treatment three needed later emergency surgery (between 3 months and 3 years) while nine required omeprazole for long-term failure of H_2 blockers (3–14 years). Five patients had liver metastases at the time of diagnosis; two died within 12 months. Two patients (one total gastrectomy, one medical treatment) developed liver metastases 21 and 15 years later respectively.

PVS greatly enhances the chance of tumour resection. Careful and lifelong follow-up is mandatory for all patients. Patients having long-term medical treatment should undergo periodic re-evaluation for possible resectional surgery.

Surgical treatment of insulinoma

S. Pedrazzoli, C. Pasquali and A. Alfano D'Andrea, *Department of Surgery, University of Padua, Padua, Italy*

The role of preoperative and intraoperative procedures for localization of insulinoma has been extensively debated in recent years. Transhepatic portal sampling (THPS) before surgery has been recommended when other tests fail to localize the tumour.

To determine the role of different investigations, 52 patients with insulinoma operated on in three consecutive periods are reviewed. Fifteen patients investigated by arteriography had successful resection in 13 cases. One was found at a second exploration and one has been found after second exploration using intraoperative ultrasonography. Twenty-six patients had exploration after THPS; the tumour was found in all 25 patients operated on in this hospital. Twelve procedures performed using intraoperative ultrasonography without THPS were successful, although three intraoperative localizations failed. Left-sided resections successfully cured symptoms in two of these.

High success rates for surgical treatment of insulinoma can be achieved with THPS or intraoperative ultrasonography. THPS is therefore unnecessary before a first operation on the pancreas for insulinoma.

Endocrine metabolic and blood pressure disturbances in the morbidly obese: modifications after Mason's vertical banded gastroplasty

J.J. Resa, J. Solano, M. Martínez, V. Aguilella, M.F. Perena and M. González, *Hospital Clínico Universitario, Zaragoza, Spain*

An analysis of the development of endocrine and metabolic changes was undertaken in a series of patients with morbid obesity who underwent a Mason's vertical banded gastroplasty.

Between November 1986 and April 1992, 50 patients who suffered from morbid obesity were subjected to a Mason's vertical banded gastroplasty. The following clinical and analytical parameters were studied after operation: glucose, cholesterol, triglycerides, sex hormones and blood pressure. The changes were observed after 6 months, which coincided with a period of fast weight loss, and again 1 year after surgery, during a period of weight stability. The outcome was then compared with preoperative findings.

A progressive decrease in glucose and triglycerides levels in the blood was seen, with a significant statistical difference ($P < 0{\cdot}05$). Cholesterol levels did not change. Systolic and diastolic blood pressure values also decreased to normal values in most patients, with statistical significance. The amounts of oestradiol, progesterone, androsterone and cortisol in the blood were disturbed in two cases (4 per cent), and high levels of aldosterone were found in ten (20 per cent) patients. Urinary testing of sex hormones and their fragments showed a high rate of anomalies, with a decrease of the values of 17-OH corticoids, 17-ketosteroids, dihydroepiandrostenedione, and aetiocholanolone.

A progressive decrease of glucose and triglyceride levels in the blood was obtained in this study. Systolic and diastolic blood pressure values also decreased to normal values. Disturbances were resolved in 80 per cent of patients once they achieved weight stability.

Clinical, histological and immunohistochemical study of phaeochromocytoma: analysis of 30 patients

J.B. Schofield, A. Nazir, M. Puccini*, A.E. Bishop, T. Krausz, J.M. Polak and J.A. Lynn, *Hammersmith Hospital and Royal Postgraduate Medical School, London, UK and *S. Chiara Hospital, University of Pisa, Italy*

A total of 34 consecutive cases of phaeochromocytoma occurring between 1981 and 1989 were identified from the Royal Postgraduate Medical School pathology index. Full pathological, clinical and follow-up data were available on 30 cases. Some 18 patients were male and 12 female (M:F 3:2); age at presentation ranged from 18 to 59 (median 43) years. Eighteen cases involved only the right adrenal gland, 11 cases involved only the left adrenal and one case was bilateral (associated with MEN IIA).

Sections were cut from paraffin blocks for morphological and immunohistochemical analysis. The following immunohistochemical markers were employed: cytokeratin, vimentin, desmin, S-100 protein, epithelial membrane antigen, neurone-specific enolase, chromogranin, neuropeptide tyrosine (NPY), C flanking peptide of NPY, Met-encephalin, dopamine-B-hydroxylase, proliferating cell nuclear antigen (PCNA) and p53 protein.

Of the 30 cases studied, only two manifested malignant behaviour, in each case liver metastasis. Morphologically, one of these cases exhibited the characteristic small cell pattern. Neither of the malignant cases was associated with MEN IIA or IIB syndromes, von Hippel–Lindau disease or neurofibromatosis. There was no clear difference in immunohistochemical staining between the benign and malignant tumours. Nuclear p53 expression was weak or absent in all cases, and no correlation was seen between PCNA reactivity and prognosis.

Ultrasonographically guided fine-needle aspiration cytology in the early diagnosis of carcinoma in multinodular goitre

J.J. Starzewski, B. Bialas, Z. Kobylański and M. Rojek, *Department of General Surgery, No. 1 Hospital, Sosnowiec and University Department of Pathomorphology, Katowice, Poland*

The incidence of unsuspected malignancy in multinodular goitre (MG) confirmed by histology is 3·7 per cent in this institution. Some 76 malignancies were found in 2052 surgical specimens of patients operated on for MG in the period 1976–1991. The value of ultrasonographically guided fine-needle aspiration cytology (FNAC) was estimated in a group of 100 consecutive patients undergoing surgery for clinically benign MG in 1992. Surgical indications included cosmesis, compressive symptoms and hyperthyroidism. Each patient had at least two punctures for FNAC; a 22-G ultrasonographically guided needle was inserted into the visualized lesion and aspirated. All samples were evaluated by a single cytopathologist. Patients with suspected malignancy according to FNAC had frozen section at the time of the planned procedure and the decision about the extent of thyroid resection was then made. Otherwise, standard subtotal thyroidectomy was performed. The results of FNAC were compared with histological diagnosis from resected specimens made by an independent pathologist. There were eight true-positive FNAC reports, 89 true-negative, one false-positive and two false-negative. Therefore the sensitivity of FNAC in the diagnosis of carcinoma in MG was 80 per cent, specificity 98 per cent, positive predictive value 88 per cent and accuracy 97 per cent.

Surgical therapy and prognostic factors in medullary thyroid carcinoma: evaluation of the German MTC study

J. Winter and F. Raue, *Department of Surgery, Klinikum Mannheim, Germany*

A total of 741 patients were reported in the German medullary thyroid carcinoma (MTC) register up to 1991. In the initial operation, total thyroidectomy was performed in 82 per cent of patients and dissection of lymph nodes in 48 per cent; in cases in which the diagnosis was known before surgery, these rates increased to 88 and 76 per cent, respectively. The 10-year survival rate for familial forms was 72 per cent and for sporadic forms 62 per cent. In a univariate analysis, the stage of disease at diagnosis, age, sex and type of disease were significant prognostic factors, with a better prognosis for young female patients with familial disease at an early stage. In a multivariate analysis, the difference in the survival rates of patients with familial disease *versus* those with the sporadic form disappeared, while prognostic information provided by age and sex was still significant. There seems to be no difference in biological behaviour between tumours of the sporadic and those of the familial type.

Gastric cancer

Evaluation of CA 72.4 in patients with gastric cancer

L. Fernández-Fernández, T. Ratia, E. Tejero, A. Tieso, J.M. Sanz, J.L. Pellicer and S. Yagüe, *Hospital General de Soria, Soria, Spain*

The CA 72.4 assay measures the tumour-associated glycoprotein TAG 72 using two monoclonal antibodies, B72.3 and CC49. The aim of this work was to evaluate the clinical usefulness of this marker in patients with gastric cancer. Also CA 72.4 was compared with carcinoembryonic antigen (CEA) and CA 19.9.

Serum levels of CA 72.4, CEA and CA 19.9 were determined in 70 healthy volunteers and before operation in 70 patients with gastric adenocarcinoma. The groups were homogeneous for age and sex. All patients with gastric cancer were staged according to the tumour node metastasis classification as IA ($n = 4$), IB ($n = 4$), II ($n = 8$), IIIA ($n = 8$), IIIB ($n = 9$) or IV ($n = 37$). At a specificity of 95 per cent the sensitivities for identification of disease of CEA, CA 19.9 and CA 72.4 were 0·26, 0·27 and 0·54 respectively and the cut-off levels 6 ng ml^{-1} for CEA, 51 µg ml^{-1} for CA 19.9 and 4·6 µg ml^{-1} for CA 72.4. At 95 per cent specificity the combined use of CEA and CA 19.9, and CEA and CA 72.4, did not improve sensitivity (0·47 and 0·54 respectively), but the combination of CA 19.9 and CA 72.4 did improve sensitivity (0·60). The use of three markers increased the sensitivity to 0·64.

These results support the role of CA 72.4 as a reliable tumour marker in the study of patients with gastric cancer, because of its specificity and sensitivity.

Prognostic factors in early gastric cancer

French Associations for Surgical Research, Ph.J. Oberlin and B.L. Millat, *Centre Hospitalier, Villeneuve St Georges, France*

From 1979 to 1988, 332 patients with early gastric cancer (EGC) were operated on in 23 centres. There were 208 men and 124 women. Data were collected retrospectively and screened for prognostic effect. Eight local excisions (2·4 per cent), 235 partial (70·8 per cent) and 89 total (26·8 per cent) gastric resections were performed. Postoperative mortality rate was respectively 0, five (2 per cent) and nine (10 per cent) in the three groups. Total gastric resections were performed when EGC was located in the lower third of the stomach in 42 cases. Cumulative 5- and 7-year survival rates were 92 and 88 per cent. Mean follow-up was 56 months. During the follow-up period there were 23 related and 37 unrelated deaths. Five patients are alive with recurrence or metastases. Cause of death was unknown in two cases. In univariate analysis, the 7-year survival rate varied with lymph node involvement (91 per cent for 299 node-negative *versus* 60 per cent for 33 node-positive; $P < 10^{-4}$), depth of parietal spread (93 per cent for 159 mucosal *versus* 89 per cent for 167 submucosal lesions; $P = 0·05$), and tumour location (95 per cent for 212 in the lower third *versus* 86 per cent for 120 in the proximal stomach; $P = 0·05$). Modified Borrmann classification, histological type, size of the tumour, extent of resection or sex had no influence on survival rate. In multivariate analysis, three variables were associated with better prognosis: no lymph node metastasis ($P < 10^{-4}$), tumour of the lower third of the stomach ($P < 0·004$), and tumour size < 15 mm ($P = 0·02$).

Extent of lymph node dissection for carcinoma of the cardia

Z. Gerzic, P. Pesko, T. Randjelovic, J. Knezevic, A. Simic and M. Kotarac, *University Clinical Centre, Institute for Digestive Diseases, Belgrade, Serbia*

Systematic lymph node dissection has been adopted as part of a standard procedure in patients undergoing curative resection for carcinoma of the cardia. Two series of patients have been compared: group A patients ($n = 132$) underwent proximal gastric resection with standard lymphadenectomy (R_1) and oesophagogastric anastomosis from 1970 to 1985. Group B patients ($n = 280$) underwent total or extended total gastrectomy with systematic lymphadenectomy (R_{2-3}) and Roux-en-Y oesophagojejunostomy from 1982 to 1992. Both patient groups were matched for age, sex, tumour node metastasis staging and histopathological type of tumour.

In group B, 148 patients were prospectively analysed. R_2 total gastrectomy was performed including *en bloc* excision of the whole stomach together with the distal 5 cm of the oesophagus, entire greater omentum, bursectomy and lymphadenectomy along the common hepatic and hepatic arteries, coeliac trunk and splenic artery, splenectomy, suprapyloric and infrapyloric lymph node dissection. The left gastric artery was always ligated at its origin. Distal pancreatic resection and splenectomy were performed in 27·7 per cent of patients; positive lymph nodes were found in 71·6 per cent of cases. Complete dissection of groups A and B (R_2) was achieved in 39·9 per cent; R_3 dissection was performed in 60·1 per cent. Absolutely curative resection was performed in 37·8 per cent, relatively curative resection in 44·6 per cent and non-curative resection in 17·6 per cent. Despite extensive lymphadenectomy, the postoperative mortality rate has steadily decreased: 25·9 per cent after proximal gastrectomy *versus* 5·4 per cent after total gastrectomy and systematic lymphadenectomy. Hence, extensive lymphadenectomy could be successfully performed without increasing mortality rates. The 5-year survival rate was 7·5 per cent in group B, compared with 39·8 per cent in group A.

Recurrence in early gastric cancer

S. Guadagni, M. Valenti, G. Carducci, E. Mancini, M. Marino, P. Gola, A. Agnifili, I. Ibi, F. Gianfelice, R. Verzaro, G. Turco, D. Ranalletta, D. Centi, M. Di Renzo, A. Sawaid and G. De Bernardinis, *Department of Surgery, University of L'Aquila, L'Aquila, Italy*

In a retrospective multicentre study of 172 cases of early gastric cancer (EGC), 11 patients died from recurrence of the gastric cancer and 13 died from unrelated causes. One patient with a gastric remnant recurrence was alive 3 years after the initial operation at the time of follow-up. The mean(s.e.) cumulative recurrence mortality rates were 7·5(2·1) per cent at 5 years and 9·4(2·7) per cent at 10 years (Kaplan–Meier method). The cumulative 10-year survival rate was 91·6(2·4) per cent excluding operative death and that from causes other than gastric cancer.

The recurrence patterns of EGC were blood-borne metastases to the liver (in four cases), recurrence from lymph nodes and peritoneum (in four cases), and recurrence in the residual stomach (five patients including those alive).

Univariate analysis showed a significant difference in recurrence mortality rates between cancers confined to the mucosa and those with submucosal invasion ($P = 0·044$) and between cancers of non-intestinal histological type and cancers of intestinal histological type ($P = 0·023$).

Using Cox multivariate analysis for eight variables (sex, age, depth of invasion, lymph node metastases, presence of ulceration, location, histological type, type of surgery), at the end of stepwise procedure adjusted for depth of invasion, age and histological type had the most significant effect on recurrence. The relative importance of the two factors was clarified by the risk ratios (5·25 for age and 4·41 for histological type).

The results of this analysis of factors influencing recurrence after surgical treatment of EGC showed a significant dominance of host- and tumour-related factors (age and histological type) over the type of surgical procedure performed.

Gastric cancer: long-term survival of patients with positive N_3 lymph nodes

F. Pacelli, G.B. Doglietto, R. Bellantone, S. Alfieri, E. Piccioni and F. Crucitti, *First Clinica Chirurgica, Catholic University, Rome, Italy*

The aim of the study was to evaluate long-term survival of patients affected by gastric cancer with positive N_3 lymph nodes undergoing gastrectomy plus extended locoregional lymphadenectomy.

During the period 1981–1992, 184 consecutive patients with histologically proven adenocarcinoma of the stomach underwent resective surgery (total gastrectomy plus R_3 lymphadenectomy, 106; distal subtotal

0007-1323/93/S032-02 © 1993 Butterworth-Heinemann Ltd

gastrectomy plus R_2 lymphadenectomy extended to hepatic pedicle and retropancreatic nodes, 78) at this surgical unit. According to Japanese nomenclature gastric resection was 'absolutely curative' in 135 N_{0-2} patients (N_{0-2} group) and 'relatively curative' in 15 N_3 patients (N_3 group). The 5-year survival rate (operative mortality excluded) was calculated according to the actuarial life-table method.

Overall 4·8 per cent (seven of 145) patients were lost to follow-up, 4·6 per cent (six of 131) in the N_{0-2} group and 7 per cent (one of 14) in the N_3 group. The 5-year survival rate was 62 per cent in the N_{0-2} group (83·0 per cent, 61·9 per cent and 45·6 per cent in stage I, II and III respectively) and 24·2 per cent in the N_3 group (stage IV). Among these, three N_3 patients are still alive 115, 79 and 44 months after operation. One additional N_3 patient died 63 months after operation without evidence of recurrent disease.

According to the unified tumour nodes metastasis staging system, N_3 positive lymph nodes in gastric cancer are regarded as M_1 (stage IV), therefore their expected 5-year survival should be zero. However, results of the present study show that, after R_3 gastrectomy, even N_3 patients can survive more than 5 years, thus confirming that the gastric resection should be considered, as in the Japanese nomenclature, 'relatively curative' rather than palliative. The therapeutic efficacy of extended lymphadenectomy in the surgical treatment of gastric cancer is confirmed.

Early gastric carcinoma: 8 years' experience

K. Saliangas, Th. Chrisidis, Ch. Savas, E. Doitsini,
N. Nikoloudis and G. Tanos, *Edessa General Hospital, Edessa, Greece*

The detection and diagnosis of early gastric adenocarcinoma is of great importance, as the outcome differs from that of advanced cancer and the 5-year survival rate is better. A total of 129 patients with gastric cancer were treated surgically during the past 8 years. The methods of investigation of the upper gastrointestinal tract were double-contrast barium meal and fibreoptic endoscopy, with at least six biopsies being taken from suspicious lesions.

Early gastric cancer was diagnosed in 13 patients (10 per cent; three women and ten men aged from 34 to 62 years). Chronic gastritis dysplasia was present in eight patients and intestinal metaplasia in five. Dysplasia and gastric polyps were observed in one patient who had been followed by endoscopy and biopsy at 6-month intervals for 2 years. Partial gastrectomy with Billroth II anastomosis was performed in eight patients. Five patients had total gastrectomy with reconstruction by Henley jejunal interposition. Lymph node metastases were detected in two patients who died at 24 and 32 months after the operation. The remaining patients are still alive without recurrence.

Endoscopic surveillance in patients presenting with dysplasia, or particularly with intestinal metaplasia, leads to early detection of gastric cancer and hence to better survival.

Gastric surgery

Influence of preoperative weight loss on effect of vertical banded gastroplasty

J.L. Hedenbro, S.G. Frederiksen, O. Jansson and S. Jisander*, *Departments of Surgery and *Oral and Maxillofacial Surgery, Lund University, Lund, Sweden*

Surgery is the only therapeutic method that has shown lasting results in the treatment of morbid obesity. Ability to lose weight by voluntary dieting has been associated with unsatisfactory weight loss after gastroplasty. This report examines the effect of preoperative intermaxillary fixation (IMF) on weight reduction induced by vertical banded gastroplasty (VBG).

A total of 24 patients entered the study and were randomly assigned to either 10 weeks of IMF or 10 weeks on the waiting list. Patient groups were similar with respect to age, sex and body mass index (BMI). All patients were urged to lose weight before operation. At the end of 10 weeks, all patients were operated on with a standard VBG (14–16 ml, 50-mm Marlex band).

Patients in the IMF group lost a median of 18 (range –12 to –36) kg, and the waiting list group lost 3 (3 to –30) kg during the 10 weeks before surgery. Total weight loss from time of inclusion to 24 months after operation was the same in both groups. Operating time, blood loss and postoperative hospital stay did not differ between the groups. There was no mortality.

	BMI (kg m^{-2})				Operation time (min)*
	Incl.	At op.	12 months	24 months	
IMF plus VBG	42·6	37·9	28·4	27·7	64 (57–90)
VBG	42·0	41·5	28·9	28·1	66 (53–86)

*Values are median (range)

These results suggest that weight loss up to 2 years after VBG is not influenced by preoperative weight loss as induced by IMF. Although no obvious advantage in having patients pretreated with IMF was found, the results indicate that jaw wiring can be used before operation for patients at risk of respiratory and other complications without endangering the 2-year result.

Clinical experience with biofragmentable Valtrac ring for sutureless anastomoses in Billroth I and II partial gastric resection

G.W. Lexer, W. Weitensfelder and G.Ch. Lexer, *Department of Surgery, Krankenhaus Friesach, Friesach, Austria*

The biofragmentable Valtrac ring (BVR) was used to create a functional and accurately sized gastroduodenostomy in Billroth I patients and a gastrojejunostomy in Billroth II patients with Brown's anastomoses. Twenty patients underwent partial gastric resection for complicated peptic ulcer disease: 13 patients had gastroduodenostomy (Billroth I) and seven patients gastrojejunostomy with Brown's anastomoses (Billroth II) using the BVR for sutureless anastomoses. In Billroth I patients the distal resection line was identified 1 cm below the pylorus and the proximal line was set exactly at the point of Mikulicz. At the distal resection line a purse-string clamp was adjusted, the duodenum was dilated up to 28 Ch and the BVR inserted. At the greater curvature and the TA90 stapler row a diameter of 28 Ch was created in the same fashion, the two parts narrowed and the gastroduodenostomy closed with a click. In Billroth II patients undergoing partial gastric resection the stomach was prepared in the same fashion as for Billroth I and the duodenal stump closed either with a GIA stapler or by hand. Thereafter the anastomoses were finished by inserting the BVR in the same way as described above for creating the gastrojejunostomy and the Brown anastomoses.

One postoperative complication occurred. This patient developed temporary mechanical small bowel obstruction because of delayed passage of ring fragments but did not need surgery. The Gastrografin test on the fifth day after operation showed no leakage of the anastomoses. A swelling could not be identified. The disappearance of the BVR was monitored by radiography. Only one emptying disturbance has been seen.

A tension-free gastroduodenostomy is an absolute requirement for a complication-free Billroth I resection. This is possible only if adequate mobilization of the duodenum has been performed and the duodenal wall is free of damage. The use of the BVR has therefore to be proved in every single case. As insertion of the BVR needs 1·5–2 cm of tissue, the duodenal stump has to be dissected free for at least 4 cm, otherwise the BVR is contraindicated. In Billroth II resections there are almost no contraindications for the use of the Valtrac ring. With exact indications the BVR offers a secure adaptation of the anastomotic wall layers and a more functional and anatomically accurately sized gastroduodenostomy and gastrojejunostomy with Brown's anastomosis.

Enterostomy: more and more a case of surgical endoscopy

L. Meyer, G. Adam, G. Kähler and J. Rupprecht, *Clinic and Policlinic of Surgery, University of Jena, Germany*

Since the introduction of percutaneous endoscopic gastrostomy (PEG) the performance of gastrostomy via a laparotomy has become rare. The simple and minimally invasive method of PEG is a great advantage for the severely ill patient with this indication. With the development of endoscopic techniques and growing experience PEG has become a very safe method, and more difficult procedures such as percutaneous endoscopic jejunostomy (PEJ) are now possible. If endoscopic passage into the stomach is impossible because of subtotal or total stenosis of the hypopharynx, oesophagus or cardia, percutaneous sonographic gastrostomy is an alternative. However, because of personal experience we prefer laparoscopic gastrostomy (LG) in these cases. The authors report on experience in indication, technical difficulties and complications after 96 PEG procedures, five PEJ and two LG, as well as on first results of percutaneous endoscopic caecostomy as a further possibility of endoscopic creation of an enterostomy.

Bariatric surgery for morbid obesity: transverse diverting or vertical banded gastroplasty: a comparative study with long-term follow-up

J.-P. Puts, J. Lerut and J.A. Gruwez, *Catholic University Hospitals, Leuven, Belgium*

A total of 79 bariatric procedures were performed over a period of 7 years: 23 were transverse diverting gastroplasty (TDG) operations (Alden or Griffen) and 56 vertical banded gastroplasty (VBG) (Mason). The mean age of patients in both series was 34 years; mean body-weight was 126 kg (mean 206 per cent of ideal weight, IW); there was no difference between groups in the change of the percentage of the IW which reached 120 per cent at 2 years' follow-up after successful treatment by either TDG or VBG. The failure rate of about 30 per cent at 2 years was similar in both series. The results (expressed in quartiles) as percentages of patients remaining overweight after treatment (excellent, 0–25 per cent; good, 26–50 per cent; fair, 51–75 per cent; poor, 76–100 per cent) show that 85 per cent of the TDG and 72 per cent of the VBG procedures gave excellent to good results, whereas 15 per cent of the TDG and 28 per cent of the VBG operations gave fair to poor results. A close follow-up of morbidly obese patients is mandatory.

In conclusion, the gastroplasties led to weight reduction in selected morbidly obese patients. Both TDG and VBG provide equal results in terms of long-term weight reduction or recurrence rate. Moreover, VBG is easier to perform, particularly in recurrent obesity.

Vertical banded gastroplasty with Narbona's technique when treating morbid obesity in patients with gastro-oesophageal reflux caused by hiatal hernia

J.J. Resa, M. Martínez, V. Aguilella, M. Pablo, M.F. Perena and M. González, *Hospital Clínico Universitario, Zaragoza, Spain*

The presence of hiatal hernia in obese patients may interfere with an antiobesity vertical gastroplasty. In this unit, a pexis of the round ligament is performed when treating gastro-oesophageal reflux, and a vertical banded gastroplasty is undertaken as an antireflux technique. Mason's technique and Narbona's technique are thus combined in morbidly obese patients with gastro-oesophageal reflux.

A total of 63 vertical banded gastroplasties were performed from November 1986 to November 1992. Four of these patients had concomitant hiatal hernia, for which they underwent vertical gastroplasty with Narbona's technique. These four patients comprised a 35-year-old man weighing 130 kg, a 29-year-old woman weighing 117 kg, a 22-year-old woman of 130 kg, and a 33-year-old man who weighed 120·5 kg. All four patients achieved weight loss without any evidence of gastro-oesophageal reflux (monitored by clinical, radiological or pH-metric techniques).

The combination of vertical banded gastroplasty with Narbona's technique is a useful method when treating morbid obesity associated with gastro-oesophageal reflux.

Roux-en-Y is a worthwhile procedure

P.P. Skinner and J.A.R Smith, *Northern General Hospital, Sheffield, UK*

The Roux-en-Y procedure has varied in popularity. Recently, poor results have been reported for the procedure.

Two groups of patients are presented: group 1 in which the Roux operation was done to relieve the symptoms of alkaline reflux and group 2 in which the procedure was done at the time of initial gastric surgery with the aim of preventing biliary bile reflux. Group 1 consisted of 15 patients: 12 showed improvement in Visick grading, 40 per cent were asymptomatic on follow-up and 80 per cent felt that surgery had been worthwhile. One patient required further surgery for a duodenal stump leak and morbidity rates were low. Some 66 per cent of patients required no further medication. Group 2 consisted of 22 patients undergoing resection for gastric carcinoma. Of these 15 were in Visick grade 1 or 2; two were classified as Visick 4 but one has been converted to Visick 1 after further resection. The mortality rate was 14 per cent in this group and, in a 5-year follow-up, 50 per cent of the patients have died.

It is concluded that good or satisfactory results can be obtained from Roux-en-Y diversion for patients with benign (80 per cent satisfied) or malignant (83 per cent satisfied) lesions. There is no need to question conventional wisdom that the two anastomoses should be separated by at least 45 cm.

Stress and gastroduodenal disease in the young

L. Stellin and F. Meneghini, *'G. D'Annunzio' University, Chieti, Italy*

The importance of emotional stress in the pathogenesis of many gastrointestinal diseases is widely accepted, whereas its implications for the development of gastroduodenal disease in young people have not yet been thoroughly considered. In previous publications, the present authors noted that about 50 per cent of the young requiring emergency care had symptoms of gastrointestinal disease and that haemorrhagic gastroduodenitis and complicated peptic ulcer were (after trauma) the most common causes of urgent admission to hospital. Furthermore, a rise in the incidence of gastrointestinal pathology in young men during military service was observed and it was hypothesized that abrupt changes in lifestyle could generate an important adaptative stress, which facilitates the development of gastroduodenal disease.

A total of 385 symptomatic men ranging in age from 18 to 26 years underwent oesophagogastroduodenoscopy, of whom 60 were evaluated psychologically using the Minnesota Multiphasic Personality Inventory. This test provides information related to emotional state, coping ability and somatic conversion tendencies. From the clinical point of view, oesophagitis accounted for 29·2 per cent of all pathological findings and hiatus hernia for 15·5 per cent. Gastroduodenitis was present in 50·8 per cent of patients and peptic ulcer in 4·5 per cent. Preliminary psychological evaluation showed a generalized difficulty in reacting to stress, as indicated by high scores on the Depression and Psychoastenia scales. High scores were also obtained in the Hysteria scale when gastroduodenitis, in the erosive form, was present, thus indicating that anxiety and psychological discomfort tend to be turned into somatic symptoms. It was also noticed that gastrointestinal pathology arises most frequently during the first 5 months of military service, especially within the third and the fourth months. From military psychosocial studies, it is now known that this is the critical time for young people in the process of adaptation to a new lifestyle and, in this situation, stress stimulation is stronger.

Geriatric surgery

Non-elective colorectal surgery: effect of age on results

J.J. Arenal, J.L. Marcos, F. Martin, C. Tinoco, A. Barrera, E. Gallo, A. Anta and E. Ortega, *Departamento de Cirugia, Hospital Pío del Rio Hortega, Valladolid, Spain*

Between 1986 and 1992, 150 consecutive patients underwent non-elective colorectal surgery. To determine whether age is the most important factor affecting outcome, patients were divided into two groups: group 1 included 65 patients aged <70 years, of mean(s.d.) age 55·5(12·5) years; group 2 comprised 85 patients aged ≥70 years, of mean(s.d.) age 79·1(5·4) years.

Colorectal resection was performed in 45 cases (69 per cent) from group 1 and in 42 (49 per cent) from group 2. Forty-two operations in group 1 (65 per cent) and 58 (68 per cent) in group 2 were performed for malignancy.

Other possible determining factors were also analysed: sex, the use of resective procedures, malignancy, reasons for surgery (peritonitis, bowel obstruction), number of risk factors (associated diseases), and admission–operation interval. As a result of multiple regression analysis it was found that local morbidity increased with age ($P < 0{\cdot}01$) and malignancy ($P < 0{\cdot}05$). Mortality rate (12 per cent in group 1 (eight of 65), and 32 per cent in group 2 (27 of 85)) was determined by the presence of associated risk factors ($P < 0{\cdot}001$), the presence of peritonitis ($P < 0{\cdot}05$) and by the admission–operation interval ($P < 0{\cdot}05$). It is concluded that age does not determine mortality in non-elective colorectal surgery even though it is a dominant factor in morbidity.

Age as a factor in decision-making for elective colorectal surgery

J.J. Arenal, J.L. Marcos, F. Martin, C. Tinoco, A. Barrera, E. Gallo, A. Anta and E. Ortega, *Departamento de Cirugia, Hospital Pío del Rio Hortega, Valladolid, Spain*

This study analysed 440 consecutive colorectal operations performed between 1986 and 1992 in a retrospective review to find out whether age is a determinant factor in deciding whether or not to undertake elective colorectal surgery. The patients were divided into two groups: group 1 included 219 patients aged <70 years (mean(s.d.) age 56·5(11·8) years); group 2 comprised 221 patients aged ≥70 years (mean(s.d.) age 76·3(4·8) years).

Colorectal resection was performed in 175 cases (79·9 per cent) from group 1 and in 175 cases (79·2 per cent) from group 2. A total of 181 (82·7 per cent) operations in group 1 and 204 (92·3 per cent) in group 2 were performed for malignancy. Other possible determinant factors were also analysed: sex; whether colorectal resection was performed; number of risk factors (associated diseases); and tumour stage.

The results were analysed by multiple regression, and show that the morbidity rate (44·3 per cent in group 1 (97 of 219) and 56·1 per cent in group 2 (124 of 221)) increased with age ($P < 0{\cdot}01$), in men ($P < 0{\cdot}01$) and in patients who had undergone resection procedures ($P < 0{\cdot}001$). In cases in which resection was performed, male sex ($P < 0{\cdot}001$) and age ($P < 0{\cdot}05$) contributed to an increase in morbidity. Mortality rates (3·2 per cent in group 1 (seven of 219) and 8·1 per cent in group 2 (18 of 221)) increased in the presence of risk factors ($P < 0{\cdot}05$) and recourse to a non-resective procedure ($P < 0{\cdot}01$). After resection, malignancy is the only factor that determines an increase in mortality rates ($P < 0{\cdot}05$) (2·3 per cent in group 1 (four of 175) and 5·7 per cent in group 2 (ten of 175)).

In conclusion, age does not determine mortality rates as a result of elective colorectal surgery, even though it is a determinant factor in the increase in morbidity rates.

Stomach surgery on elderly patients for gastric carcinoma: frontiers in surgical treatment

C. Bloechle, J.R. Izbicki, W.T. Knoefel, J. Limmer and C.E. Broelsch, *Department of Surgery, University Hospital Eppendorf, Hamburg, Germany*

Surgical treatment for gastric carcinoma in patients aged over 70 years was evaluated by a retrospective clinical trial. From January 1989 to November 1992, 24 patients with a mean age of 78·2 years underwent operation for gastric carcinoma; cefotaxime was given as a perioperative antibiotic. Curative surgical therapy was achieved in 15 patients, while nine patients underwent palliative treatment. The procedures performed were: nine gastrectomies; seven high distal resections with reconstruction according to Billroth I in four patients and Billroth II in three patients; and two proximal resections with oesophagogastrostomy. Six patients underwent exploratory laparotomy.

The patients presented with a variety of concomitant diseases, as might be expected of this age group. Associated morbidity included arterial hypertension, cardiac insufficiency (II–III New York Heart Association), chronic coronary insufficiency, pulmonary insufficiency, diabetes mellitus II and renal insufficiency, in decreasing frequency. The mean value of preoperative risk evaluation according to the American Society of Anesthesiologists (ASA) was 2·9 for the group having gastrectomy, 2·8 for the group having gastric resection, and 3·0 for the group having exploratory laparotomy. In addition, three patients who underwent emergency operation because of perforation of the gastric tumour were classified ASA grade 4·0.

Mortality rates, early and late morbidity rates, and survival time were recorded. The early postoperative mortality rate (within 40 days) was 25 per cent. Two patients in the gastrectomy group died, including one having a palliative procedure. Four patients died in the exploratory laparotomy group, including two patients operated on as an emergency. Altogether, 18 patients were discharged a mean of 21·4 days after operation. After a mean follow-up period of 22·5 months, seven of the 15 patients with an R_0 resection have died within a mean time of 14·3 months after operation. Eight patients, including four with early gastric cancer, are alive after a mean interval of 17·2 months after operation.

In conclusion, surgical treatment of gastric carcinoma is realistic in elderly patients.

Surgical treatment of biliary disease in patients aged over 70 years

G. Csáky, L. Papp, J. Berecz, L. Juhász and P. Orosz, *County Hospital, Miskolc, Hungary*

A retrospective analysis of the results of 162 biliary operations performed during a 5-year period on patients aged over 70 years is reported.

Eighty-seven were elective operations (mortality rate 3·5 per cent) and 75 acute operations (mortality rate 6·2 per cent). During the same period 321 endoscopic retrograde cholangiopancreatographies (ERCPs) and 120 endoscopic sphincterotomies (ESs) were carried out in patients aged over 70 years, of whom 12 died (7·4 per cent).

The outcome of patients undergoing bile duct exploration was analysed. Three of ten patients undergoing a negative exploration died compared with five of 40 patients who underwent a positive exploration. To minimize postoperative morbidity and mortality, ERCP before elective surgery is recommended and, in selected cases, ES and stone extraction, leaving the callous gallbladder *in situ*.

It is considered that further study is necessary to determine whether urgent ERCP and, if bile duct calculi are diagnosed, ES with stone extraction, is justified before emergency operation on elderly patients.

Herniorrhaphy in the elderly

M.R. Madsen, *Odense University Hospital, Odense, Denmark*

All patients aged 80 years and over who were admitted with hernias during a 1-year period to the Department of General Surgery in Ringkoebing County, Denmark, entered a prospective study. Of 39 patients admitted, three refused operation. Among those remaining 23 were men and 13 women; median age was 84 (range 80–90) years. Fifteen cases (42 per cent) were admitted as emergencies.

Thirty-one patients had inguinal hernias, four had femoral hernias, and one an obturator hernia. All incarcerated femoral and obturator hernias contained non-viable intestine that required resection, while resection was necessary in only one of eight incarcerated inguinal hernias. All patients who required resection had a laparotomy.

0007–1323/93/S036–02 © 1993 Butterworth-Heinemann Ltd

There were six major and two minor complications after 14 emergency operations, and one minor complication after 22 elective operations ($P = 0{\cdot}0007$). No association was found between coexisting disease and complications. Two patients died, both after emergency operation (14 per cent).

It is concluded that elective hernia repair can be performed safely even in the presence of serious coexisting disease; however, emergency hernia repair carries a high risk of complications even in the absence of coexisting disease.

Acute and elective surgery for colorectal cancer in patients aged over 75 years

A. Papachristodoulou, G. Zografos, C. Fotiades, N. Kakaviatos, J. Gogas and G. Skalkeas, *Athens University, Laikon Hospital, Greece*

The records of 343 patients who underwent surgery for colorectal cancer were reviewed. Age, sex, site of tumour, clinical presentation, surgical management, histopathological stage and postoperative outcome were analysed retrospectively.

There were 102 patients (29·7 per cent) aged over 75 years (group 1) and 241 (70·3 per cent) under 75 years (group 2). The male to female ratio was similar in both groups. Elderly patients were admitted urgently in a greater proportion than were younger patients. A predominance of colostomy and Hartmann's procedure was noted in group 1 compared with group 2. In addition, septic complications more frequently followed both elective and emergency operations in the elderly group. The operative mortality rate was 10·7 per cent for group 1 and 2·9 per cent for group 2; total morbidity rates were 19·6 and 14·9 per cent respectively.

Despite advances in abdominal surgery and postoperative care, age remains a risk factor for outcome after surgery for colorectal cancer.

Cholecystectomy in patients aged 60 years or over: a comparison of open *versus* laparoscopic operation

M.V. Planells Roig, R. García Espinosa, A. Moya Sanz and D. Rodero Rodero, *'La Fe' Hospital, Valencia, Spain*

The aim of the study was to demonstrate the superiority of laparoscopic cholecystectomy *versus* open cholecystectomy in terms of morbidity and mortality rates, period of hospitalization and immobilization, time before restoration of bowel movements, and duration of procedure.

Patients undergoing elective laparoscopic cholecystectomy were compared prospectively with a historical group matched for age, sex, body mass index, associated medical illnesses and clinical presentation. The patients were aged ⩾ 60 years; all controls underwent routine cholangiography.

	Laparoscopic cholecystectomy ($n = 43$)	Control ($n = 34$)	P
Associated diseases	13	15	n.s.
Body mass index >27 kg m^{-2}	20	24	n.s.
Sex ratio (M:F)	6:37	8:26	n.s.
Mean(s.d.) age (years)	67·0(4·7)	67·5(3·4)	0·5
Duration of operation (min)	60·0(38·2)	90·0(35·2)	<0·001
Hospitalization period (days)	3·0(1·3)	9·5(2·8)	<0·001
Immobilization (h)	20·4(3·8)	72·0(15·2)	<0·001
Oral intake (h)	16·5(2·0)	48·0(7·9)	<0·001
Morbidity	2	7	<0·05

Laparoscopic cholecystectomy is a well tolerated, safe procedure compared with open cholecystectomy in patients aged ≥ 60 years. In this subgroup of patients laparoscopic cholecystectomy makes prophylactic cholecystectomy a feasible therapy for oligosymptomatic gallbladder disease and avoids the common policy of leaving the gallbladder *in situ* after endoscopic retrograde cholangiopancreatography.

Hernia

Interleukin 6 in laparoscopic *versus* open hernia repair

P.E. Banwell, A.D.K. Hill, A. Darzi, N. Menzies-Gow, J.R.T. Monson and P.J. Guillou, *St Mary's Hospital, London, UK*

Interleukin (IL) 6 initiates the acute-phase response to tissue injury. The magnitude of the systemic IL-6 response is related to the severity of surgery. Laparoscopic mesh hernia repair is a more invasive procedure than open herniorrhaphy as the operation requires intrusion into the peritoneal cavity and insertion of a polypropylene mesh. It was hypothesized that laparoscopic mesh hernia repair was physiologically more perturbing than open inguinal hernia repair. Twenty-two patients were prospectively randomized to three groups. Patients in group 1 (nine cases) had a laparoscopic inguinal hernia repair using a polypropylene mesh. Those in group 2 (ten cases) had an open hernia repair using a polypropylene mesh, while those in group 3 (three cases) had an open hernia repair using nylon darn. The plasma IL-6 level was measured before and at 5 and 24 h after surgery.

	Before surgery	After surgery	
		5 h	24 h
Laparoscopic mesh	6·4(1·7)	13·7(2·7)	13·1(3·1)
Open mesh	3·8(0·3)*	11·4(2·2)*	15·5(2·5)*
Open darn	2·9(0·1)*	7·5(1·8)*	7·8(1·9)*

Values are mean(s.e.m.) expressed in pg ml^{-1}. *P not significant *versus* laparoscopic mesh (Student's t test)

The advantages, if any, of laparoscopic over conventional hernia repair at present remain unproven. However, these results suggest that performing hernia repair laparoscopically is no more physiologically injurious than conventional inguinal herniorrhaphy.

Outpatient inguinal hernia repair

J.A. Bulen, *Hernia Center of North County, San Diego, California, USA*

The effectiveness of hernia repair in an outpatient setting was analysed and current approaches to hernia surgery in one unit are described.

A total of 500 consecutive inguinal hernias (429 primary, 71 recurrent) were repaired in 457 patients between January 1990 and October 1992. A 91 per cent follow-up rate at approximately 1 year was achieved. Patients were analysed with respect to many factors including type of operative procedure, anaesthesia, postoperative pain, time off work, recurrence, morbidity and mortality.

In all, 401 patients (88 per cent) were operated on in outpatient facilities. Most of the remaining 56 (12 per cent) were hospital inpatients who were undergoing surgery for other more serious complaints at the same time. Of the 457 patients, 281 (61 per cent) had local anaesthesia with 'Managed Anaesthesia Care'; 161 (35 per cent) received general, eight (2 per cent) spinal and seven (2 per cent) epidural anaesthesia. It was possible for 308 of the patients (67 per cent) to return to active life within 1 week. Complications were haematoma (ten, of which three were explored), neuralgia (nine), seroma (eight), fever of uncertain origin (one), laryngospasm after general anaesthesia (one), missed hernia in a nearby Pfannenstiel incision (one) and later development of a femoral hernia (one). There were no deaths, wound infections or recurrences.

In conclusion, through the coordinated efforts of surgeons, anaesthetists, patients and support personnel, excellent results can be obtained when inguinal hernias are repaired in outpatients.

Large inguinal hernias may be treated under local anaesthesia

P. Chiotasso and M. Ketata, *CHU Purpan, Toulouse, France*

Surgeons are often reluctant to use a local anaesthetic technique when repairing large inguinal hernias. The purpose of this study was to test the efficacy of a local anaesthetic technique. The anaesthetic comprised 200 ml of 0·5 per cent lidocaine, injected subcutaneously in the groin and near the anterior superior iliac spine to cause a block of the genital branches of the ilioinguinal and genitofemoral nerves. The peritoneal sac was injected with lidocaine and not usually opened, but simply pushed back into the abdomen. All repairs were by the Shouldice technique. At the end of the procedure, the estimated size of the peritoneal sac, the presence of pain and the necessity of converting from local to general anaesthesia were recorded.

From January 1986 to December 1992, all patients having an inguinal hernia of >6 cm in diameter were included in the study. A total of 111 consecutive patients were defined as having a large hernia and operated on. Three patients were excluded, having had a general anaesthetic; among the remaining 108 cases (103 men, five women; mean age 59·8 (range 21–92) years) there were 60 right-sided hernias, 37 left-sided and 11 bilateral (of which four were also large), giving a total of 112 large hernias. The mean diameter of the sac was 8·6 (range 6–30) cm. Seven patients were operated on for recurrent large hernia. Nine patients described pain which necessitated repeated injection of local anaesthetic. No patient needed to convert from local to a general anaesthetic.

Audit of hernia repair with absorbable sutures

A.C. Dick, G.T. Deans, N. Eames and S.T. Irwin, *Belfast City Hospital, Belfast, UK*

A prospective study was conducted to determine whether inguinal hernia repair could be safely performed with absorbable suture materials over a 3-year period.

Analysis is available for 125 operations involving 119 patients. Mean follow-up was 21·8 (range 4–36) months, with 95 procedures monitored for more than 1 year. Shouldice repairs were performed in 94 per cent of cases. PDS and Vicryl accounted for 97 per cent and 98 per cent of sutures used for repair and skin closure respectively. Mean postoperative hospital stay was 2·1 (range 1–10) days, with no hospital infection and three haematomas. Review identified one infection, three further minor haematomas and five cases of wound or scrotal pain. There have been two recurrences.

Preliminary results suggest that hernia repair with absorbable sutures is comparable to traditional non-absorbable repair and warrants further investigation.

Herniography for occult hernia and groin pain

N. Eames, G.T. Deans, J.T. Lawson and S.T. Irwin, *Belfast City Hospital, Belfast, UK*

A prospective study was performed to determine the value of herniography in the assessment of occult hernia and unexplained groin pain.

All patients presenting with a history of unexplained groin pain with no clinically apparent hernia underwent herniography using a standard technique.

To date, 28 patients (24 men) have been studied for up to 2 years. There were no complications from the procedure. Herniography identified an occult hernia in ten patients, confirmed subsequently at surgery. A further ten patients were deemed to have been spared surgery because of the herniogram. At follow-up, of those with a negative herniogram, no patient has developed a hernia and symptoms have resolved in 87 per cent. The clinical finding of a cough impulse was associated with a hernia in only 33 per cent of herniograms.

Herniography is concluded to be a safe and reliable diagnostic technique in the management of occult groin pain.

Laparoscopic *versus* open inguinal hernia repair

G.J. Maddern, P. Devitt, P. Malycha and G. Rudkin, *Royal Adelaide Hospital, Adelaide, South Australia*

To evaluate the selective merits of laparoscopic inguinal hernia repair and conventional open hernia repair a randomized study was conducted.

All patients were day cases randomized to a standardized open hernia repair under local anaesthetic or a laparoscopic hernia repair under general

0007–1323/93/S038–02 © 1993 Butterworth-Heinemann Ltd

anaesthesia. Forty patients underwent open hernia repair (36 men, four women; median age 67 (range 23–81) years) and 40 laparoscopic repair (38 men, two women; median age 65 (range 20–80) years); ten of these patients had bilateral repairs.

Operating time for open hernia repair was 35 (range 25–70) min, for unilateral laparoscopic hernia repair 35 (range 30–80) min and for bilateral laparoscopic hernia repair 65 (range 45–80) min. Three open hernia repairs required conversion to general anaesthesia. One patient who underwent laparoscopic hernia repair was admitted for intra-abdominal bleeding and two who had open hernia repair required overnight admission for cardiac and psychological problems. Patients were discharged more quickly after open hernia repair (median time to discharge 142 (range 90–385) min) than laparoscopic hernia repair (median 220 (range 120–555) min; $P<0{\cdot}01$). Pain scores, activity scores and analgesia requirements were not significantly different during the 3 days after surgery in either group. Patients returned to work more rapidly after laparoscopic hernia repair (within 15·5 (range 5–57) days) than open hernia repair (30 (range 16–61) days). One hernia recurred, and there was one incidence of small bowel obstruction among patients who underwent laparoscopic repair.

It is concluded that both repairs can be performed successfully as day procedures although an earlier return to work is possible after laparoscopic herniorrhaphy.

Day-case inguinal hernia repair under local anaesthesia with sedation

J. Marin, A. Gallardo, C. Pérez, S. Marrero and M.D. Martinez, *Surgical Day Unit, Hospital El Tomillar, Sevilla, Spain*

During a 1-year period 270 unselected patients with inguinal hernia underwent repair as a day case under local anaesthesia in combination with intravenous propofol sedation. There were 239 men and 31 women with an age range 11 to 78 years. Of the 300 operations performed, 171 (57 per cent) were Bassini–Shouldice, 90 (30 per cent) were Lichtenstein, 20 (7 per cent) were Ferguson and 19 (6 per cent) used the Prolene plug.

A total of 248 (92 per cent) of the patients were discharged the same day with an average length of stay in the unit of 4 h. Morbidity rate was 9 per cent. There was no mortality. The large majority of the patients (92 per cent) preferred the outpatient method; 73 per cent were followed by a home care service, and 27 per cent by telephone.

In conclusion, ambulatory hernia repair is possible and patient acceptability is high. Local anaesthesia with propofol sedation is safe and decreases fear in anxious patients.

Polytetrafluoroethylene patches for incisional hernia repair

J. Miholic and R. Koller, *Chirurgische Universitätsklinik, Vienna, Austria*

Abdominal incisional hernias are a continuing challenge because of their high recurrence rate. This study compared the use of polytetrafluoroethylene (PTFE) patches with conventional methods of hernia repair.

The recurrence-free rate was assessed in 25 patients who had undergone repair of incisional hernias following midline laparotomy using PTFE patches (1 mm) and sutures, and in 70 cases operated on within the past 2 years by different teams in the same institution using conventional techniques (simple closure with a double flap method).

The recurrence-free rate was estimated according to Kaplan and Meier. The impact of putative risk factors such as age, body mass index (BMI), defect size, number of previous hernia operations, and PTFE patch *versus* conventional repair was tested for significance using the Wilcoxon test and Cox multiple proportional hazards regression.

Recurrences were observed at follow-up in one PTFE case and in 41 patients after conventional repair. The recurrence rate after 18 months estimated according to Kaplan and Meier was 5 per cent for PTFE cases and 63 per cent for controls ($P < 0{\cdot}001$). The recurrences were diagnosed after a median interval of 8 months. Of the 42 recurrences, 39 (93 per cent) were observed within the first 10 months. Age, BMI, defect diameter and number of previous hernia operations were not significantly associated with an increased risk of failure. A relative risk of 19·9 for conventional repair compared with PTFE was estimated by multiple regression ($P<0{\cdot}001$). After correction for PTFE *versus* control none of the other variables studied was of additional significance in the multivariate model. A significant reduction of recurrence was observed within a median follow-up of 10 months of incisional hernia repair using PTFE patches and sutures. Almost all failures were encountered within 10 months of surgery. The short-term results indicate a significant improvement in the repair of incisional hernia by the use of PTFE patches and sutures compared with conventional surgery.

Short-stay surgery for inguinal hernia: a prospective study in 500 consecutive patients

B. Millat, A. Fingerhut, M. Gignoux, J.-M. Hay, F. Yazdani and the French Associations for Surgical Research, *France*

The feasibility of discharge within 48 h after hernia repair was evaluated in 500 unselected consecutive male patients scheduled for uncomplicated unilateral non-recurrent inguinal hernia repair. Fifty-nine patients were found unsuitable for early discharge on medical or social grounds. Of 411 patients suitable for short stay, 84 refused an early discharge and 42 were retained because of local or general complications. Discharge within 48 h was possible in 304 patients; 51 of these underwent day-case surgery. Physically undemanding employment, lower age, low medical risks and local anaesthesia were factors related to acceptance and success of short-stay surgery. These factors may be interdependent.

Expanded polytetrafluoroethylene darn repair of inguinal hernia: 5 years' experience

V.G. Velmachos, D. Bastas, G. Garinis, N. Labrinaki, N. Kitromilis and C. Kakos, *'SOTIRIA' General Hospital, Athens, Greece*

The aim of the present study is to report 5 years' experience in the repair of inguinal hernia using a darn technique with an expanded polytetrafluoroethylene (ePTFE) suture. A total of 184 patients, 23–72 (mean 52·3) years old, underwent elective lateral inguinal hernia repair by a single consultant surgeon, 68 for direct and 116 for indirect inguinal hernias. The 'ePTFE darn' technique is the 'nylon darn' method (Moloney's technique) applied and modified in two areas; instead of the nylon suture, a monofilament suture is used, made from ePTFE. The transversalis fascia repair is reinforced by an ePTFE suture stitched in an interlacing manner, after reinforcement of the internal ring by the same suture. After operation suture sinus formation, deep sepsis and discharging haematoma was observed in one patient (0·5 per cent), superficial wound infection healed without complication in four patients (2·2 per cent) and there was an overall recurrence rate of 1·6 per cent (three patients). None of the patients developed symptoms of inguinal nerve entrapment, sinus formation or testicular swelling. The average postoperative hospitalization was 3·7 days. The ePTFE suture was tolerated well by the tissues, in all cases, with no local reaction. All patients were followed for 5 years after the operation.

It is concluded that, in ePTFE darn technique, the use of ePTFE suture is well tolerated by the tissues. The reinforcement of the transversalis fascia, stitched in an interlacing manner with the same material, reduces the recurrence rate.

Hydatid disease

Modification of capsule dome excision in the surgical treatment of hydatid disease of the liver: 15 years' experience

L. Iosifidis, S. Stylogiannis, S. Prigouris and M. Lorentziadis, *Evangelismos Hospital, Athens, Greece*

Surgical treatment of hydatid disease of the liver still presents several serious technical problems. Postoperative biliary fistula and infection are the main causes of prolonged hospitalization and are the most frequent cause of morbidity in this disease. Reported here are 158 cases of hydatid disease of the liver (97 involving the right, 23 the left lobe of the liver, 15 at the hilum, 61 with multiple locations), that were treated surgically during the past 15 years. The technique in use included: (1) wide excision of the dome of the capsule; (2) identification of open biliary ductules (which was assisted by the injection of water under pressure, through the cystic or common bile duct after cholecystectomy); and (3) avoidance of a drainage tube whenever possible.

The mean postoperative hospital stay was 8·7 days for 57 cases where no drainage tube was used and 15·4 days for 97 cases where a drainage tube was used. There were two (1·3 per cent) postoperative deaths and 15 (9·5 per cent) complications related to the operative procedure (biliary leakage in three cases, infection in nine, and gastric paresis in three).

It is concluded that this technique is efficient, easy to perform and a safe surgical treatment for hydatid disease of the liver, with major advantages compared with the standard techniques in use.

Surgical treatment of hydatid liver disease

S. Koçak, M. Dolapçi, U. Gür, C. Bumin and I. Ceylan, *Ankara University Medical School, Ankara, Turkey*

Surgical treatment of hydatid liver cysts is controversial. Experience with 189 patients is reported. Of these, 58 patients had complicated cysts before operation and the postoperative complication rate in these patients (53 per cent) was higher than in the remaining 131 patients (12·9 per cent) ($P < 0{\cdot}001$). Patients with uncomplicated cysts before operation were divided into four treatment groups.

Group	No.	Treatment	Complication rate	Mean hospital stay (days)
1	24	Hepatectomy or cystopericystectomy	2 (8)	10·1
2	45	Omentoplasty or primary closure	3 (7)	9·7
3	41	Tube drainage of the narrowed pericyst	9 (22)	19·1
4	21	Simple tube drainage	3 (14)	17·8

Values in parentheses are percentages

The complication rate in groups 1 and 2 was higher than in the other two groups ($P < 0{\cdot}008$), but there was no statistical difference in the complication rates between groups 1 and 2 ($P = 0{\cdot}88$) and groups 3 and 4 ($P = 0{\cdot}36$).

In conclusion, morbidity rates in hydatid cyst surgery are related to preoperative complications. Tube drainage should be abandoned if possible, and radical resections are not better than omentoplasty or primary closure. If the pericyst cavity is drained, it should not be narrowed.

0007–1323/93/S040–01 © 1993 Butterworth-Heinemann Ltd

Infection

Nosocomial infection after oncological surgery: results of a prospective study

S. Arnaud, G. Houvenaeghel, J.P. Brun, M. Inchauspe, D. Francon and J.L. Blache, *Institut J. Paoli–I. Calmettes, Marseille, France*

A prospective study investigating the incidence of nosocomial infection was conducted for oncological surgery. A total of 90 patients underwent a variety of surgical procedures.

The overall incidence of nosocomial infection was 61 per cent (55 infections) during the study period. This high rate is related to infections of varying seriousness. The most common infections occurred in the surgical wound (20 per cent), respiratory tract (19 per cent), urinary tract (10 per cent) and bloodstream (9 per cent).

The incidence for surgical wound infection was: clean (14 per cent), clean contaminated (18 per cent), contaminated (36 per cent) and dirty (12 per cent). This overestimates the rate for clean and clean contaminated procedures since only high-risk patients are usually hospitalized in the intensive care unit. The rate of nosocomial infection related to contaminated procedures remains high.

The ω-3 fatty acids increase myocardial contractility during endotoxic shock in the rat *in vitro*

J.S. Bagley, M. Walsh and R.A. Forse, *Aberdeen Royal Infirmary, Aberdeen, UK*

During Gram-negative sepsis there is myocardial depression believed to be mediated by the release of endotoxin. Dietary fish oils have attracted considerable interest in this context since their constituent ω-3 lipid fraction can modulate the release of cytokines and prostaglandins. Fifty-two Sprague–Dawley rats were fed 20 per cent beef tallow (saturated lipid) or 20 per cent fish oil for a period of 5 weeks after which they were infused with either 1 mg kg^{-1} endotoxin or saline control over 24 h. The animals were then killed and the force of contraction of the atrial heart muscle measured in response to the β_1-agonist isoprenaline in an *in vitro* organ bath. The ventricular portion of the heart was frozen and used later to measure the β_1 receptor density (B_{max}) and affinity (K_d) using radioligand binding. The *in vitro* bath data were analysed using curve-fit techniques to find the maximum response and the dose of isoprenaline inducing half maximum response (EC_{50}).

Endotoxin induced myocardial depression as illustrated by left shift in the dose–response curves (increased mean(s.e.m.) EC_{50}) in both endotoxin-treated groups (3·38(0·46) and 3·52(0·58) μg *versus* 1·79(0·35) and 1·73(0·42) μg, $P = 0·0058$ endotoxin *versus* saline, two-way ANOVA). In addition there was a significant increase in the maximum response to β_1-stimulation in the fish oil-fed animals (0·46(0·05) and 0·50(0·04) g *versus* 0·40(0·04) and 0·37(0·04) g, $P = 0·042$ fish oil *versus* beef tallow, two-way ANOVA). While there was no significant difference in B_{max} in the experimental groups, K_d was higher in the fish oil-fed animals (41(2) and 45(3) pM *versus* 40(3) and 40(3) pM, $P < 0·05$ fish oil *versus* beef tallow, two-way ANOVA).

The data suggest that a fish oil diet may be useful in the treatment or prophylaxis of septic shock where reduced responsiveness to β_1-adrenergic stimulation is a factor.

Endotoxin causes myocardial depression in the rat while causing β-adrenergic receptor up-regulation

J.S. Bagley, M. Walsh and R.A. Forse, *Aberdeen Royal Infirmary, Aberdeen, UK*

The myocardial depression of septic shock has a major impact on survival. Endotoxin is believed to mediate myocardial depression by impairing response to adrenergic stimulation. This study measured cardiac β-receptor (βIR) density in a low-dose endotoxin model of sepsis, and observed pulse and contractile response to isoprenaline (ISO) stimulation.

A total of 30 Sprague–Dawley rats were infused with 1 mg kg^{-1} of endotoxin (EN) or normal saline (NS) for 24 h via the jugular vein. The animals were then killed and the atria suspended in an *in vitro* organ bath. The ventricles were immediately frozen in liquid nitrogen for later crude plasma membrane preparation. The force of contraction and pulse rate were measured in response to increasing doses of ISO added to the bath. Ventricular membranes were bound with ^{125}iodocyanopindolol and the number (B_{max}) and affinity (K_d) of the βIR for each heart computed by Scatchard analysis.

ISO (μg l^{-1})	0	2·5	5	10	20
EN force (g)	0·38(0·03)	0·57(0·05)*	0·69(0·05)*	0·79(0·05)*	0·79(0·05)*
NS	0·46(0·02)	0·85(0·05)	0·97(0·05)	0·98(0·05)	0·97(0·05)
EN pulse	338(7·1)	423(10)	453(9·8)	476(9·7)	498(9·8)
NS	321(4·8)	416(9·4)	448(8·1)	471(7·1)	496(5·9)

Values are mean(s.e.m.). * $P < 0·05$ (EN *versus* NS, Student's *t* test)

There was a reduction in stimulated force of contraction after endotoxin. In contrast, the stimulated pulse rate was almost entirely unaffected by endotoxin. There was a significant increase in receptor density in the endotoxic animals (EN 84·6(5) fM g^{-1} *versus* NS 70·4(3) fM g^{-1}, $P = 0·04$), while K_d was no different. Thus, the cardiac depression was not explained by a reduction in receptor number. This makes receptor desensitization an unlikely cause of the myocardial depression found in this model. Indeed, there seems to be an up-regulating influence during endotoxin administration.

Respiratory infection following major surgery: a prospective audit

Y. Bazza, J. Bancewicz, C. Farrington and S. Hollis, *University Department of Surgery, Hope Hospital, Salford, UK*

Respiratory infection is known to be common following major surgery, but there have been few studies of this problem in the past 20 years. A prospective audit of postoperative complications following major surgery in a unit with a high proportion of complex cases was carried out. A total of 443 patients were studied: complications occurred in 128 (28·9 per cent) cases and there were 39 deaths (8·8 per cent). Respiratory infection accounted for 71·1 per cent of all complications and 38 per cent of deaths. Respiratory problems were the major reason for admission to the intensive care unit. Age, smoking, emergency surgery, severity of operation, use of a nasogastric tube, blood loss and poor preoperative physiological scores were significant risk factors. The use of respiratory stimulants had no protective effect. Laparoscopic surgery was associated with significantly fewer respiratory infections.

Pathogenic organisms were cultured in 74 cases, of which the commonest was *Haemophilus influenzae*. Infection occurred usually within 72 h of operation or when the patient resumed oral fluids.

Respiratory infection is the commonest complication of major surgery and accounts for a large proportion of postoperative deaths. It may be possible to reduce the incidence by reducing the use of nasogastric tubes. There may also be a place for narrow-spectrum antibiotic prophylaxis.

Perineal gangrene

J.C. Bernal-Sprekelsen, A. Vázquez, J. Garciá Romero, F. Puchades, F. Villalba, M. García-Botella, E. Artigues and R. Trullenque, *Hospital General Universitario de Valencia, Spain*

Perineal gangrene (PG) is still a serious infection despite aggressive surgery and modern antibiotics. In all, 21 patients (six women, 15 men) with a median age of 65 (range 44–85) years have been treated by the authors over the past 10 years, 19 of whom presented as emergency cases and two following postoperative complications. Routine and repeated bacteriological samples were taken until proven bacteriological cure. Aggressive surgical treatment was performed in all cases, although only two patients needed a colostomy. The most commonly used antibiotics were combinations of gentamicin and metronidazole or cefotaxime and metronidazole. The main causes of PG in the present series were anorectal

0007-1323/93/S041-02 © 1993 Butterworth-Heinemann Ltd

infection (nine cases) and urological disease (seven). Pathological conditions were associated with 90 per cent of cases of PG, the most prevalent being diabetes mellitus (72 per cent of cases) and peripheral vascular disease (18 per cent). The bacteriological study identified mixed infections in 90 per cent of cases. Bacteriological cure was proven in 72 per cent of the patients between days 7 and 15 after onset. Six patients (29 per cent) died, four from septic shock and two from pulmonary embolism. The mean(s.d.) hospital stay was 28(12) days. PG is a severe condition that requires early and extensive surgery, combined antibiotic therapy, thromboembolic prophylaxis and close follow-up.

Interleukins 6 and 8 are prognostic indicators of mortality in severe intra-abdominal sepsis

M.R.B. Keighley, D. Youngs and R.T. Patel, *Department of Surgery, Queen Elizabeth Hospital, Birmingham, UK*

Proinflammatory cytokines have been implicated in the adverse sequelae of patients with severe intra-abdominal sepsis (IAS), which is still responsible for a significant number of deaths and the outcome is not readily predictable. The Acute Physiology and Chronic Health Evaluation (APACHE) II score of predicting outcome has several drawbacks.

This study aimed to compare the APACHE II score with levels of plasma cytokines and circulating endotoxin to predict outcome of severe IAS. A total of 41 patients were studied within 24 h of onset of the sepsis syndrome and at serial time points. There were 19 deaths (46 per cent). At enrolment, raised plasma interleukin (IL) 6 levels were detectable in all patients with sepsis and were >2000 pg ml^{-1} in 15 of the 19 who died (χ^2 = 23·7, P<0·001). IL-8 levels were >2000 pg ml^{-1} in 11 of those who died (χ^2 = 11·2, P < 0·001). The specificity of plasma IL-6 and plasma IL-8 levels in predicting mortality with a cut-off at 2000 pg ml^{-1} was 95 and 91 per cent respectively and these are better predictors of adverse outcome compared with the APACHE II score. Levels of tumour necrosis factor, IL-1β and endotoxin did not correlate with death. Raised levels of plasma IL-6 and IL-8 not only clearly demonstrate an important role in sepsis but if >2000 pg ml^{-1} relate to a poor prognosis.

IL-6 and IL-8 determination on a routine basis may help in planning future strategies to decrease the mortality associated with sepsis.

Septic shock in rats: tumour necrosis factor–prostaglandin E_2 modulation under intravenous somatostatin perfusion

J.I. Landa, K. Llanos, M. Grau, J.A. Sanchez, R. Gomez, J.M. Ramia and J.L. Balibrea, *Centro de Investigación, Univ. Complutense, Madrid, Spain*

The objective of this study was to determine whether somatostatin can modify the production of tumour necrosis factor (TNF) and plasma prostaglandin (PG) E_2 in septic shock.

Forty male Wistar rats of mean(s.d.) weight 360(10) g each received 2·2 × 10^{-7} units bacille Calmette–Guérin intraperitoneally. After 15 days, 0·5 mg kg^{-1} lipopolysaccharide B (*E. coli* 0127:B8) was given intravenously. Twenty rats were perfused intravenously with physiological serum at 0·1 ml h^{-1} for 24 h, the other 20 with intravenous somatostatin at 2 μg h^{-1}. Animals were killed in groups of ten (five from each experimental arm) at various times. In each rat, measurements were made of TNF and PGE_2, and histological analysis was performed.

All animals given physiological serum developed diarrhoea. Histological examination showed slight oedema of the lamina propria with an increased number of cells. Rats given intravenous somatostatin did not develop clinical or histological changes.

	Time after treatment (h)			
	1·5	3	6	24
TNF				
Serum	2220(694·5)	820(253·7)	0	0
Drug	770(101·9)*	0	0	0
PGE_2				
Serum	388·7(50·9)	304(31·8)	160·6(29·4)	51·8(7·7)
Drug	2152·8(1156·9)*	1365·3(591·6)*	676·3(330)*	82(22·5)

Values are mean(s.d.). *P < 0·001 (somatostatin *versus* serum)

Somatostatin inhibits the production of TNF in this animal model of septic shock, and increases levels of PGE_2.

Laparoscopic procedures

Pulmonary function after laparoscopic and open cholecystectomy

A. Agnifili, S. Guadagni, I. Ibi, R. Verzaro, P. Gola, F. Gianfelice, G. Turco, E. Mancini, G. Carducci, M. Marino and G. De Bernardinis, *Department of Surgery, University of L'Aquila, L'Aquila, Italy*

Upper abdominal surgery causes postoperative changes in pulmonary function. Few studies have been reported concerning pulmonary function after laparoscopy. Two groups of patients with gallstones treated randomly by either laparoscopic cholecystectomy (LC) ($n = 25$) or by open cholecystectomy (OC) ($n = 25$) were compared. Each group was homogeneous for age, sex and American Society of Anesthesiologists status. The technique of anaesthesia was identical in all patients. Respiratory function was analysed by spirometry, clinical examination and chest radiography. Forced vital capacity (FVC), peak expiratory flow (PEF), forced expiratory volume in 1s (FEV$_1$), mid-expiratory flow at 50 per cent of FVC (MEF$_{50}$), and mid-expiratory flow at 25 per cent of FVC (MEF$_{25}$) were assessed before and after operation until these parameters returned to normal values. In the LC group the ventilatory data remained abnormal for not more than 48 h. In the OC group it was often not possible to perform respiratory evaluation in the first 48 h because of discomfort and it took 5–7 days for respiratory function to return to normal.

These results demonstrate that pulmonary function after laparoscopy recovers faster than after laparotomy.

How minimally invasive is laparoscopic cholecystectomy?

A.Ö. Aktan, O. Büyükgebiz, C. Yeğen and R. Yalin, *Marmara University Hospital, Istanbul, Turkey*

Postoperative serum cortisol, growth hormone and insulin responses were determined in two groups to determine the extent of surgical stress induced by open ($n = 20$) and laparoscopic ($n = 20$) cholecystectomy. The groups were matched for age, sex ratio and duration of surgical procedures. The group undergoing open cholecystectomy revealed significant elevations of serum cortisol, growth hormone and insulin levels 8 h after surgery ($t = 1{\cdot}94$, $P = 0{\cdot}03$; $t = 1{\cdot}8$, $P = 0{\cdot}03$ and $t = 2{\cdot}7$, $P = 0{\cdot}005$). In the group undergoing laparoscopic cholecystectomy, only the increase of growth hormone was significant ($t = 2{\cdot}01$, $P = 0{\cdot}03$). In both groups cortisol and growth hormone levels gradually returned back to control values 48 h after surgery. The increased insulin levels persisted in both groups 24 and 48 h after surgery. It is concluded that acute surgical stress induced by open cholecystectomy is more severe than that caused by laparoscopic surgery as reflected by serum hormone determinations. The hormonal convalescence rate was similar for both groups. It appears that laparoscopic cholecystectomy is minimally invasive as far as the hormonal responses are concerned.

New technologies in laparoscopic cholecystectomy: ultrasonography, Cusa and argon coagulator

A. Benevento, G. Carcano, A. Cuffari, P.F. Interdonato, M. Bianchi and R. Dionigi, *University of Pavia in Varese, Varese, Italy*

Laparoscopic cholecystectomy represents the 'gold standard' for treatment of symptomatic gallstones and gallbladder polyps. Increasing experience with this technique has broadened the indications to include acute cholecystitis and chronic sclerotic cholecystitis. In such conditions pathological modifications of the anatomy of the biliary tree could enhance the risk of injuring the common bile duct during isolation of the cystic duct, or that of bleeding from the hepatic bed or from an unidentified cystic artery.

In performing simple cholecystectomy the presence of anatomical variations of the biliary and arterial trees and the possibility of choledochal gallstones, descended from the cystic duct during laparoscopic manoeuvres, should be considered. Laparoscopic cholangiography is not widely performed due to the potential risk of further choledochal injuries and the long time usually required to perform this procedure. The laparoscopic 10-MHz Aloka probe is used to perform safe, rapid and reliable ultrasonographic examination of the triangle of Calot and hepatoduodenal ligament during laparoscopic cholecystectomy. The cystic duct, cystic artery and common bile duct are evaluated before and after gallbladder removal, to exclude potential hazards in the biliary tree and to verify the absence of residual choledochal stones.

The Cusa dissector facilitates the careful anatomical preparation of the cystic duct and cystic artery. Accurate dissection of the gallbladder from the hepatic bed is also performed with this probe such that even minimal vessels are accurately spared. The argon laser is then used to allow a safer haemostasis of the liver surface.

The high cost of this technique is outweighed by the absence of even minimal bleeding and by the safety in sparing the hazard of biliary tree injury.

Laparoscopic splenectomy

G.B. Cadière, J. Bruyns, J. Himpens, P. Van Alphen, A. Efira and S. Dewit, *Hôpital Universitaire Saint-Pierre, Brussels, Belgium*

Seven patients were treated by laparoscopic splenectomy for idiopathic thrombocytopenic purpura between January and December 1992. Two were human immunodeficiency virus seropositive.

There were two men and five women with an average age of 38 years. All presented a refractory or relapsing idiopathic thrombocytopenic purpura (average platelet count 19 500 mm^{-3}). The splenic volume was normal in all cases.

Before operation, pneumococcal vaccine, human immunoglobulins and platelets were given to raise the number of platelets (average 111 800 mm^{-3} before operation). Five trocars were used. The peritoneal layer covering the hilum of the spleen was divided with a coagulating hook. The short gastric vessels were isolated, clipped and divided. The hilar artery and vein were divided with an Endo-GIA stapler in the first case and ligated in the six other cases. Removal of the spleen was possible in a plastic bag that was partially exteriorized. The spleen was crushed with a forceps and removed piecemeal or aspirated with a powerful suction device. A drain was left in the upper quadrant in the first six patients.

No conversion to laparotomy was necessary. There were no peroperative or postoperative complications. Average operating time was 4 h. Average blood loss was estimated at 262 ml. Active bowel sounds were present and oral intake was allowed on the first day. Drains were removed on the second day (average drainage was 128 ml). The platelet count was normal on the second day (average 258 000 mm^{-3}). Mean hospital stay was 3 days. No complications were seen after 1 month of follow-up.

In conclusion, laparoscopic splenectomy is feasible for spleens of normal volume. This approach is to the patients' benefit.

Prospective study of laparoscopic proximal gastric vagotomy

G.B. Cadière, J. Bruyns, J. Himpens, P. Van Alphen, D. Urbain and G. Hubloux, *Hôpital Universitaire Saint-Pierre, Brussels, Belgium*

Between April 1992 and February 1993, 30 consecutive patients (26 men and four women, mean age 38 (range 19–65) years) underwent proximal gastric vagotomy (PGV) without pyloroplasty by strictly laparoscopic means. The mean body mass index was normal at 22·6 (range 17–30) kg m^{-2}. No patient had associated systemic disease. Two patients had undergone previous gastric surgery (one pyloroplasty and one closure of a perforated ulcer). Six others had undergone lower abdominal procedures. Twenty-three patients were operated on electively, because of chronic ulcer disease alone (16 cases) or associated with gastro-oesophageal reflux disease (seven). Seven patients were operated on as an emergency for perforated peptic ulcer. Thirteen patients underwent fundoplication during the same procedure; seven underwent associated perforated ulcer closure and one cholecystectomy. The procedure consisted of selective severance of all fibres originating from Latarjet's nerve supplying the lesser gastric curvature, cephalad of the crow's foot, care

0007–1323/93/S043–07 © 1993 Butterworth-Heinemann Ltd

being taken not to injure the main trunk. Dissection included the distal 8-cm length of oesophagus in all cases.

There was no perioperative mortality or morbidity. There were no conversions to open laparotomy. Mean operative time was 172 (range 90–270) min. Postoperative stay was 2 days in the elective group and 5 days in the emergency group. This difference was due to prolonged intravenous antibiotic therapy and gastric suction in the perforated ulcer group (5 days *versus* 1 day in the elective group).

During follow-up (range 1–10 months), 14 of 17 patients were symptomless (Visick grade 1 or 2). Three patients were staged as Visick 3, because of ulcer pain (one case), heartburn (one), or regurgitation (one). Postoperative gastroscopy was performed on 11 patients, eight being normal. In one patient, gastritis and symptomless oesophagitis was observed, one had a healing duodenal ulcer and one an erosion on the lesser curvature due to a migrated clip.

It is concluded that laparoscopic PGV is feasible and carries a low morbidity rate. It can be combined with the laparoscopic treatment of perforated ulcer. However, long-term functional results must be awaited.

Preliminary results of laparoscopic repair of perforated duodenal ulcer

N. Cheshire, A. Darzi, N. Menzies-Gow, P.J. Guillou and J.R.T. Monson, *St Mary's Hospital, London, UK*

Laparoscopic repair of perforated duodenal ulcers offers several advantages. Laparoscopy confirms the diagnosis, and the absence of an upper abdominal incision in a frequently frail and elderly group of patients allows early mobilization, reducing postoperative complications.

A series of ten consecutive patients with perforated duodenal ulcer underwent operation using a laparoscopic technique. Mean age was 62 years. All patients had a laparoscopic omental patch repair (sutured or stapled) with peritoneal washout.

Repair	n	Operating time (min)	Hospitalization (days)
Stapled	3	25*	5
Sutured	7	110	6

Values are means. $^*P < 0·01$ (Student's t test)

There were no deaths. One patient developed a chest infection after surgery. Early mobilization and discharge was a notable feature.

In conclusion, laparoscopic repair of perforated duodenal ulcer is a safe and effective technique. The stapled method is rapid and obviates the requirement for tedious and time-consuming intracorporeal or extracorporeal suturing.

Shoulder pain after laparoscopic surgery: reason and consequence

P. Chiotasso, J.P. Avinzac and G. Istvan, *CHU Purpan, Toulouse, France*

After laparoscopic surgery, patients occasionally describe a transient right shoulder pain of variable intensity. The aim of this study was to evaluate the role of the residual pneumoperitoneum and its consequences on postoperative pulmonary function. At the end of the surgical procedure, the pneumoperitoneum was blown out by careful manual compression of the abdomen. Abdominal radiography was performed on the first day after surgery with patients in an upright position. The area of pneumoperitoneum in the right and left subdiaphragmatic spaces was measured. The shoulder pain was assessed by means of a questionnaire. All patients had pulmonary function tests on the day before surgery, and the first postoperative day.

From March 1992 to November 1992, 24 patients (13 women, 11 men; mean age 50·1 (range 21–80) years) having laparoscopic surgery, entered the study. On the first postoperative day, four patients (group 1) experienced right shoulder pain (three also had left shoulder pain); 20 patients (group 2) had no pain. The mean (range) surface of the pneumoperitoneum was 16·25 (14·29–21·87) cm^2 in group 1 and 0·77 (0–5·94) cm^2 in group 2 ($P = 0·0048$, t test). There was a mean decrease in forced vital capacity on the first postoperative day of 37·1 per cent (4·04 falling by 1·49 litres) in group 1, but only 16·4 per cent (3·4 falling by 0·55 litres) in group 2; however, this difference is not statistically significant ($P = 0·16$, t test).

It is concluded that after laparoscopic surgery the shoulder pain is related to a residual pneumoperitoneum and is probably responsible for a postoperative decrease in forced vital capacity.

Intraperitoneal onlay mesh technique for laparoscopic groin herniorrhaphy: preliminary results in 123 cases

J.P. Cossa, H. Johanet, P. Mongredien, J.Y. Roussel, J.Y. Le Goff, J.P. Marmuse and G. Benhamou, *Hospital Bichat-Claude Bernard, Paris, France*

Primary groin hernia repair using a prosthetic mesh to create a new inguinal floor is an increasingly popular technique. In the present study a transperitoneal laparoscopic approach was used; results are presented which evaluate operating time, postoperative pain, length of hospital stay and work interruption.

Between May 1992 and February 1993, 123 groin hernias have been repaired in 116 patients. The technique involves laying a polypropylene mesh over the myopectineal orifice (after reduction of the sac and separation of the vas and spermatic vessels) and securing it in place with staples. In total, 100 men and 16 women (mean age 50 (range 19–85) years) have been treated. In seven cases, the hernia was bilateral. The hernia was inguinal in 119 cases, femoral in four and both inguinal and femoral in two. Inguinal hernias were categorized by the Nyhus classification: 61 type II, 49 type IIIA, four type IIIB, and seven type IV.

The mean operating time was 73 (range 25–180) min. Four conversions to open surgery were performed: two because of bowel adherence in the sac and two because of intolerance of the pneumoperitoneum under an epidural anaesthetic. There were no operative complications. Forty-five patients required no postoperative analgesia; 50 needed analgesics only for 24 h after surgery. Mean hospital stay was 3·3 (range 0–12) days. One patient was readmitted 14 days after operation because of an infected haematoma. To date, 92 patients have been examined with a minimum follow-up of 1 month; all have normal activity including 25 heavy-duty workers.

In conclusion, laparoscopic groin hernia repair seems to be a reliable, safe and easily reproducible technique. Postoperative comfort should allow early recovery of professional activity. Even though results are encouraging, a longer follow-up is necessary fully to evaluate the effectiveness of this approach.

Acute-phase response after laparoscopic and open cholecystectomy

L. Dominioni, A. Benevento, G. Carcano, A. Chiappa and R. Dionigi, *University of Pavia, Varese, Italy*

The aim of this work was to assess the acute-phase alterations of blood lymphocyte subsets, plasma proteins and selected hormones in patients undergoing laparoscopic cholecystectomy (LC) and open cholecystectomy (OC) to compare the effects of surgical trauma resulting from the two procedures.

A total of 57 well nourished candidates for cholecystectomy for uncomplicated cholelithiasis, with no indication for common bile duct exploration, were prospectively randomized into two groups undergoing either LC (n = 30) or OC (n = 27), using the same type of general anaesthesia. In each patient blood samples were drawn before operation and at various time intervals after surgery to determine the concentration of lymphocyte subsets CD3, CD4, CD8, OKDR and the plasma levels of C-reactive protein (CRP), cortisol and prolactin.

The duration of operation and general anaesthesia was similar in the two patient groups. The mean(s.d.) postoperative hospital stay was shorter after LC than after OC (3·1(0·5) *versus* 7·1(1·6) days; $P < 0·001$). After OC a significantly greater ($P < 0·05$) depression of blood CD3 and OKDR counts was found, as compared to LC. Moreover, OC patients showed a significantly greater postoperative acute-phase increase of plasma CRP

($P<0{\cdot}001$), of cortisol ($P<0{\cdot}05$) and of prolactin blood levels ($P<0{\cdot}001$).

The significantly lower acute-phase responses of immunological and metabolic parameters observed after LC support the concept that the laparoscopic procedure is less traumatic.

Laparoscopic surgery for benign colorectal disease: a multicentre prospective study

J. Etienne, C. Jehaes, A. Kartheuser and A. de Neve de Roden for the BGES, *St-Luc Hospital, Brussels, Belgium*

Laparoscopic colectomy appears more controversial than other laparoscopic procedures. The aims of this prospective study were to evaluate the feasibility of laparoscopic colorectal surgery in benign disease, and to assess the operative and early postoperative outcome in a homogeneous group of patients.

Between May and November 1992, 35 patients (24 women, 11 men) were included in the study. Mean age was 50 (range 17–81) years. Nineteen patients had undergone previous abdominal surgery. Indications included Crohn's disease (11 patients), colonic polyps (nine), complications of diverticulosis (nine), colonic inertia (four) and sigmoid volvulus after initial decompression (two). In six patients a conversion to open laparotomy was performed (one with abscess, one adhesion, one cancer, one Crohn's fistula, one obesity and one for anatomical reasons).

Laparoscopic operations performed included sigmoid colectomy (nine), ileocolic resection (seven), left hemicolectomy (five), right hemicolectomy (four), total colectomy with ileorectal anastomosis (three), and colotomy for polypectomy (one). The specimen was removed through a small abdominal incision (mean 5 (range 3–10) cm length) in 26 cases and there were three transanal extractions of the resected colon. The mean length of specimens was 39 (range 15–105) cm. Anastomosis was performed either extracorporeally (16 patients) or intracorporeally (13). There was no mortality, while morbidity rate was 26 per cent. Mean time to pass flatus was 3 (range 1–7) days and to resume a soft diet 5 (range 3–7) days. The mean hospital stay after surgery was 9 (range 5–23) days.

These results indicate that laparoscopic colorectal surgery is safe and feasible in selected patients, even when previous abdominal surgery has been performed.

Laparoscopic highly selective vagotomy for duodenal ulcer disease

B. Helms and H.-D. Czarnetzki, *Klinikum Rostock Suedstadt, Rostock, Germany*

The great success of medical ulcer treatment argues for conservative therapy, but continuous long-term drug therapy requires patient compliance and is expensive. Therefore a minimally invasive, acid-reducing operation may have a place in ulcer management. Highly selective vagotomy (HSV) has been evaluated in large studies over a long period. The results are acceptable, with low rates of complications and the absence of bowel resection or opening being powerful arguments. Laparoscopic HSV is a difficult operation.

Fifteen patients with good results are presented. Operation time was from 2·6 to 3·75 h. On the second day after operation the patients were pain-free and ate normally. Normal leisure activities were resumed after 1 week as a rule. There were no major complications, only two infected trocar sites. Acid output reduction to 30 per cent of normal was shown in six patients 6 months after operation, but this is too short to assess long-term effects. Physiologically, HSV has minimal effects on gastric vagal innervation, and does not cause gastric outlet obstruction. There is no place for truncal vagotomy in the therapy of uncomplicated duodenal ulcers. The Taylor procedure may only be a compromise for difficult laparoscopic cases. Precisely performed laparoscopic HSV with cutting of the nervus criminalis on the oesophagus and the vagal branches up to the crow's foot has an acid output reduction comparable to conventional surgery. Closure of the serosa of the lesser curve prevents adhesions, allowing subsequent fundoplication for reflux. Laparoscopic HSV is a realistic alternative to long-time drug therapy, being cheaper and a permanent cure.

Laparoscopically assisted colorectal surgery

M.J. Hershman, *Royal Liverpool University Hospital, Liverpool, UK*

The role of laparoscopic colorectal surgery is currently being evaluated. Fourteen patients (median age 57 years) underwent laparoscopically assisted colorectal surgery. The operations performed were: right hemicolectomy (Crohn's disease, $n = 4$; carcinoma, $n = 4$); left hemicolectomy (carcinoma, $n = 2$); subtotal colectomy (colitis, $n = 1$; colonic inertia, $n = 1$); and abdominoperineal excision ($n = 2$). In all cases the colon was mobilized laparoscopically and delivered through a small incision for resection and/or anastomosis. In one patient with caecal carcinoma laparoscopy was converted to laparotomy because of anatomical uncertainty. Median duration of surgery was 135 min and median postoperative hospital stay 5 days. In all the patients with carcinoma, excision margins were clear; a median of eight lymph nodes were excised. These data suggest that laparoscopic surgery will play an increasing role in the treatment of colorectal disease. However, the outcome of surgery for colorectal malignancy will be apparent only at follow-up.

Laparoscopic inguinal hernioplasty with a reinforced polyester prosthesis

J. Himpens, G.B. Cadière, J. Bruyns and P. Van Alphen, *Hôpital Universitaire Saint-Pierre, Brussels, Belgium*

Laparoscopic hernioplasty has been performed for 3–4 years. Reports of complications such as nerve entrapment, intestinal obstruction and recurrence are numerous. An attempt has been made to obviate these problems by using a different type of prosthesis made of a soft reinforced polyester mesh which has proven inertness. It contains a frame of superelastic metal (Nitinol), which speeds up the placement procedure and also provides stability. Circumferential fixation is not necessary, one- or two-point fixation being sufficient.

Between 1 January 1992 and 28 February 1993, 85 patients with 108 hernias were treated using this new prosthesis. No cases of nerve entrapment were encountered. There was no clinical evidence of intraperitoneal migration of the mesh. One patient had a clinical recurrence. During the same period, 41 patients with 61 hernias were treated using a preperitoneally placed polypropylene prosthesis, stapled on its circumference, care being taken not to place any staples caudad of Poupart's ligament. Again, there was one recurrence. However, three cases of nerve entrapment and two of intraperitoneal migration with subsequent small bowel obstruction (at 4 and 6 months) were encountered. Five reoperations were necessary to resolve these complications.

This experience indicates that laparoscopic inguinal hernioplasty using a reinforced self-expanding polyester mesh has a low complication rate.

Laparoscopic appendicectomy: advantages over open operation

N. Hunt, A. Darzi, A.D.K. Hill, P.D. Carey, P. Super, P.J. Guillou and J.R.T. Monson, *St Mary's Hospital, London, UK*

Recent reports have suggested that laparoscopic appendicectomy (LA) confers some advantages over open appendicectomy (OA). In a prospective study results in the first 75 patients undergoing LA were compared with those in the last 50 patients who underwent OA. All patients had signs and symptoms suggesting acute appendicitis. The mean age was 30 (range 9–74) years. Postoperative recovery, complications and return to normal activities were compared in the two groups.

	LA ($n = 75$)	OA ($n = 50$)
Operating time (min)	70	46
Hospital stay (days)	2·8	4·2
Complications	10	7
Negative rate (%)	24	27
Return to normal activity (weeks)	2·3	4·2

Although the overall complications were similar in the two groups, three patients developed major postoperative complications after LA. These included small bowel perforation due to a diathermy injury, right iliac fossa haematoma and small bowel obstruction. Hospital discharge was significantly shorter after LA. Follow-up showed a shorter bed stay at home and faster return to normal activity after LA.

In conclusion, these data demonstrate that LA is superior to OA in terms of hospital stay and return to normal activity, but the potential for significant postoperative complications is a concern.

Laparoscopic *versus* open cholecystectomy

M. Krawczyk, K. Zieniewicz, B. Najnigier, W. Patkowski and P. Nyckowski, *Medical Academy, Warsaw, Poland*

Two groups of 300 patients, who had undergone laparoscopic or open cholecystectomy, were studied to compare the effectiveness and complications of the two procedures. The groups were not randomized. Clinical findings in both groups were similar (laparoscopic and open cholecystectomy respectively): recurring biliary colic 59·6 and 50·7 per cent; chronic cholecystitis 28·0 and 34·7 per cent; gallbladder hydrops 7·6 and 8·9 per cent; and empyema 4·8 and 5·7 per cent. No patient in either group required reoperation. Bile duct injury occurred in one patient from each group. Postoperative bile leak affected one and four patients undergoing laparoscopic and open procedures respectively. Wound infection occurred in two patients after laparoscopic and nine after open cholecystectomy. There were no pulmonary complications after laparoscopic cholecystectomy but 19 per cent after open cholecystectomy. Average hospital stay was 2·1 and 9·6 days after laparoscopic and open procedures respectively.

It is concluded that laparoscopic cholecystectomy is a safe procedure, has a low morbidity rate and decreases the cost of treatment. Laparoscopic cholecystectomy should replace open cholecystectomy.

Laparoscopy in right lower quadrant pain in young women: a controlled study

J. Lauroy, G. Champault, A. Belhassen, P. Olivares, N. Rizk and P. Boutelier, *Department of Surgery, Hôpital J. Verdier, Bondy, France*

Of 187 patients presenting during 1 year with abdominal pain, 66 were young women with non-specific right lower quadrant pain.

These patients were randomized in two groups of 33 patients each. One group underwent a diagnostic laparoscopy, the other group had conventional diagnostic investigations only. Laparoscopy enabled a diagnosis to be made in 97 per cent of cases and the simultaneous treatment of acute appendicitis in two-thirds of the patients in that group. The conventional group had only a 28 per cent accurate diagnosis. The mean hospital stay of the laparoscopy group was significantly less than that of conventionally treated patients ($P = 0·01$).

Arguments of cost–efficiency and of healthcare favour laparoscopy as the investigation of first choice in non-specific abdominal pain in young women.

Laparoscopic treatment of small bowel obstruction: results in 25 patients

H. Levard, J. Mouro, L. Schiffino, M. Karayel, G. Berthelot and F. Dubois, *HIUP, Paris, France*

Laparoscopic treatment of small intestinal obstruction could be associated with immediate advantages and it might be expected that the recurrence rate will be decreased because of the diminution in the number of wound scars.

Between September 1989 and September 1991, 25 patients (16 men and nine women; mean age 53·8 years) underwent laparoscopy for acute small intestinal obstruction. These patients had previously undergone a total of 43 laparotomies, on average 13 years before. Thirteen patients had undergone one previous laparotomy, five had two previous laparotomies, four had three, and two had four. One patient had no previous history of surgery.

Laparoscopic treatment was possible in nine patients including three with bands and six with more generalized adhesions. In 16 patients, laparoscopy had to be converted to open laparotomy, 13 immediately and three secondarily. Immediate failure was due to the impossibility of finding and/or treating the cause in seven cases, intestinal injury in four cases, intestinal necrosis which required resection in one, and missed right colonic carcinoma in one. The causes of secondary failure were incomplete liberation of the adhesions (one case), recurrent volvulus (one), and missed left colonic carcinoma (one). The mean hospital stay and the duration of postoperative ileus were both significantly shorter in the laparoscopy group than in the laparoscopy plus laparotomy group ($P < 0·001$). Two complications, with one death, occurred in the laparoscopy plus laparotomy group.

In conclusion, laparoscopic treatment of intestinal obstruction is possible but in fewer than half of cases. Failures are related to the difficulty with which the abdomen may be explored. Laparoscopic treatment should not be pursued if difficulties arise. Its role in the prevention of recurrence is not yet possible to assess.

Laparoscopic abdominoperineal resection of the rectum: assessment of adequacy of excision

C. Lewis, A. Darzi, R. Goldin, N. Menzies-Gow, P.J. Guillou and J.R.T. Monson, *St Mary's Hospital, London, UK*

In laparoscopic abdominoperineal resection of the rectum (Lap-APR) an abdominal incision is completely avoided as the tumour is delivered through the perineal incision. The view provided in the pelvis by laparoscopy is significantly better than at laparotomy and allows excellent anatomical definition and meticulous dissection. In the present study, adequacy of excision was compared in patients undergoing Lap-APR ($n = 7$) with those undergoing open abdominoperineal resection (Op-APR) ($n = 16$). In all patients the procedure followed malignant disease; Duke's staging and Jass score were similar in both groups. The tumour was not macroscopically fixed in any patient.

	Lap-APR ($n = 7$)	Op-APR ($n = 16$)
Radial margin (cm)	0·5 (0·1–1·5)	0·9 (0·1–3·6)*
Radial margin involved (no. of patients)	0	2*
Median (range) no. of nodes	9·5 (6–14)	6 (1–14)*

**P* not significant (Mann–Whitney *U* test)

Nodal harvest and the extent of radial excision were similar in both groups. However, two patients in the open group had microscopic radial margin involvement although they were macroscopically clear at surgery. Although long-term follow-up is required to monitor local cancer recurrence, laparoscopic rectal dissection appears as effective as open surgery and may allow a more precise assessment of excision margins.

Laparoscopic cholecystectomy under epidural anaesthesia: an ideal combination of minimally invasive surgery and minimally invasive anaesthesia

G.W. Lexer, G.Ch. Lexer, B. Lexer and F. Lehofer, *Krankenhaus Friesach, Friesach, Austria*

Epidural anaesthesia has been reported to have beneficial effects in surgical procedures. In the present study the outcome of using epidural anaesthesia in patients undergoing laparoscopic cholecystectomy was evaluated. A total of 61 unselected patients (39 women, 22 men), mean age 46·9 (range 20–86) years, mean weight 71·7 (range 46–125) kg with symptomatic gallstone disease underwent laparoscopic cholecystectomy under epidural anaesthesia. Ventilatory measurements and arterial blood gas analyses were performed before operation in the horizontal supine position with analgesia applied at the T5–T10 level, after intra-abdominal insufflation of carbon dioxide for pneumoperitoneum and at the end of the procedure. During the procedure patients were maintained with an oxygen insufflation of 3 litres per min through an anaesthetic face mask. Intraoperative sedation was given if necessary. No significant changes in minute ventilation or arterial blood gas measurements were observed. Furthermore, no intraoperative or postoperative anaesthetic or surgical complications occurred. Our experience demonstrates that epidural anaesthesia is safe to use in conjunction with laparoscopic cholecystectomy and is an acceptable anaesthetic technique even for unselected patients.

Laparoscopic peroperative cholangiography

B. Mansvelt, C. Bertrand, A. Pourbaix and A. de Neve de Roden, *Jolimont Hospital, Haine Saint-Paul, Belgium*

Between January 1990 and October 1992, 371 laparoscopic cholecystectomies were performed. From July 1990, 309 patients had attempted peroperative cholangiography (POC). The technique was successful in 277 cases (90 per cent). Of these, 214 patients showed no clinical or biological symptoms of common bile duct (CBD) stones. Seventeen CBD stones (7·9 per cent) were demonstrated by POC. Nine of them were detected by preoperative intravenous cholangiography (IVC) and eight (3·7 per cent) were thus unsuspected. Among the 63 other patients with symptoms of choledocholithiasis, 11 (17 per cent) had a CBD stone shown by POC. Five (7·9 per cent) were not revealed by IVC. In conclusion, POC was successfully attempted in 90 per cent of cases, and allowed detection of 5 per cent of CBD stones unsuspected by preoperative IVC.

How to avoid complications in laparoscopic cholecystectomy

M. Morino, V. Festa, C. Garrone and P. Simone, *Clinica Chirurgica, University of Turin, Italy*

Laparoscopic cholecystectomy is widely accepted as the treatment of choice for cholecystolithiasis. Between March 1990 and December 1992, 750 laparoscopic cholecystectomies were performed. The conversion rate to open surgery was 2·5 per cent (19 patients). One patient died (0·13 per cent). There were seven (0·9 per cent) major and eight (1·1 per cent) minor complications, which were due to four risks specific to the procedure: blind introduction of the first trocar (one perforation of the colon), main bile duct injury (one), clip migration (one biliary fistula) and injuries produced by electrocauterization (one duodenal perforation, one perforation of the colon). Each of these risks can be avoided by meticulous application of the following rules: use of a Hasson cannula, routine intraoperative cholangiography, ligation of the cystic duct in the presence of inflammation, and avoidance of monopolar coagulation in dissecting Calot's triangle. Conversion to open surgery should usually be undertaken as the result of a difficult or anatomically unclear dissection. Observation of these rules enabled a series of 200 consecutive laparoscopic cholecystectomies to be performed without any major complications.

Laparoscopic cholecystectomy: a prospective evaluation of postoperative comfort, hospital stay and interruption of activity in an 'all-comers' population

S. Msika*, C. Rey and G. Leseche*, *Services de Chirurgie Digestive, *Centre Hospitalier Henri IV, Meulan and Clinique Sainte Marie, Vernon, France*

The development of laparoscopic cholecystectomy (LC) in the treatment of gallstones is explained by its theoretical reduction of pain, shorter hospitalization and quicker recovery after surgery. The aim of this prospective study was to evaluate duration of pain, analgesic consumption, hospital stay, and return to work and preoperative physical activities in patients undergoing LC.

Between January and December 1992, 103 patients (84 women, 19 men) with symptomatic gallstones eligible for LC were studied prospectively. Mean age was 52·5 (range 17–88) years. Thirty-six patients (35 per cent) had a professional activity, 33 (32 per cent) were retired and 27 (26 per cent) had a home activity. Conditions of the study were defined before surgery as agreement of the patient: (1) to leave hospital on day 3 after surgery if there are no complications; (2) to ask for analgesics in case of pain; and (3) to remain absent from work for 2 weeks after discharge. Conversions to laparotomy were excluded from the study; LC was successful in 103 of 112 patients (92 per cent). Twenty-six patients (25 per cent) required urgent LC for acute cholecystitis and 77 (75 per cent) underwent elective LC; of these, the laparoscopic procedure was performed after endoscopic sphincterotomy for expected bile duct stones in five cases and after mild acute pancreatitis in six.

There were no postoperative deaths, major complications or reoperations. There were ten minor complications. Mean spontaneous consumption of analgesics was 1·5 g paracetamol on the day of LC, and 0·4, 0·13 and 0·07 g on days 1, 2 and 3 after surgery. Thirty five patients (34 per cent) did not need analgesics during the hospital stay; 68 (66 per cent) requested them from day 1 after surgery. Mean analgesic consumption after LC for acute cholecystitis was 1·9 g paracetamol on the day of surgery, but similar to other patients on other days. The mean hospital stay was 4 days. Thirty-two patients (31 per cent) stayed for more than 3 days (mean 6 days) because of minor complications (ten), asthenia (14) or personal convenience (eight); of these, 16 had acute cholecystitis. There were no rehospitalizations. The mean absence from work was 17 days, but was 20 days in 'professional' patients and 14 days in those 'at home'.

This study confirms that pain is resolved quickly after LC; hence hospital stay may be reduced to 3 days for elective LC, allowing a more rapid return to work than the typical 4-week absence after the open procedure. Moreover, LC may be applied safely to a large majority of patients.

Irrigation and clot removal at laparoscopy

C.C. Nduka, A.D.K. Hill, A. Darzi and J.R.T. Monson, *St Mary's Hospital, London, UK*

Advances in laparoscopic surgery have been facilitated by improved instrumentation. High-pressure irrigation devices with hydrodissection capabilities use mechanical pumps or pressurized carbon dioxide. The efficacy of these devices is compared with that of a simple pressure bag with regard to flow rates and time required for fragmentation and removal of a blood clot. A model using 500 g clotted blood and 2 m of small bowel was used to simulate haemoperitoneum. The pressure bag and carbon dioxide devices were connected to a standard vacuum pump (600 mmHg); the mechanical irrigation device had a built-in suction capability (760 mmHg).

Irrigation device	n	Mean clot breaking time (s)	Mean clot suction time (s)	Mean clot clearance time (s)	Irrigation flow rate (ml min^{-1})
Pressure bag	3	10·6	177	188	100
Mechanical	3	7·7	179	186	430
CO_2 pump	3	9·1	177	186	370

The mechanically driven irrigation system had the highest irrigation flow rate. The simple pressure bag connected to a standard vacuum pump was as effective at clot removal as both the mechanically driven suction–irrigation device and the carbon dioxide pump irrigation system connected to a standard vacuum pump. A simple pressure bag connected to a standard vacuum pump is recommended for removing clots. More expensive irrigation devices should be reserved for hydrodissection.

Laparoscopic oöphorectomy: a novel surgical method for ovarian ablation in breast cancer

D.M. O'Hanlon, Y. El Tayeb, J. O'Donoghue, M. O'Donohoe, P. Horgan, D. Maher and H.F. Given, *National Breast Cancer Research Institute, Department of Surgery, University College Hospital, Galway, Ireland*

Premenopausal patients with breast cancer benefit from ovarian ablation as adjunctive therapy. Laparoscopic oöphorectomy has recently been introduced into this unit as the chosen method of ovarian ablation. Fourteen patients have undergone this procedure within the past year. Thirteen patients underwent the procedure at initial presentation, and one patient presented with a local recurrence 2 years after mastectomy. The mean(s.d.) age of patients was 41·1(3·9) years. All patients had stage I or II disease at presentation; two patients had lobular carcinoma, the remainder ductal carcinoma. A closed laparoscopic technique was employed. The initial cannula was introduced via a subumbilical incision. Two further cannulas were introduced in the right and left iliac fossas. Clips and electrocautery were used and the ovary was removed through the subumbilical incision. Complications were minor. The first patient required conversion to an open procedure and also suffered from a minor wound infection. The remaining procedures were uneventful. Follow-up ranged from 1 to 11 months. Two patients experienced moderately severe menopausal symptoms and the remaining patients experienced minor symptoms. This is a safe and relatively easy procedure to perform. In contrast to pelvic irradiation it provides well defined total ovarian ablation.

An endoscopic view of the surgical anatomy of the inguinal region

P.A. Paraskeva, A. Darzi, P.J. Guillou and J.R.T. Monson, *Academic Surgical Unit, St Mary's Hospital, London, UK*

Recent advances in technology have led to a rapid increase in the use of laparoscopy in general surgical procedures. One such recently introduced procedure is laparoscopic hernia repair; potentially, this offers a shorter time to recovery and to return to normal activity, and a significant reduction in groin discomfort for patients. In most laparoscopic procedures, e.g. laparoscopic cholecystectomy and laparoscopic appendicectomy, the anatomy encountered by the surgeon through the laparoscope is essentially the same as that seen in standard procedures. In contrast, laparoscopic repair of an inguinal hernia requires a new interpretation of anatomy and the development of a different technique for repair. The orientation of the anatomy of the inguinal region as seen laparoscopically is unfamiliar to most surgeons. For the procedure to be completed successfully, with neither damage to anatomical structures nor postoperative recurrence, a detailed anatomical knowledge is essential.

In this study, the intra-abdominal anatomy of the inguinal region is described with the aid of diagrams and photographs of dissected post-mortem specimens to aid the surgeon in understanding the anatomy of the region. In addition, the critical elements of repair are discussed with respect to anatomical landmarks.

Laparoscopic hernioplasty with polypropylene prosthesis: a study in 30 patients

S. Pous Serrano, R. Garcia Espinosa, A. Moya Sanz,
P. Garcia Pastor, J. Galeano Senabre, C. Lopez Martinez,
C. Serna Ballester, F. Pacheco Ferrer and D. Rodero Rodero,
'La Fe' Hospital, Valencia, Spain

This technique is a useful alternative to avoid the problems of inguinal hernia surgery.

Thirty patients were operated on using this technique from June 1992 to January 1993. The patients chosen were without complicated and/or recurrent groin hernia. Those where general anaesthesia was contra-indicated were not selected. The mean (range) age was 55·4 (22–76) years; all patients were male.

The mean (range) duration of symptoms was 31·1 (1–360) months. The clinical diagnosis was 23 inguinal hernia, three inguinoscrotal hernia and four recurrent hernia. The mean(s.d.) duration of surgery was 64·4(17·1) (range 45–100) min. Intraoperative diagnosis was 23 indirect and seven direct hernias. In all cases a polypropylene prosthesis, attached at Cooper's ligament and inguinal ligament, was placed using staples. In the later patients the prosthesis was covered using a peritoneal flap. Two cases (7 per cent) were converted to open surgery: one for uncontrolled bleeding and the other for undetermined problems.

Postoperative pain was present in 36 per cent of patients; the remainder required no analgesics. Postoperative paralytic ileus lasted a mean(s.d.) of 8·3(5·3) h. Patients were able to walk at a mean(s.d.) of 15·6(8·9) h. Mean(s.d.) hospital stay was 2(1·1) days. Two patients had complications (scrotal haematoma and urinary retention). Although the follow-up is short no recurrences were found. However, while these early results are encouraging, a stringent clinical trial and long-term follow-up is necessary before the role of this new surgical procedure is validated.

Contraindications to laparoscopic cholecystectomy

B.I. Rees and D. Oshodi, *University Hospital of Wales, Cardiff, UK*

A number of relative contraindications to laparoscopic cholecystectomy have been proposed. These include previous operation, morbid obesity, acute cholecystitis and stones in the common bile duct.

A retrospective analysis of 600 laparoscopic cholecystectomies performed by a single surgeon was undertaken to determine whether these relative contraindications led to increased morbidity rates, an increased conversion rate to open procedure or longer operating times.

In all, 128 patients had one or more relative contraindications to laparoscopic cholecystectomy. Morbidity rates were not increased in patients with these risk factors. Acute cholecystitis made the operation longer, but did not increase the conversion rate. It is suggested that attempts at laparoscopic surgery should be made despite these risk factors.

Laparoscopic cholecystectomy: early results and experience

Second Surgical Department, Medical Academy of Gdańsk, Gdańsk, Poland

Laparoscopic cholecystectomy has rapidly become the procedure of choice in our practice for patients with symptomatic gallbladder disease. Since December 1991, 251 cholecystectomies have been undertaken; the patients comprised 25 men and 226 women, ranging in age from 14 to 87 years. The operative technique we employ requires the insertion of three or four cannulas and uses monopolar electrocautery to dissect the gallbladder from the liver bed. The average operating time is 89·5 min. Conversion to an open procedure has been necessary in nine (3·6 per cent) patients. A total of 24 (9·6 per cent) operative complications occurred. There were four cases of bleeding from the site of trocar insertion and six cases of gallbladder rupture. Bile stones were spilled during the procedure in three patients. Bleeding from the blood vessels of Calot's triangle was observed in nine patients. All of these were successfully managed laparoscopically. No common bile duct injury occurred. Most patients who had undergone laparoscopic cholecystectomy were discharged within 48 h of surgery.

We conclude that the procedure is safe and can be performed satisfactorily in most patients with symptomatic gallbladder disease.

Laparoscopic inguinal hernia repair

A. Sigurdsson and C.W.O.W. Windsor, *Department of Surgery, Worcester Royal Infirmary, Worcester, UK*

Laparoscopic inguinal hernia repair (LIHR) may improve the speed of recovery while maintaining low recurrence rates. Patient-led demand for the operation may not be balanced in the short term by the results of prospective randomized trials of LIHR *versus* conventional open hernia repair. A prospective audit of LIHR may therefore play a major role in both short- and long-term assessment of the safety of the procedure, the quality of life and the recurrence rates after LIHR. Some early results of a prospective audit of laparoscopic transabdominal preperitoneal mesh repair of 37 patients are given.

Median operating time was 55 min and median cost of consumables £48. Median (range) diameter of direct defects was 3 (1·5–4·5) cm and of indirect defects 2 (1–4) cm. Complications were minor: three superficial wound infections, three scrotal bruises, and two cord haematomas. In two patients laparoscopic repair was converted to open operation. One recurrence has occurred, suggesting that the mesh used was of inadequate size. The median time to return to normal activity was 4 days and to return to work 12 days.

The results of postoperative visual analogue pain scoring over 3 weeks and the use of analgesia will be presented with comments on operative technique. The present results encourage further close assessment of LIHR.

Laparoscopy of emergency surgical abdominal disease

S. Stamenov, D. Serbezova and B. Stoytchev, *Surgery Clinic ORB, Targovishte, Bulgaria*

Diagnosis of acute surgical diseases (traumatic and inflammatory) is often difficult and errors often occur. Unnecessary laparotomies are performed and surgical intervention is delayed; in both cases operative mortality is higher. Emergency laparoscopy is a valuable diagnostic method and may even be useful in patients with postoperative complications.

This report analysed results of 541 laparoscopies (324 emergency cases). Most emergency laparoscopies were for cases with acute cholecystitis ($n = 89$), abdominal trauma ($n = 48$), perforated ulcer ($n = 40$), acute pancreatitis ($n = 30$), and early postoperative complications ($n = 17$). The risks and complications of laparoscopy in this series were insignificant.

With the help of laparoscopy, an accurate diagnosis can be made, the proper method of treatment planned and the appropriate approach to the abdomen decided.

Complications of laparoscopic cholecystectomy

H. Tasçi, Y. Çiçek, S. Pekmezci, C. Gökdoğan and S. Önes, *Cerrahpasa Medical Faculty, Department of General Surgery, University of Istanbul, Turkey*

Between August 1991 and January 1993, 600 laparoscopic cholecystectomies (LCs) were performed. Of the 600 patients undergoing LC, 474 (79 per cent) were female and 126 (21 per cent) were male. Mean age of the patients was 51 (range 19–80) years. Seventeen laparoscopies (2·8 per cent) were converted to laparotomy because of technical difficulties. The mean operating time was 43 (range 15–120) min. There was no mortality or extrabiliary morbidity. There were four cases (0·6 per cent) of biliary morbidity (bile duct injury). Peritonitis caused by bile leakage was found in two cases. The postoperative hospital stay was 2–7 days; 62 per cent left on the first or second day after operation.

It is concluded that LC can be safely performed with low morbidity, and offers shorter hospitalization and postoperative recovery.

Laparoscopic repair of inguinofemoral hernia recurrence

S. Valletta, F. Favretti, A. Zanella, M. Bonenti, A. Da Rold and E. Burigo, *Ospedale Civile, Belluno, Italy*

The application of a preperitoneal non-reabsorbable mesh (Rives–Stoppa method) has proved to be a valid approach to the treatment of inguinofemoral hernia recurrence. Basically the same operation, performed laparoscopically, is described. A total of 21 patients (14 men, seven women; age range 36–71 years) underwent 'open' laparoscopy under general anaesthesia. To identify the hernia defect, the peritoneum was incised from the top of Hasselbach's triangle to a point lateral and superior to the internal inguinal ring. Two peritoneal flaps were created, the hernia sac pulled into the abdomen and the entire inguinofemoral region was well exposed and then covered by a mesh of 76·2 × 127 mm which was stapled to the inguinal wall by clips. Lastly the peritoneal flaps were approximated and stapled.

The average operating time was 80 min. The postoperative pain and early complication rate were insignificant. All patients left hospital on the second day after operation and there were no further recurrences.

Although the present results are encouraging, to date the laparoscopic method for hernia repair has not been proved superior to open surgery in the long term. The postoperative benefit to patients is so far the most persuasive argument in its support.

Laparoscopic cystic artery haemodynamics

R. Vashisht, R.G. Springall and D.M. Nott, *Charing Cross Hospital, London, UK*

Laparoscopic cholecystectomy (LC) is now the preferred method for treatment of cholelithiasis. However, dissection in the area of Calot's triangle can be difficult in the presence of adhesions and inflammation, making exposure of the cystic artery and duct hazardous. A laparoscopic Doppler probe (LDP) has been developed for the identification of the cystic artery in an attempt to facilitate safe dissection. In a consecutive series of 20 patients undergoing LC the LDP was used to detect the cystic artery and the resulting Doppler waveform was analysed on computerized software and the end diastolic ratio (EDR) determined. The gallbladder was graded histologically according to the degree of inflammation (0–6). The EDR is a measure of resistance to flow within the artery. The LDP successfully identified the cystic artery in 100 per cent of cases. Median EDR was 0·47 (range 0·32–0·72). The EDR correlated with the degree of inflammation ($r = 0·86$). In conclusion, the addition of a LDP during surgery improves the safety of dissection and predicts the degree of inflammatory response in the gallbladder wall.

Liver

Effects of allopurinol and *Ginkgo biloba* extract on hepatic ischaemia and reperfusion injury in dogs

L. Bozatli, F. Çelik, Y. Kiliç, O. Çubukçu, L. Eldem, Ö. Arikan, K. Güler, Ö. Ekinci and G. Azakli, *Göztepe Social Insurance Hospital, Istanbul University Medical School, Istanbul, Turkey*

The effect of allopurinol and *Ginkgo biloba* extract on hepatic injury after a period of ischaemia was investigated in dogs. Total ischaemia of the liver was induced in dogs for 1 h while haemodynamic stability was maintained by venovenous bypass. One group of animals ($n = 6$) received allopurinol (50 mg per kg body-weight daily, given orally for 2 days before operation). Control dogs ($n = 6$) were given a corresponding volume of solution, while a third group ($n = 6$) was given *Ginkgo biloba* extract (100 mg per kg body-weight intravenously) 1 h before induction of liver ischaemia. Hepatic enzymes were measured 0, 2 and 7 days after operation. Hepatic biopsies were performed at the time of initial laparotomy before induction of ischaemia and 2 and 7 days after operation. More cellular damage was observed on biopsy specimens obtained from the control group and increases in enzyme levels were also more marked during the 5 days after operation. Enzymatic studies and histopathological changes revealed that allopurinol and *Ginkgo biloba* extract were both effective in protecting hepatic cells against the damage caused by warm ischaemia.

Liver ischaemia and reperfusion in the rat: role of chloroquine, a phospholipase inhibitor, in postischaemic liver blood flow

R. Chavez-Cartaya, P. Ramirez* and N.V. Jamieson, *University of Cambridge, Cambridge, UK and *Universidad de Murcia, V. Arrixaca, Spain*

Breakdown of phospholipids in the membrane unit of the ischaemic cell may play an important role in the pathogenesis of ischaemia and reperfusion injury. Phospholipases, activated during ischaemia through a calcium–calmodulin mechanism, may be involved in this process of membrane damage.

Choloroquine, a phospholipase antagonist, is used to study the role of this enzyme in the pathogenesis of ischaemia and reperfusion liver injury. The experimental procedure consists of the temporary interruption of blood flow to the left lateral and medial lobes of the rat liver and subsequent reperfusion after a period of ischaemia, recording the postischaemic liver blood flow with a He–Ne laser Doppler flowmeter as an indicator of ischaemia–reperfusion liver injury. The experimental group was pretreated with chloroquine for 5 days before ischaemia. In this group, the recovery of liver blood flow after ischaemia was better than in the untreated controls ($P < 0·001$).

These results suggest a role for phospholipases in the pathogenesis of liver ischaemia and reperfusion injury.

Protective effect of University of Wisconsin–Belzer solution against lipid peroxidation of membranes during simulated oxidative stress following liver ischaemia in rats

B. Dippe, H. Petrowsky, D. Kreisel, O. Richter, P. Geck, M. Schneider, H.J.C. Wenisch and A. Encke, *Departments of Surgery, Biochemistry, Pathology, University of Frankfurt Medical Centre, Frankfurt, Germany*

Reoxygenation of the ischaemic liver is accompanied by pathological biochemical processes which are mainly ascribed to the generation and effects of toxic oxygen radicals. These radicals peroxidize membrane lipids and thus damage the integrity of the cell membranes. The most commonly used preservative solution, University of Wisconsin (UW)–Belzer, is designed to limit the generation and effect of these radicals by a combination of allopurinol and glutathione. The protective effect of UW–Belzer compared with Ringer's solution on the lipid peroxidation of the membranes under simulated oxidative stress conditions after different periods of ischaemia was determined.

A total of 72 liver explants of male Lewis rats were stored at 4°C following perfusion with UW–Belzer or Ringer's solution. The liver samples were homogenized in phosphate buffer solution for 1 min and thus saturated with atmospheric oxygen after perfusion (0 h, 3 h, 6 h, 12 h, 24 h and 36 h) and at 3 h, 6 h, 12 h, 24 h and 36 h of cold storage. The membrane lipids were subsequently completely peroxidized by addition of the lipid-soluble radical initiator 2,2'-azo*bis*(2,4-dimethylvaleronitrile). A product of lipid peroxidation, malondialdehyde (MDA), was measured immediately after homogenization and after completion of lipid peroxidation. The difference (δMDA) was then calculated.

The difference in MDA values is a measure of unperoxidized membrane lipids. High δMDA values correspond to a lower lipid peroxidation after reoxygenation.

	Mean(s.d.) δMDA (μmol per g protein)					
	0 h	3 h	6 h	12 h	24 h	36 h
Ringer's	0·72(0·18)	0·57(0·10)	0·63(0·16)	0·52(0·16)	0·61(0·18)	0·19(0·15)
UW–Belzer	2·16(0·61)	2·00(0·22)	1·94(0·21)	1·37(0·40)	1·22(0·53)	0·33(0·24)
*P**	<0·05	<0·01	<0·01	<0·01	<0·05	n.s.

* Mann–Whitney *U* test; n.s., not significant

The results show UW–Belzer solution to have a distinct protective effect against lipid peroxidation up to 6 h after preservation. This effect decreases with time; after 36 h there is no significant difference compared with preservation with Ringer's solution.

It is concluded that the protective effect of UW–Belzer solution against lipid peroxidation is sufficient to prevent membrane damage by toxic oxygen radicals for a period of up to 6 h only.

Hepatic transplantation following total hepatectomy and Whipple's operation for fibrolamellar hepatocarcinoma

A. Edo, M. Varas, I. Díaz, J.L. Lázaro, J. Balsells, E. Murio, R. Charco and C. Margarit, *Liver Transplant Unit, Hospital General Universitario Vall d'Hebrón, Barcelona, Spain*

A case of fibrolamellar hepatocarcinoma treated with total hepatectomy, duodenopancreatectomy and split liver transplantation is presented.

A 22-year-old woman was diagnosed as having fibrolamellar hepatocarcinoma involving both lobes of the liver. She was accepted as a candidate for hepatic transplantation after extratumoral dissemination was dismissed. After 2 months on the waiting list and taking advantage of an urgent retransplantation for a child, it was decided to split the donor liver using the right lobe for this patient.

An exploratory laparotomy confirmed massive invasion of the hepatic parenchyma and the irresectability of the tumour. Involvement of hilar and hepatic lymph nodes was found. A radical operation including total hepatectomy, cephalic duodenopancreatectomy and lymphadenectomy of the coeliac axis, hepatic artery and superior mesenteric artery was performed. Subsequently, implantation of the right hepatic lobe and reconstruction of digestive continuity with anastomosis of the pancreas, biliary tree and stomach to a jejunal loop were performed.

In the postoperative period the patient presented with a biliary leak owing to partial necrosis of the extrahepatic biliary tree that required surgical treatment with repair of the bilioenteric anastomosis. The patient was discharged 2·5 months after transplant, and at present she has normal function of the graft and a low-flow biliary leak.

Role of PIVKA-II/DCP and other tumour markers in the diagnosis of hepatocellular carcinoma

G.L. Grazi, A. Mazziotti, C. Legnani, R. Miniero, E. Jovine, A. Gallucci, G. Palareti and G. Gozzetti, *Second Department of Surgery, University of Bologna, S. Orsola Hospital, Bologna, Italy*

Screening programmes for hepatocellular carcinoma (HCC) are based on repeated ultrasonography (US) and evaluations of α_1-fetoprotein (AFP),

0007–1323/93/S050–05 © 1993 Butterworth-Heinemann Ltd

but many tumours are still missed in the early stages; efforts are made to improve the detection rate of HCC and thus its resectability.

Over a 2-year period, 211 patients were tested for AFP, serum ferritin (SF), tissue polypeptide antigen (TPA), carcinoembryonic antigen (CEA) and des-γ-carboxy prothrombin (DCP or PIVKA-II). Of these, 103 (48·8 per cent) had HCC (of these 79 had cirrhosis) and the remaining 108 (51·2 per cent) had liver cirrhosis (30 patients), liver metastases (20), benign liver lesions (26), non-HCC tumours (18) or other miscellaneous diseases (14). Effectiveness tests were assessed for each marker and cross-tabulated with clinical data to evaluate differences between groups.

AFP and DCP levels were higher in the HCC group (P < 0·05). TPA, CEA and SF were not helpful in discriminating HCC. The combined use of AFP and DCP improved the sensitivity by almost 20 per cent.

	Level	Sensitivity*	Specificity*	Negative predictive value*	Accuracy*
AFP (ng dl^{-1})	20	53·5	98·1	66·5	74·5
CEA (ng dl^{-1})	7	24·4	74·4	48·3	48·8
SF (ng dl^{-1})	140	64·2	64·1	62·7	63·3
TPA (units l^{-1})	95	69·7	65·7	68·2	66·6
DCP (units l^{-1})	0·09	54·4	88·0	63·9	69·3
AFP and/or DCP	–	84·3	77·0	68·9	78·0

*Values are percentages

Nineteen patients with HCC (18·4 per cent) were AFP+/DCP- and 21 (20·4 per cent) AFP-/DCP+: in these cases DCP was of more value in patients without cirrhosis and in Child A patients with cirrhosis when compared with AFP (P < 0·05). The DCP sensitivity rate diminished with worsening liver function (P < 0·05).

DCP is as accurate as AFP as a tumour marker of HCC, especially for patients with preserved hepatic function still amenable to surgery. The serum positivity for either one of the two markers is the modality of choice in the serological diagnosis of HCC.

Resection of hepatocellular carcinoma complicating cirrhosis: a multicentre study

H.C. Hennet, H. Levard and A. Fingerhut, *French Association for Surgical Research, Bois-Colombes, France*

Hepatocellular carcinoma (HCC) is a complication of cirrhosis. Resection, whenever possible, is presently the treatment that provides the best results, although outcome is related to tumour stage and the severity of cirrhosis. Doubt still exists concerning the risks of resection for HCC. The choice is between partial or complete resection of the liver for small HCC and the palliative treatment of large tumours by hepatic transplantation.

The purpose of the present retrospective multicentre study by the French Association for Surgical Research is to report the results of resection for HCC with cirrhosis performed between January 1984 and December 1988 in 18 French surgical centres. A total of 153 resections were performed (between one and 49 resections per centre). Most resections were performed for patients with Child's grade A disease (72 per cent). Emergency resections were performed in 7 per cent of patients and partial resection in 95·8 per cent; only six patients underwent hepatic transplantation.

Intraoperative ultrasonography was used in 61 per cent of patients. The operative mortality rate was 20 per cent and postoperative complications occurred in 61 per cent of patients. The 1-, 3- and 5-year overall survival rates were 52·7, 30·1 and 17·9 per cent respectively. The survival rate was significantly related to the number of nodules resected and size of tumour but not to the presence of a capsule surrounding the tumour. From the present data it is not possible to compare resection with other therapeutic methods for HCC in cirrhotic liver.

Experience with 102 hepatic resections: indications, techniques and results

C. Margarit, A. Edo, J.E. Murio, J. Balsells, R. Charco, J.L. Lázaro, E. Gifre, I. Díaz and J. Bonnín, *Liver Transplant Unit, Hospital General Universitario Vall d'Hebrón, Barcelona, Spain*

Experience in the past 4 years with 102 hepatic resections in 100 patients, 31 women and 69 men (mean age 56 years), is presented. Indications for liver resection were: 30 secondary tumours, most of them from colorectal cancer; 49 primary tumours, mainly (44) hepatocellular carcinoma (HCC) in liver cirrhosis; two liver resections for trauma and 21 liver resections because of benign disease.

Liver function assessed before operation was normal in 56 cases. Only the 44 patients with liver cirrhosis graded as A or B, according to the Child–Pugh classification, were considered for resection.

A total of 59 anatomical resections (39 major procedures) and 43 non-anatomical resections, mainly of a cirrhotic liver, were performed. Intraoperative ultrasonography was used to delineate liver tumour with safe margins, avoiding large resections in patients with cirrhosis. Hilar clamping was performed in 41 per cent of cases. Frequently, associated procedures were performed: two portocaval shunts, five colectomies, one gastrectomy, one pancreatectomy and one nephrectomy.

The postoperative morbidity was three haemorrhages, eight biliary leaks, and 13 mild liver failures in patients with liver cirrhosis. Ten (10 per cent) patients died after operation, most of them in the HCC–cirrhosis and Klatskin tumour groups. Mortality rate was 3 per cent for secondary tumours and 0 per cent for benign diseases. This experience suggests that risk factors for liver resection are liver cirrhosis, severe cholestasis and associated major procedures.

Intraoperative ultrasonography and enhanced computed tomography in the detection of hepatic metastases

W.F.A. Miles, J. Crosbie, L. Turnbull, P. Allan and O.J. Garden, *The Royal Infirmary, Edinburgh, UK*

Seventy-two patients with primary colorectal cancer underwent intraoperative ultrasonography and iodized oil emulsion-enhanced computed tomography (IOECT) of the liver at the time of colonic resection. All of these patients had subsequent IOECT at 6-monthly intervals. Eight (11 per cent) of these patients had palpable hepatic metastases at operation. Fifteen (21 per cent) had metastases detected by intraoperative ultrasonography; in 12 patients (17 per cent), these were confirmed by the immediate postoperative IOECT scan. In two of the 15, metastases were not present on initial IOECT but appeared on subsequent scans. In one patient, the intraoperative ultrasonography result was unconfirmed after 12 months' follow-up. A further three patients who showed no evidence of hepatic metastases at the time of operation developed metastases after a mean follow-up of 14 months. Intraoperative ultrasonography detected more of the patients with hepatic metastases than did palpation alone (P<0·05, Fisher's exact test). Follow-up IOECT detected more patients with metastases than IOE scanning in the perioperative period (P < 0·01) which in turn detected fewer patients with metastases than did intraoperative ultrasonography.

In conclusion, patients undergoing curative colonic resection for colorectal cancer should have intraoperative hepatic ultrasonographic assessment of the liver followed by delayed IOECT to maximize the detection of those with overt and occult hepatic metastases.

Preoperative prediction of resectable hepatic tumours

B. Moran, N. O'Rourke, G. Plant and M. Rees, *Basingstoke District Hospital, Basingstoke, UK*

While the safety and efficacy of hepatic resection have been widely reported, accurate preoperative assessment is essential to avoid unnecessary laparotomy. Computed tomography (CT) correctly identifies 70 per cent of individual liver lesions when compared with findings at laparotomy. CT during contrast enhancement of the liver via the portal vein, or computed tomographic portography (CTP), is thought to be superior to conventional CT. This study evaluated preoperative CTP in 60 patients and on a lesion-by-lesion analysis compared CTP with palpation, intraoperative ultrasonography and histology of the resected liver. The majority, 54 of 60 patients (90 per cent), had metastases (47 colorectal, seven non-colorectal).

At laparotomy, four patients (7 per cent) were inoperable because of disseminated peritoneal metastases in one, hilar node involvement in one and irresectable liver disease (which had been predicted by CTP) in two patients. Fifty-six (93 per cent) underwent partial hepatectomy. CTP accurately identified and located all lesions found at histology in 51 of 56 patients (91 per cent). In five patients CTP predicted resectability, but missed a small superficial deposit in two and had a false-positive finding in the other three. On a lesion-by-lesion analysis CTP identified 110 of 116 lesions (95 per cent).

CTP predicted resectability in 58 of 60 patients (97 per cent). CTP had a sensitivity of 96 per cent and a specificity of 93 per cent in lesion identification and localization, and is the procedure of choice in preoperative selection of candidates for partial hepatectomy.

Warm ischaemia–reperfusion of the liver: possible antioxidant activity of δ-bilirubin

R. Navidad-Novalvos, T. Ratia, J.J. Díaz-Gil and J.L. Castillo-Olivares, *Clínica Puerta de Hierro, Madrid, Spain*

δ-Bilirubin can be isolated from the serum of hepatectomized rats and is a product formed by the binding of bilirubin and albumin; it is capable of stimulating hepatocellular mitosis both *in vivo* and *in vitro*. In the light of this activity, it was named liver growth factor (LGF). It was recently shown in cultured hepatocytes and myocytes from the human ventricle that bilialbumin can perform an important antioxidant function in situations of oxidative stress. This antioxidant capacity appears to be even greater than that exerted by α-tocopherol. The aim of this study was to assess *in vivo* the antioxidant capacity of δ-bilirubin in an oxidative stress situation such as hepatic ischaemia–reperfusion.

The study dealt with 35 Wistar rats, 80–90 g, freely fed. All were subjected to laparotomy under ether anaesthesia with induction of warm ischaemia of 70-min duration in the left and middle lobes by clamping the afferent vascular branches and shunting the circulation via the branches of the right lobes. Thus ischaemia of approximately 70 per cent of the liver mass was achieved. The serum δ-bilirubin concentration was determined by reversed-phase high-performance liquid chromatography with blood sampling 5, 60 and 70 min after induction of ischaemia and 5, 15 and 60 min after reperfusion of the ischaemic lobes. At the same times, biopsy specimens were taken from the hepatic lobes to determine the tissue levels of malondialdehyde (MDA), an indicator of lipid peroxidation, using the thiobarbituric acid (TBA) test.

		Ischaemia			Reperfusion		
	Sham	5 min	60 min	70 min	5 min	15 min	60 min
δ-bilirubin (μg ml^{-1})	0·38	0·68	1·17	1·63	1·35	1·33	2·16
MDA (nmol g^{-1})	27·40	33·81	27·58	9·46	5·25	20·99	25·57

Values are mean(s.d.)

The differences between δ-bilirubin and MDA values were significant at every point ($P < 0{\cdot}01$). The maximum standard deviation was never greater than 19 per cent with respect to the means. Throughout the ischaemic period and after 5 min of reperfusion the δ-bilirubin and MDA levels were inversely related. After 70 min of ischaemia, the bilialbumin levels were four times higher than those observed in sham-operated animals, while the tissue MDA levels were three times lower than those of the sham group. After 15 min of reperfusion and maximum oxidative stress, both levels increased.

δ-Bilirubin can exert a physiologically significant antioxidant action in situations of cellular oxidative stress in the liver.

Evaluation of blood clearance of ^{99m}Tc-HIDA as a test of hepatic function: preliminary results in healthy, cirrhotic and transplanted liver

P. Ramirez, R. Chavez-Cartaya, T. Fuente, J. Sanchez, A. Piñero, J. Lujan, R. Robles, F. Sanchez and P. Parrilla, *Departamento Cirugia, Hospital V. Arrixaca, Murcia, Spain*

This study aimed to evaluate blood clearance of ^{99m}Tc-trimethyl-Br-IDA as a test of hepatic function, and to analyse the differences in levels of ^{99m}Tc-HIDA excretion between patients with normal or a transplanted liver.

A total of 18 patients were studied: six with a T tube in the biliary tree because of choledocholithiasis (controls); six with transplanted livers with normal liver function tests (transaminases, bilirubin, Quick test, bile flow); and six with alcoholic cirrhosis of Child's grade C. After administration of an intravenous bolus of 50 μCi of ^{99m}Tc-HIDA, a blood clearance test was performed in all patients and ^{99m}Tc-HIDA bile concentration during 3 h was determined in controls and those with transplanted liver. The tests on these two groups were performed on day 7 after operation.

The blood clearance of ^{99m}Tc-HIDA showed statistically significant differences between controls and cirrhotic patients ($P < 0{\cdot}001$), but not between controls and those with a transplanted liver. The maximum peak of bile elimination of ^{99m}Tc-HIDA was significantly earlier in controls than in patients with a transplanted liver ($P < 0{\cdot}001$), and 90 min after bolus administration the bile concentration of ^{99m}Tc-HIDA was significantly greater in the latter group than in the controls ($P < 0{\cdot}001$).

Measurements of blood clearance of radiolabel proved a simple, economic and fast test of liver function. Patients with transplanted liver show a delay in ^{99m}Tc-HIDA bile elimination in the first week after transplantation.

Influence of pentoxifylline on the extent of necrosis and lipoperoxidation after partial hepatic ischaemia in the rat

T. Ratia, R. Navidad, P. Martinez, I. Arribas and J.L. Castillo-Olivares, *Clínica Puerta de Hierro, Madrid, Spain*

Ischaemia–reperfusion is an important cause of liver injury in transplantation and major hepatic surgery. The effect of pentoxifylline on post-ischaemic liver injury is evaluated.

Partial ischaemia (70 per cent) was induced in male Wistar rats (250–300 g) by occluding the left branches of the portal vein, hepatic artery and bile duct for 70 min. Three experimental groups were studied: sham operated ($n = 5$), vehicle-treated ($n = 10$) and pentoxifylline-treated (50 mg kg^{-1} intraperitoneally 30 min before reperfusion, $n = 10$). Blood samples were taken before inducing ischaemia and 6 h after reperfusion. A piece of the left hepatic lobe was taken from each animal at 15 min after reperfusion and homogenized for determination of TBA-reacting substances. All rats were sacrificed 24 h after reperfusion by exsanguination. Sections taken from the left lobe were stained with haematoxylin and eosin and examined by light microscopy. A score was used to evaluate necrosis, congestion and inflammatory infiltration in each animal.

A significantly lower increment in mean(s.e.m.) alanine aminotransferase and aspartate aminotransferase 6 and 24 h after reperfusion was observed in the pentoxifylline-treated group compared with vehicle-treated animals (9082(6836) and 5635(3866) *versus* 13 871(3683) and 8717(1234) units). TBA-reacting substances in homogenates of lobes from pentoxifylline-treated rats were also significantly lower (31·15(2·90) *versus* 40·63(12) nmol ml^{-1}). Necrosis in the pentoxifylline-treated group was less extensive (45–50 per cent) than in vehicle-treated rats (80–85 per cent). Neutrophil accumulation was also reduced. It is concluded that pentoxifylline may ameliorate hepatic postischaemic injury.

Intraoperative oxygen saturation measurement of liver tissue in warm ischaemia in partial liver resection

E. Rembs, R. Ernst, K.H. Bauer and V. Zumtobel, *Chirurgische Klinik der Ruhr-Universität Bochum, St Josef Hospital, Bochum, Germany*

Little is known of the ischaemic tolerance of the human liver and its effects on the state of the metabolism in liver surgery. In a first series with the new method of direct and invasive tissue oxygen saturation ($P\text{O}_2$) detection, the $P\text{O}_2$ of liver tissue in partial liver resections was measured. The data were compared with clinical parameters and metabolic analyses of the intermediate products of glycolysis.

A mean liver $P\mathrm{o}_2$ of 41 mmHg was measured in healthy patients. The $P\mathrm{o}_2$ was measured before and during clamping of the liver, and in the consecutive reperfusion phase in 14 patients undergoing partial liver resection. Before clamping the ligamentum hepatoduodenale these patients showed no difference compared with healthy individuals. After discontinuation of the blood flow a fast decrease to a $P\mathrm{o}_2$ of a mean of 7 mmHg was seen. After an ischaemic period of 30 min and a reperfusion time of 30 min, the $P\mathrm{o}_2$ returned to preischaemic levels. The results correlated with metabolic measurements and the further clinical follow-up without the onset of liver failure.

Intraoperative $P\mathrm{o}_2$ measurement gives a reliable intraoperative statement on perfusion, function and recovery of the liver after warm ischaemia.

Diagnosis, aetiology and therapy of liver abscess

W. Schweizer, M. Berthold, M. Naef, H.U. Baer and A. Czerniak, *University Clinic of Visceral and Transplantation Surgery, Inselspital, Bern, Switzerland*

A retrospective evaluation of the clinical symptoms, aetiology, diagnostic approach and therapy in 56 patients with liver abscesses (1984–1991; 44 pyogenic, 12 amoebic) was conducted. Main symptoms were fever, right upper quadrant tenderness, hepatomegaly and jaundice. Ultrasonography and computed tomography were used for diagnosis.

Patients with pyogenic liver abscesses are generally older (70–80 years) and there is usually a severe underlying disease. The patients are in a bad general condition. The treatment consists of antibiotic treatment and in most cases additional drainage (mostly percutaneous and rarely surgical). Patients with amoebic liver abscesses are younger (around 30 years) and their general condition is good. Serology is an important diagnostic method and very accurate. The treatment consists of antibiotics alone.

The mean time of hospitalization was 33 days with an in-hospital mortality rate of 14 per cent in patients with pyogenic abscesses and 6·5 days with a mortality rate of zero in amoebic abscesses. In recent years surgical drainage has been more and more abandoned in favour of radiological drainage. Surgery remains important in pyogenic abscesses for the therapy of the underlying disease (biliary, pancreatic, gastric, colonic diseases).

Non-colorectal liver metastases: indications for resection

J. Sturm, M. Raute and M. Trede, *Surgical University Clinic, Mannheim, Germany*

Between 1973 and 1992, 145 patients with colorectal liver metastases underwent surgery. In the same period, 43 resections of non-colorectal metastases were performed in 40 patients. A total of 17 patients had symptoms, and in the most cases large tumours up to 18 cm in diameter were present. Primary sites included endocrine tumour (five), sarcoma (eight), melanoma (one) and other carcinoma (26).

Wide anatomical resection was necessary in 14 patients (35 per cent), no patient died during operation and there were two complication-related postoperative deaths. Three patients, one of whom died, with wide anatomical resections had liver insufficiency. The mean survival after resection was 27·8 months; however, 11 (28 per cent) patients are still alive, five for > 5 years after resection of a non-colorectal liver metastasis. The longest surviving patient is still alive 11 years after hemihepatectomy for a leiomyosarcoma.

Resection of non-colorectal liver metastases has to be regarded as palliative, but in individual cases a very satisfying result, with the gain of several years without recurrence or symptoms, can be achieved. Regarding the results of this study, the best indications for resection of non-colorectal metastases are symptomatic metastases and secondaries of endocrine tumours, hypernephromas, melanomas or well differentiated sarcomas.

Temporary partial hepatectomy: a new *in vivo* model for studying liver regeneration

E. Tagliaferri, M.A. Secchi and L. Lambotte, *Experimental Surgery Laboratory, UCL, Brussels, Belgium*

Changes such as an increase in hepatocyte growth factor levels in the plasma or proto-oncogene expression in the liver can be detected within a few hours after 70 per cent partial hepatectomy. A signal for regeneration is thus present very early, but it is not clear whether these early changes observed are sufficient to produce the DNA synthesis 24 h later. To address this question, male Wistar rats were submitted to 70 per cent functional 'temporary partial hepatectomy' by occluding the vascular pedicle of the anterior lobes and cooling them locally below 12°C. After 3 h, the lobes were perfused and reinserted in the abdominal cavity. After a further 19 h, 50 μCi [^{3}H]thymidine was injected and the liver was removed 2 h later. After such a partial hepatectomy, mean(s.e.m.) DNA synthesis (40 825(6937) d.p.m. per mg DNA, $n = 8$) was significantly higher than in intact rats (3389(131) d.p.m. per mg, $n = 3$; $P < 0{\cdot}01$), sham operated animals who underwent a similar manipulation but without occlusion and cooling (16 657(1678) d.p.m. per mg, $n = 9$; $P < 0{\cdot}01$), or after 40 per cent partial hepatectomy (18 057(2554) d.p.m. per mg, $n = 4$; $P < 0{\cdot}05$). The stimulation of DNA synthesis was significantly lower than that observed after a classical 70 per cent partial hepatectomy performed immediately (147 239(13 095) d.p.m. per mg, $n = 8$; $P < 0{\cdot}001$) or after 3 h local cooling (132 473(29 987) d.p.m. per mg, $n = 5$; $P < 0{\cdot}001$). In conclusion, although significant DNA synthesis is obtained after temporary partial hepatectomy, additional factors seem essential for the full regenerative response to partial hepatectomy to be obtained.

Hepatic transcatheter arterial embolization with Lipiodol, doxorubicin and Gelfoam in hepatocellular carcinoma

A.J. Torres-Garcia, *Madrid, Spain*

Surgical resection can be potentially curative in hepatocellular carcinoma. However, the resectability rate is low (approximately 20 per cent), survival in non-resected patients poor (mean 6 months) and recurrence after excision frequently encountered in the liver remnant. Therefore, several therapeutic transarterial approaches have been attempted. This study reports an initial experience using iodized oil (Lipiodol), doxorubicin and Gelfoam embolization by a percutaneous endovascular technique.

Between October 1991 and November 1992, 13 patients entered the study (12 men, one woman; mean age 65 (range 36–72) years). All presented with histologically proven hepatocarcinoma in a cirrhotic liver. There were two tumours in the left lobe, five in the right lobe and six bilateral. All were diffuse or presented satellite masses (in two cases satellite masses could be detected by computed tomography (CT) only after Lipiodol injection). According to Okuda's classification four were stage I, six stage II and three stage III. The α-fetoprotein levels were $< 20\,\mathrm{ng\,ml^{-1}}$ in three cases, $20–200\,\mathrm{ng\,ml^{-1}}$ in four and $> 200\,\mathrm{ng\,ml^{-1}}$ in six. Tumour size of the main mass, assessed by CT, ranged between 3 and 10 cm. The hepatic artery of the lobe mainly affected was selectively catheterized. A solution of Lipiodol (18 ml) and doxorubicin (60 mg) in a water-soluble non-ionic contrast medium was injected and the arterial branch then occluded with Gelfoam in the 13 patients. After 7 days, the contralateral liver was embolized in the same way in nine patients. This double procedure has been repeated every 6 months in the follow-up period. One patient has already received three courses of double embolization and two have received two. Mean follow-up is 7 (range 1–15) months. Clinical biochemistry is studied every 3 months and CT at 3, 6 and subsequent 6-monthly intervals.

The procedure caused no mortality and only minimal morbidity; fever and pain in two cases was responsive to conventional therapy. Tumour size has remained constant in five patients and was significantly reduced (by 25–50 per cent) in four. The follow-up of the remainder is limited. The α-fetoprotein levels, when raised, decreased after the procedure in all patients. In one patient a left hepatectomy was performed 1 month after embolization; all tumour tissue was necrotic with no signs of active tumour cells. Two patients died during follow-up. The actuarial survival rate is 80 per cent at 1 year.

In conclusion, liver transcatheter arterial embolization with Lipiodol and doxorubicin is a safe procedure, can be repeated during follow-up, allows identification of satellite masses not detectable with conventional CT, controls tumour growth and can be useful as a prior step to liver resection or transplantation. However, a longer follow-up is needed to determine its influence on survival.

Survival rate after resection for hepatocellular carcinoma in cirrhosis

G. Urso, G. Viti, M. Taffurelli, V.M. Greco, E. Pasqualini and D. Marrano, *Istituto di Clinica Chirurgica Generale dell'Universita di Bologna, Italy*

A total of 32 patients suffering from hepatocellular carcinoma (HCC) and cirrhosis have been treated (25 men and seven women). Surgical treatment consisted of 17 wedge resections, 11 lobectomies and four exploratory laparotomies. Hepatic resection was performed in 28 patients who presented with the following characteristics: Child's grade A cirrhosis in 16 patients, grade B in ten and C in two; focal lesions in 18 patients, multiple or diffuse lesions in ten; neoplasm diameter less than 5 cm in 14 patients, more than 5 cm in 14, with a range from 2 to 16 cm; capsule present in 18 patients and absent in ten; vessel thrombosis was present in 14 patients and absent in 14. According to the Edmondson classification, 14 patients were at level I and/or II and 14 were at level III and/or IV.

The actuarial 4-year survival rate is: 66·7 per cent for Child's grade A patients, no survival at 3 years for grades B and C; 31·7 per cent for patients with focal lesions and 42·9 per cent for those with multiple lesions; 39·3 per cent for patients with tumour diameter less than 5 cm and 20 per cent for neoplasms more than 5 cm; 64 per cent for capsulated tumours and 19 per cent for non-capsulated; 21·7 per cent in cases with vessel thrombosis and 51·9 per cent in patients without; and 60 per cent for patients with Edmondson I/II and no survival for patients with Edmondson III/IV.

In conclusion, hepatic resection is indicated in the treatment of HCC in patients with cirrhosis only when the cirrhosis is Child's grade A and the lesion is solitary, superficial, small (less than 5 cm) and possibly encapsulated.

Neurosurgery

Interactive image-directed neurosurgery: a report of the first 100 cases in Europe of frameless stereotaxy

C.L. Chandler*, H.B. Coakham*† and D.R. Sandeman†, *Imperial Cancer Research Fund and †Department of Neurosurgery, Frenchay Hospital, Bristol, UK*

The precision of image-directed neurosurgery has previously been obtained only using frame-based stereotactic systems which require peroperative scanning. These have limited applications to general neurosurgery. This paper describes experience with a new system that avoids the need for a stereotactic frame by registering the patient's head to an accurate three-dimensional reconstruction of two-dimensional scan data. Near-instantaneous reformatting of the scan data allows the constant updating of the position of a pointer to be shown relative to the preoperative image. The surgeon is then able to visualize key intracranial relationships of structure and pathology before and during surgery. This provides: (1) an accurate interactive guidance system that allows the surgeon to plan; and (2) precise access to the pathology and extent of resection, which results in smaller craniotomies, less morbidity and a subsequent reduction in operating time and inpatient stay. The system is described and the authors discuss the indications for its use, which include: accurate localization of small deep-seated intrinsic lesions; precise navigation around the skull base; and trans-sphenoidal, vascular and epilepsy surgery. This system represents a major advance in neurosurgical precision and has applications in other surgical disciplines, particularly spinal, orthopaedic, ear, nose and throat, ophthalmic and plastic surgery.

Regional differences in managing subarachnoid haemorrhage: a 3-year audit

D.T. Hope, J.C. Stephenson, V. Orpe, I. Chambers and A.D. Mendelow, *Newcastle General Hospital, Newcastle and Queen's Medical Centre, Nottingham, UK*

All 85 patients with subarachnoid haemorrhage admitted to the Neurosurgical Units of Queen's Medical Centre and Newcastle General Hospital between January 1990 and December 1992 have been audited. The purpose was to look at different patterns of referral and presentation. Of particular interest were the World Federation of Neurological Societies (WFNS) grade on admission (and on day of surgery), and the intervals from bleed to admission and from admission to surgery. The total length of stay in each regional unit was audited and the outcome as judged at discharge. The authors have tried to identify areas where the quality of care may be improved in the management of subarachnoid haemorrhage. The patients with good grades, WFNS I or II, still show wide variations in the timing of surgery, possibly reflecting the availability of beds, angiogram facilities, and the number of consultants. Newcastle tended to operate earlier and Nottingham later although the overall outcome was similar. Delayed surgery was associated with a higher rebleed rate in patients with good WFNS grades. Direct comparison of outcome between surgical units can be misleading unless strict criteria for comparison can be agreed. To measure quality of care standards must be established and British neurosurgery has, as a specialty, been slow to set these.

Extreme lateral suboccipital transcondylar approach to the clivus and craniocervical junction

D.A. Lang, G. Neil-Dwyer and F. Iannotti, *Wessex Neurological Centre, Southampton University Hospital, Southampton, UK*

Access to the anterior rim of the foramen magnum, craniocervical junction, clivus and front of the lower brain stem can be obtained by using an anterior, lateral or posteriolateral approach. The access used should provide good visualization of the pathology and the surrounding anatomical structures with minimal retraction of neural structures. Ideally the skull should be entered and anatomical routes followed in such a way that between the surgeon and the lesion is a short straight line. The preferred approach to this region depends on the exact site of the lesion, the nature of the pathology and the aim of the operation. Of particular importance is the superior extent of the lesion, its relationship to the neuraxis and its position relative to the midline.

Experience is reported of the transcondylar suboccipital approach used in 12 patients to remove lesions related to the anterior rim of the foramen magnum, the lateral clivus, the front of the lower brain stem and for access to the vertebrobasilar circulation. This paper discusses some of the limitations imposed both by the location of the pathology and the nature of the lesion. The need for flexibility and the necessity for combined anterior and transcondylar suboccipital approaches in selected cases are emphasized.

Neuro-otological team approach to surgical management of acoustic neuroma

R.H. Lye and R.T. Ramsden*, *Departments of Neurosurgery and *Otolaryngology, The Royal Infirmary, Manchester, UK*

A combined neurosurgical and otolaryngological approach to the management of patients with acoustic nerve tumours is advocated, and the results of adopting this policy in the management of a consecutive series of 250 patients with 254 acoustic tumours are presented.

Operation was via the translabyrinthine or suboccipital approach. There was a 2 per cent (five patients) perioperative mortality rate. In 89 per cent of tumour removals (226 procedures) the facial nerve was preserved in continuity, and normal or good facial function was observed in 79 per cent (197 patients). Few patients had useful hearing before operation and attempts at hearing preservation in this series were unsuccessful.

Complications included major brain stem ischaemia in three patients (1 per cent), cerebrospinal fluid fistula in 12 (5 per cent) and troublesome facial dysaesthesia in 17 (7 per cent). Not surprisingly, morbidity rates appeared to be increased among patients with larger tumours.

Some patients complained of an unusual type of postoperative dreamlike state that appeared to be a form of hypnagogic hallucination. Neurophysiological mechanisms that might be responsible for this phenomenon are discussed.

The flexibility of a bidisciplinary surgical approach has proven advantageous, and its adoption is recommended.

Growth characteristics of acoustic neuroma: the fate of capsule fragments remaining after tumour removal

R.T. Ramsden* and R.H. Lye, *Departments of Neurosurgery and *Otolaryngology, Manchester Royal Infirmary, Manchester, UK*

The case histories of 26 patients in whom a fragment of tumour capsule remained attached to important structures after removal of acoustic nerve tumours were reviewed to define the growth characteristics of tumour rests. All patients were monitored using computed tomography and, in some instances, magnetic resonance imaging (MRI).

Of 12 patients who underwent subtotal tumour removal, eight (aged 27–73 years) had a solitary acoustic schwannoma. One patient died from cerebrovascular disease but the other seven were well at the last review (mean 39 (range 18–60) months). Five of the eight patients had no evidence of regrowth at a mean of 25 (range 8–42) months after surgery. Three patients showed evidence of tumour regrowth at 21, 22 and 69 months after operation.

An additional four patients aged 15–51 (mean 31·5) years had central neurofibromatosis and presented with bilateral acoustic nerve tumours. Two of these four patients exhibited evidence of tumour regrowth at 13 and 54 months. Conversely, two patients showed no evidence of regrowth at 33 and 45 months after operation.

Fragments of tumour capsule were left attached to important structures in 14 other patients, who subsequently underwent MRI enhanced with gadolinium diethylenetriamine penta-acetic acid at a mean of 70 months (range 6 months to 12 years) after operation. In seven of the patients tumour could still be detected, and in four of these the tumour rests appeared to have enlarged.

It appears that acoustic neuromas grow slowly but even tiny tumour remnants may persist for many years. An appropriate management policy is discussed.

Microsurgical treatment of brain metastases

R. Roselli, M. Iacoangeli, A. Pompucci, R. Trignani and M. Scerrati, *Institute of Neurosurgery, Catholic University, Rome, Italy*

The surgical treatment of single or solitary brain metastases was unrewarding until a few years ago. Microsurgical techniques and intraoperative use of ultrasonography have decreased the surgical morbidity and mortality rates. In an earlier series (March 1988 to March 1992) concerning 41 hemispheric metastases treated surgically, the mortality rate was 2·4 per cent and morbidity rate 14·6 per cent.

To assess surgically related prognostic factors, 11 hemispheric metastases (single or solitary) from solid cancer treated during the period from January 1992 to March 1993 have been studied. Specifically, these tumours had to be subcortically located (up to 2 cm from the cortical surface) and small in size (3 cm or less in maximum diameter).

After linear skin incision, single burr hole and circular small craniotomy, the lesions were removed through the crown of the involved gyrus or by an intergyral approach. All metastases were localized using ultrasonography and resected microsurgically (tumorectomy). The mean operative time was <2 h. Only one patient had transient neurological deterioration (campimetric deficit). The Karnofsky performance score was always above 0·80. No deaths occurred. These results are due to microsurgical techniques, intraoperative use of ultrasonography and better case selection. A shorter operative time and a minimal craniotomy could be additional positive prognostic factors for supratentorial, small and superficial metastases.

Alkaline elution in cell culture of human glioma: a simple method to quantify drug-induced DNA lesions

M. Senkal, J.C. Tonn, M. Kemen, H.-H. Homann and R. Schönmayr, *Neurosurgical Department, University of Giessen and Department of Surgery, Ruhr-University, Bochum, Germany*

The alkaline elution method has been used to examine the effect of different chemotherapeutic drugs on DNA in several experimental tumours. To quantify drug-induced DNA lesions in human glioma the alkaline elution method was used to measure mitoxantrone-induced DNA single-strand breaks in cell cultures of human astrocytoma and glioblastoma tumours. Mitoxantrone is an anthracene derivative which could be potentially used for chemotherapy of malignant brain tumours.

Glioblastoma or astrocytoma tumours were cultured from patients who had undergone surgery. No chemotherapy or radiotherapy were given before surgery. The cell cultures were incubated for 1 h with different concentrations of mitoxantrone (0, 0·01, 0·1 and 1·0 μg ml^{-1}) at 37°C. Protein-associated and protein-free DNA strand breaks were measured using the alkaline filter methods.

It was found that the alkaline elution method could be adapted to measure DNA lesions in malignant brain tumours and that mitoxantrone induces DNA strand breaks in a dose-dependent manner in both glioblastoma and astrocytoma cells. Although only a small effect was observed at a mitoxantrone concentration of 0·01 μg ml^{-1}, there was a linear increase of DNA strand break frequency induced by the drug between 0·01 and 1·0 μg ml^{-1}. However, the DNA hourly elution rate indicating the strand break frequency increased significantly at the higher concentrations of 0·1 and 1·0 μg ml^{-1} mitoxantrone.

Mitoxantrone is not in therapeutic use for malignant brain tumours at present. However, these results suggest that it has a potential use in patients if a high tissue concentration can be achieved.

Nutrition

Effect on visceral protein synthesis of enteral diets with different proportions of medium-chain triglycerides in portocaval-shunted rats

J.A. Baena, E.M. Gémar, J.E. Murio, E. García- Arumí, M.A. Arbós, S. Schwartz and J. Bonnín, *Hospital General i Universitari Vall d'Hebrón, Barcelona, Spain*

Portocaval shunt in healthy rats induces several metabolic changes similar to chronic liver failure. Patients with chronic hepatic failure show a deficient nutritional status, with changes in protein, lipid and carbohydrate metabolism. The liver protein synthesis is impaired and the main fuel for the liver is derived from lipids (69 per cent *versus* 40 per cent in healthy people).

Medium-chain triglycerides (MCT) have been shown to have a beneficial effect on liver protein synthesis with parenteral nutrition in several clinical situations, and in the experimental portocaval shunt. MCT have been used in diets for liver failure, but the effect on liver protein synthesis has not yet been studied. The aim of this work was to evaluate the effect of varying proportions of MCT and long-chain triglycerides (LCT) on liver and jejunal protein synthesis in a model of end-to-side portocaval shunt.

Four groups of 15 rats were subjected to end-to-side portocaval shunting. After 15 days of feeding with standard diet *ad libitum*, they were fed an enteral diet for 8 days, with different proportions of MCT:LCT. Quantitative intakes of nitrogen, lipids and carbohydrates were the same for all groups, in a weight proportion of 20:30:50 respectively. Four groups were established according to the MCT:LCT proportion: A, 0:100 (control), B, 20:80, C, 50:50, and D, 80:20. Protein synthesis was calculated using the flooding dose method of [^{14}C]leucine, described by Garlick and McNurlan.

The nitrogen and calorie intakes were similar for groups A, B and C and less in group D. The urinary urea excretion was similar in all groups. The protein synthesis in the liver, in K_s terms, was higher in groups B and C. The jejunal protein synthesis was similar in all groups.

In conclusion, the addition of MCT to the enteral diet had a negative effect on the liver protein synthesis.

Postoperative enteral nutrition: experience in 311 patients receiving total enteral nutrition after major upper abdominal surgery

H.-H. Homann, M. Kemen, H. Servatius, M. Senkal and V. Zumtobel, *Ruhr-University Bochum, St Josef Hospital, Bochum, Germany*

Enteral feeding via a needle catheter jejunostomy (NCJ) following gastrointestinal surgery is an effective mode of feeding and is less expensive than parenteral nutrition. The positive effects of enteral nutrition on postoperative immune function, decreased translocation from the gut and maintenance of gut structure may improve the clinical outcome in patients undergoing major gastrointestinal surgery.

In a retrospective study, gastrointestinal side-effects related to feeding scheme and type of diet, and catheter-related complication rate, were evaluated in 311 such patients with placement of a NCJ and postoperative enteral nutrition, from 1982 to 1992. Enteral nutrition was started at 3–5 days after surgery in 95 patients, using a peptide-based enteral diet, the rate of gastrointestinal side-effects was 40 per cent and led to discontinuation of enteral nutrition in 24 cases (25 per cent). A group of 100 patients received a non-elemental diet, diarrhoea occurred in 30 per cent of cases and enteral nutrition was discontinued in 12.

The remaining 116 patients received total enteral nutrition with a non-elemental diet starting 12 h after surgery, the nutritional goal of approximately 8400 kJ day^{-1} being reached on day 3 after surgery, diarrhoea was noted in 18 per cent and required cessation of enteral nutrition in nine patients. One catheter dislocation into the abdominal cavity was reported, infection of the catheter entrance at the lateral abdominal wall led to surgical intervention in three cases.

It is proposed that enteral feeding after gastrointestinal surgery should be started within 12 h after operation using catheters placed beyond the pylorus, such as NCJ or percutaneous endoscopic jejunostomy. The use of elemental diets has no indication in the postoperative period. The early use of fibre-supplemented nutrition should be investigated in further studies, but may be superior to other formulae regarding the occurrence of gastrointestinal side-effects.

Oesophagus

Surgical treatment of nutcracker oesophagus: long-term follow-up

G. Cardillo, D. D'Ugo, P. Granone, V. Porziella, G. Castrucci, L. Mascellari and A. Picciocchi, *Department of Surgery, Catholic University of Rome, Italy*

Nutcracker oesophagus (NO) represents the most common oesophageal motility disorder in patients with non-cardiac chest pain and is found in 27–48 per cent of these patients; it is characterized by normal peristaltic progression with simultaneous contractions <10 per cent and mean distal oesophageal wave pressure >180 mmHg. Changes in motility patterns have been reported in the literature so that at the present time NO diagnosis needs to be confirmed with a second manometric examination performed at least 3 months later. In some instances NO can be manifested by severe incapacitating symptoms refractory to medical therapy. However, surgical treatment is very rare (up to now not more than ten cases have been published in the literature). In the present study long-term follow-up of three cases of NO associated with mid-thoracic oesophageal diverticula treated surgically at this institution between 1988 and 1990 is reported.

All patients (two women, one man, mean age 65·4 years) were evaluated by means of barium meal, endoscopy, manometry, 24-h pH manometry and oesophageal scintigraphy. Mean(s.d.) distal oesophageal wave pressure was 198(15) mmHg. Patients complained of dysphagia and severe chest pain refractory to prolonged medical treatment. Serial electrocardiograms were within normal limits and repeat thallium stress testing showed no evidence of cardiac ischaemia. A repeat motility test confirmed the presence of NO. Patients underwent extended oesophagomyotomy through the left chest, performed from the distal margin of the high-pressure zone at the point where transverse gastric veins are visible up to the aortic arch, carefully preserving the vagus nerve, a modified Belsey IV procedure was also performed. In two patients a stapled diverticulectomy was performed because of the large size of the diverticular pouch.

No major complications occurred in these patients. The mean follow-up was 3·8 years (range 38–51 months). All patients show satisfactory relief of dysphagia and chest pain. Manometric control showed normal peristalsis in the proximal oesophageal body. Along the length of the myotomy absent or low-amplitude peristalsis was recorded.

In conclusion, it is suggested that in a very few selected cases (incapacitating symptoms and associated diseases) long oesophagomyotomy is a useful therapy in the treatment of NO.

Aorto-oesophageal fistula caused by a foreign body

J.B. Comes, J. Puig-La Calle, N. Farreras, R. Sales, L.H. Allende and F. Lluis, *Hospital de la Sta Creu i St Pau, Barcelona, Spain*

Aorto-oesophageal fistula is an uncommon and usually lethal condition. There are several causes, such as thoracic aortic aneurysm or carcinoma of the oesophagus. However, little attention has been directed to fistulas caused by a foreign body, with only 89 cases reported in the literature, and just one recorded survivor.

This report details a case of aorto-oesophageal fistula caused by an ingested chicken bone. A 64-year-old man was admitted to the emergency room because of upper gastrointestinal bleeding. He recalled an episode of retrosternal chest pain after eating chicken 8 days before. The site of bleeding could not be visualized by upper gastrointestinal tract endoscopy. The patient suddenly collapsed 2 h later due to hypovolaemic shock. After a second unsuccessful attempt at endoscopy, a Sengstaken–Blakemore balloon was placed and the bleeding arrested. Computed tomography showed free air in the mediastinum. During this exploration, the patient suffered a cardiac arrest and died. Post-mortem examination revealed an oesophageal perforation (caused by the chicken bone) with aortic perforation and a mediastinal fistula.

Suggestions for diagnosis and treatment of this fearsome complication are discussed.

Surgery for oesophageal perforation

P.E. Goretzki, O. Horstmann, P. Verreet and H.-D. Roher, *Chirurgische Universität Klinik A, Düsseldorf, Germany*

Various therapeutic strategies have been stressed in the treatment of patients with oesophageal perforation but the mortality rate has remained high at approximately 40–60 per cent. Since endoscopic procedures in the diagnosis and treatment of oesophageal stenosis are now widely used, perforation as a complication of these procedures occurs more often. This study investigated whether these patients will also suffer from such high mortality rates. From 1986 to 1993, 14 patients with oesophageal perforation were treated. In eight patients an iatrogenic perforation of a malignant stenosis was detectable during diagnostic ($n = 3$) or therapeutic ($n = 5$) endoscopic procedures. The four patients with oesophageal resection survived, whereas a conservative approach in four patients was lethal in two (one mediastinitis, one bleeding). All six patients with oesophageal perforation (four iatrogenic, two Boerhaave's syndrome) related to benign oesophageal diseases survived. With the exception of one patient with collar oesophageal perforation and conservative treatment all were operated on directly after referral, 1–7 days after perforation. In conclusion, oesophageal perforation with early adequate operative treatment does not carry the reported high mortality rate.

Gastric antral patch oesophagoplasty for benign oesophageal stricture

T.B. Hugh and B. Li, *St Vincent's Hospital, Sydney, Australia*

Transmural oesophageal stricture because of either reflux or corrosive ingestion is a formidable surgical problem. A new procedure, gastric antral patch oesophagoplasty, provides an alternative to oesophageal resection and replacement for this condition, and has been performed in 16 patients. 15 had reflux-associated strictures and one stricture was due to corrosive ingestion. All had severe irreversible strictures, and most had undergone multiple previous operations.

A full-thickness patch of gastric antral wall, with a blood supply based on the gastroepiploic arcade, was used to widen the strictured segment of oesophagus and was combined with an antireflux procedure where appropriate. Follow-up ranged from 2 to 11 years. Excellent results, with restoration of normal swallowing, were obtained in 12 patients, four patients required further occasional oesophageal dilatation. There were no deaths.

Gastric antral patch oesophagoplasty is a useful alternative to oesophageal resection in patients with irreversible benign oesophageal stricture.

Vigorous achalasia: short *versus* extended myotomy

L. Martinez de Haro, P. Parrilla, A. Ortiz, G. Morales, V. Garay and J. Aguilar, *V. Arrixaca Hospital, University of Murcia, Spain*

Vigorous achalasia has been considered an indication for surgical treatment in which a thoracic approach is recommended for extending Heller's myotomy along the whole of the oesophageal body to the point where the manometric study shows high-amplitude waves. Clinical results and postoperative manometric studies in 16 patients with vigorous achalasia undergoing abdominal surgery with myotomy of the lower oesophageal sphincter (LOS) not extended to the oesophageal body were analysed to assess whether an extended myotomy is necessary in the surgical treatment of this form of achalasia.

The clinical results were excellent to good in all cases. As assessed radiologically, surgery induced a significant decrease ($P < 0{\cdot}01$) in the diameter of the oesophagus. From a manometric viewpoint, the most significant postoperative changes were a decrease in the resting pressure of the LOS and oesophageal body, and notable reductions both in wave amplitude at all levels of the oesophagus and in the percentage of repetitive waves.

These results suggest that vigorous achalasia can be treated surgically in the same way as classical achalasia and question, at least from a therapeutic viewpoint, the use of the term 'vigorous' achalasia.

Oesophagoplasty for benign oesophageal stricture in children

O. Mutaf, G. Ozok and A. Avanoğlu, *Ege University Medical Faculty, Department of Paediatric Surgery, Izmir, Turkey*

A total of 111 children with caustic oesophageal stricture requiring oesophagoplasty are reported. Eighty had a retrosternal colonic transplant: a two-stage oesophagocolostomy in 68 and a one-stage cervical anastomosis in 12. In the retrosternal group there were two cases of total necrosis and three cases of terminal necrosis of the cervical end of the transplant; 12 patients developed anastomotic stenosis at the cervical end of the transplant. The incidence of cervical anastomotic stenosis was 50 per cent (six) in the single-stage group compared with 9 per cent (six) in the two-stage group.

Ten patients underwent a right thoracic retrohilar colonic transplant; seven had redundancy of the graft compared with 9 per cent (seven) in the retrosternal group

Three patients had a jejuno-oesophagoplasty that resulted in total transplant necrosis in two cases and terminal necrosis in one. The remaining 18 patients had segmental resection of the intrathoracic oesophageal stenosis followed by end-to-end anastomosis. The overall mortality rate was 3·6 per cent (four patients). Twenty-six patients were followed for 15 years; 21 had excellent results and five had residual problems. In the authors' experience, although various oesophagoplasty techniques are available with acceptable mortality, the associated morbidity rate remains significant since none of these confers normal oesophageal motility after the substitution procedure. Therefore, every effort should be made to preserve the native oesophagus.

Prophylactic digitalization in thoracic oesophageal surgery

A.J. Ritchie, A. Kennedy, J. McGuigan and J.R.P. Gibbons,
Aberdeen Royal Infirmary, Aberdeen and Royal Victoria Hospital, Belfast, UK

Cardiac dysrhythmia is associated specifically with thoracic operations, resulting in the prophylactic use of digitalis In a prospective trial of 130 patients, 80 underwent oesophagogastrectomy and 50 total thoracic oesophagectomy (TTO) after random allocation to prophylactic digitalization or not. Digoxin was given by a standardized oral regimen and serum levels adjusted according to serum radioimmunoassay

Screen electrocardiographic monitoring commenced at induction of anaesthesia and continued for 96 h and on alternate days thereafter until discharge. All dysrhythmias were recorded and assessed blind by a cardiologist. In oesophagogastrectomy, only patients with malignant disease suffered dysrhythmia (46 per cent digitalized, 32 per cent not). In TTO the overall incidence was 60 per cent In both groups prophylactic digitalization neither significantly prevented nor controlled dysrhythmia.

It was concluded that prophylactic digitalization is not necessary in surgery for benign disease and does not control or prevent this complication in other groups

Oesophagus: cancer

Oesophagectomy with thoracotomy in thoracic oesophageal carcinoma: 10 years' experience

N. Abecasis, J.C. Mendes de Almeida, A. Bettencourt, C Santos Costa and J.M Mendes de Almeida, *Instituto Português de Oncologia, Lisbon, Portugal*

Surgical treatment of oesophageal carcinoma remains one of the hardest tasks confronting surgeons, because of the intense care that patients require to reduce morbidity and mortality, as well as the limited success in long-term control of the disease. A complete clinicopathological data record was kept of all patients operated on between April 1983 and November 1992, including a complete follow-up of 90 7 per cent of them. Presented is experience with the operation considered optimal by the authors when the goal of surgery is cure of the disease.

A total of 75 patients (65 male, ten female) were operated on. The operation had a curative intent in 76 per cent of cases and was palliative in 24 per cent (presence of residual tumour at the end of operation). Of oesophagogastric anastomoses, 80 per cent were performed within the thorax and 20 per cent in the neck Locations of the tumours were divided into upper, middle or lower third

Overall hospital mortality rate was 16 per cent (12 patients) In-hospital major morbidity rate (excluding mortality) was also 16 per cent. The causes of both are presented Pathological staging of tumours was as follows (values are percentages). T_{is} 2, T_1 2; T_2 20, T_3 56, T_4 21. In all, 33 per cent of patients had no lymph node metastasis (N_0), while 67 per cent already had nodal metastases (N_1)

Presented are the actuarial survival rates of the patients at 5 years according to the penetration of the tumour in the oesophageal wall and according to the presence or absence of regional or distant lymph node metastases

Results of surgical treatment of Barrett's adenocarcinoma

J Malaise, B. Hermans, J.M. Collard, J.B. Otte and P.J. Kestens, *Department of Digestive Surgery, St Luc Hospital, Brussels, Belgium*

From 1984 to 1992, 28 patients with Barrett's adenocarcinoma and four with high-grade dysplasia arising in Barrett's metaplasia were admitted to this department for oesophageal surgery. Surgery consisted of subtotal oesophagectomy in 24, distal oesophagectomy in seven, or bypass operation in one. Operation was carried out with curative intent in 28 patients, four patients underwent palliative surgery owing to non-resectable metastatic lymph nodes in three and a positive margin at postoperative histological examination in one. After operation all patients were discharged home.

Postoperative examination of the resected specimens revealed the presence of neoplastic cells in two of the four patients operated on for high-grade dysplasia. Actuarial survival rate (3- and 5-year) of the 26 patients with adenocarcinoma who underwent potentially curative oesophagectomy was 58 and 41 per cent, respectively Median survival was 16 months for patients with metastatic lymph nodes *versus* 29 months for those with normal lymph nodes, and 22 months for patients with a transparietal tumour *versus* 30 months for those with a non-transparietal tumour. Of the two patients with high-grade dysplasia, only one was alive at 2 years and one died from an unrelated cause at 5 years

Oesophageal resection with extensive lymph node dissection is the treatment of choice for adenocarcinoma arising in Barrett's mucosa High-grade dysplasia present on two successive oesophageal biopsies is an indication for oesophagectomy, as adenocarcinoma is already present in 50 per cent of cases.

Endoscopic palliation of malignant oesophageal stricture with BiCap tumour probe set

P. Misiuna, M. Chmurzyński, A. Dabrowski, G. Wallner and K. Zinkiewicz, *Department of General Surgery II, Medical Academy, Lublin, Poland*

Patients with irresectable malignant oesophageal stricture may benefit from endoscopic palliation One of the methods is bipolar electrocoagulation with the BiCap Tumour Probe This procedure was performed 29 times in 19 patients with irresectable planoepithelial carcinoma and obstructive symptoms The clinical and endoscopic criteria for treatment were. circumferential malignant stricture, oesophageal stricture >5 mm in each direction, no tracheo-oesophageal fistula and life expectancy >30 days.

Treatment was performed endoscopically with local anaesthesia after premedication. In all patients, remission of dysphagia symptoms was observed after 3–5 days. Diminution of dysphagia symptoms lasted 3–8 months BiCap procedures were repeated in some patients when dysphagia recurred. No serious life-threatening complications were observed

It is suggested that this method is a useful approach to endoscopic therapy of oesophageal neoplasms.

Endocrine cells in Barrett's oesophagus: specificity and clinical implications

A J Ritchie, C. Johnston, J. McGuigan and J.R.P. Gibbons, *Aberdeen Royal Infirmary, Aberdeen and Royal Victoria Hospital, Belfast, UK*

Immunohistochemical methods were used to map the number and distribution of endocrine cells and their regulatory peptide products that are implicated in neoplastic transformation in 43 patients undergoing oesophageal resection for benign and malignant disease with and without Barrett's changes. Only 14 per cent of adenocarcinomas contained endocrine cell populations whereas 62 per cent of intestinal and 78 per cent of gastric metaplasias contained specific endocrine cell populations. The intestinal and gastric populations mimicked those expected in normal tissue whereas in 69 per cent of dysplasias the cell populations became aberrant A pattern of endocrine cell differentiation mimicked by that of normal counterpart tissue has not been previously described in Barrett's oesophagus. In addition, the profusion of endocrine cells and the loss of specificity as dysplasia develops have important clinical implications

Surgery for carcinoma of the oesophagus: experience in Latvia

V. Utkin, *Second Department of Surgery, Latvian Academy of Medicine, Riga, Latvia*

The incidence of oesophageal carcinoma in Latvia is 3·8 per 100 000 population A total of 105 patients have been treated in the past 20 years. Radical surgery was performed in only 55 cases (52 4 per cent).

For small tumours the operation of choice is transhiatal oesophagectomy with cervical oesophagogastric anastomosis (eight operations), for advanced carcinoma the method of choice is the Lewis operation with high intrathoracic oesophagogastric anastomosis (28 operations). In other cases, the Thorek (16) or Garlock–Sweet thoracoabdominal operation (three) was performed

Leakage at the oesophagogastric anastomosis was observed in 18 cases The postoperative mortality rate was 16 3 per cent

The survival rate at 1, 3 and 5 years was 65·5, 24·7 and 9·4 per cent respectively

Modified three-stage resection for oesophageal carcinoma

T.N. Walsh and T.P.J. Hennessy, *University Department of Surgery, St James's Hospital, Dublin, Ireland*

The greater safety and ease of construction of anastomosis in the neck are acknowledged advantages of the McKeown three-stage resection. It is time consuming, however, requiring three separate operations with resultant increased morbidity A modification of this technique has been devised in which right thoracotomy allows early tumour assessment, mobilization and wide dissection followed by synchronous abdominal and neck dissection A 6-year experience with this technique was analysed using Cox's proportional hazards model.

Some 116 patients underwent resection The male female ratio was 1 5:1. There were 75 (65 per cent) squamous cell carcinomas, 37 (32 per cent) adenocarcinomas and four (3 per cent) adenoid cystic tumours There

0007–1323/93/S060–02 © 1993 Butterworth-Heinemann Ltd

was a significant difference between men and women in terms of tumour type and stage, with significantly more women having early-stage squamous tumours ($P < 0{\cdot}05$). Nine patients died in hospital (7 8 per cent). The 1-, 2- and 5-year survival rates were 50, 31 and 26 per cent Factors that had a survival advantage included lower third or cardial site, clear resection margins, node-negative disease and female sex.

We believe that this modification provides acceptable mortality and favourable long-term survival and is the most appropriate procedure for the majority of oesophageal tumours

Chemotherapy, radiotherapy and surgery *versus* surgery alone for oesophageal squamous carcinoma

T.N Walsh, N. Noonan, PWN. Keeling, B. Breslin and T.P.J. Hennessy, *University Department of Surgery, St James's Hospital, Dublin, Ireland*

Overall survival following resection of oesophageal squamous carcinoma is around 20 per cent at 5 years and in the absence of screening for early cancer is unlikely to be improved by more radical surgery. Multimodal therapy has a potential role but few studies confirm a survival advantage A prospective randomized clinical trial was started in May 1990 in which the results of chemotherapy (cisplatin and 5-fluorouracil), radiotherapy (40 Gy) and surgery (CRS) were compared with those of surgery alone. Of a total of 56 patients recruited to the squamous cell limb, 41 have completed treatment and been followed for more than 3 (mean 10 8, range 3–28) months

	CRS group (n = 20)	Surgery group (n = 21)	P
Patients withdrawn	2	0	n s
Tumours of stage 0–2A (%)	80	38	0 01
Patients with complete regression	6	0	n s
90-day mortality	2	1	n s.
Survival (months)			
Mean	12·2	8 8	n s
1 year (%)	80	50	n s

n.s , Not significant

Some 30 per cent of patients of the CRS group were tumour-free at operation and significant downstaging of the whole group was observed. While a survival advantage is not yet apparent, these findings suggest that CRS may enhance long-term survival The trial continues

Oesophagus: reflux

Gastro-oesophageal reflux after cholecystectomy: a manometric explanation

P.J. Byrne, P. Lawlor, M. Caldwell, T.N. Walsh and T.P.J. Hennessy, *University Department of Surgery, St James's Hospital, Dublin, Ireland*

Gastro-oesophageal reflux develops in over 30 per cent of patients after cholecystectomy, but lower oesophageal sphincter pressure (LOSP) is not significantly changed. The sphincter function index (SFI) (the product of LOSP and percentage abdominal length), which is a more accurate indicator of cardia competence, was used to assess sphincter function in this study.

Patients were investigated before and 3 months after surgery using 24-h ambulatory pH and stationary manometry. Patients in group 1 ($n = 11$) did not experience reflux after cholecystectomy, patients in group 2 ($n = 13$) had significant reflux after operation, and those in group 3 ($n = 16$) underwent antireflux surgery.

	Mean(s.e.m.) preoperative SFI	Mean(s.e.m.) postoperative SFI	P*
Group 1 ($n = 11$)	903(95)	1223(133)	n.s.
Group 2 ($n = 13$)	718(98)	507(115)	0·018
Group 3 ($n = 16$)	198(29)	1041(171)	0·001

*Wilcoxon signed rank test; n.s., not significant

Group 1 showed no conspicuous change in the SFI after cholecystectomy, while in group 2 the SFI was significantly reduced. This difference was not evident on LOSP measurement alone. Nissen fundoplication produced a competent sphincter in group 3 patients, which was reflected by a significant increase in SFI. Gastro-oesophageal reflux after cholecystectomy is caused by sphincter incompetence, the aetiology of which is unclear. Restoration of competence by antireflux surgery was confirmed in group 3 patients. The SFI is a more accurate measurement of sphincter competence than LOSP alone.

Laparoscopic Nissen fundoplication

G.B. Cadière, J. Bruyns, J. Himpens and P. Van Alphen, *Hôpital Universitaire Saint-Pierre, Brussels, Belgium*

A total of 95 patients (55 men, 40 women) of mean age 47 (range 17–76) years not responding to conservative treatment for gastro-oesophageal reflux disease (GORD) were treated with laparoscopic Nissen fundoplication. Of these, 72 patients presented with heartburn accompanied by oesophagitis grade II or III as diagnosed by endoscopy. In 11 patients heartburn was accompanied by grade I oesophagitis, whereas in 12 patients an atypical pain was accompanied by grade II oesophagitis. In these latter 23 cases, manometry and pHmetry linked the symptoms to GORD. The mean duration of previous medical treatment was 34 (range 6–180) months. The American Society of Anesthesiologists (ASA) operative risks were as follows: 80 grade I, 13 grade II and two grade III. Thirty-five patients had had previous abdominal surgery.

Five cannulas were needed for operation. The lesser omentum and then the phreno-oesophageal ligament were incised with a coagulation hook. The posterior wall of the oesophagus was dissected from right to left until the left crus could be seen. The short gastric vessels were subsequently isolated and clipped, thereby permitting mobilization of the greater curvature. A fundal floppy wrap at least 5-cm long was created and sutured by five separate intracorporeal knots.

There were four peroperative complications: one gastric perforation, two pleural perforations and one liver laceration. There were three conversions to laparotomy: one because of a defective needle holder and two because of left liver lobe hypertrophy. The mean hospital stay was 3·9 (range 2–10) days. Morbidity included one wrap necrosis and two pulmonary complications (hospital stay 10 days). One patient presented an incisional hernia on a trocar site on the linea alba. No recurrent heartburn has been observed in a short follow-up period (mean 227 (range 4–626) days). Mild dysphagia during the first 3 months after operation occurred in 12 patients. There was, however, no long-term dysphagia. There was one case of gas bloat and one case of clip migration into the oesophagus. Endoscopy was performed in 36 patients during the third postoperative month. A normal mucosa was seen in 35 patients, and one patient presented with asymptomatic grade I oesophagitis.

Nissen's fundoplication is feasible by laparoscopy. This technique improves the patient's comfort and shortens the hospital stay. Further evaluation and long-term follow-up are warranted.

Manometric evaluation of the lower oesophageal sphincter in gastro-oesophageal reflux disease: a modern approach

M. Costantini, G. Zaninotto, M. Anselmino, C. Boccù, L. Nicoletti, F. Bagolin and E. Ancona, *Istituto di Chirurgia Generale II, Università di Padova, Italy*

Gastro-oesophageal reflux disease (GORD) is a multifactorial process, in which a defective lower oesophageal sphincter (LOS) is often implicated. Identification of patients with GORD and a defective LOS is relevant, since these patients show frequent relapses after medical treatment and may benefit from surgery. To improve the accuracy of oesophageal manometry in detecting a defective LOS, a computer-aided system was developed that allowed calculation of new LOS manometric parameters, in addition to pressure, and overall and abdominal lengths.

A total of 158 consecutive patients were evaluated with 24-h pH monitoring of the distal oesophagus and stationary oesophageal manometry. LOS evaluation was performed with four side holes at the same level oriented by 90° angles, withdrawing the probe across the cardia at a slow constant speed ($1\ \mathrm{mm\ s^{-1}}$). Pressure data were acquired at 20 Hz and stored on a computer. LOS resting pressure at the respiratory inversion point (LOSP), LOS overall and abdominal length were measured. The mean LOSP inside the sphincteral curve (mLOSP), the area under the sphincteral curve (LOS-AUC) and the three-dimensional LOS 'vector volume' (LOS-VV) were also calculated. A defective LOS was identified if any of these parameters fell below the fifth percentile of the control group (14 healthy subjects).

On the basis of pH monitoring, 53 patients were diagnosed as having GORD; of the others, 18 had primary oesophageal motor disorders, 30 irritable bowel syndrome and 42 GORD-like dyspepsia, 15 were evaluated after Nissen–Rossetti fundoplication. LOSP and mLOSP values showed excellent correlation ($r = 0{\cdot}88$) and no statistical differences. Patients with GORD showed LOSP, mLOSP, LOS-AUC and LOS-VV values significantly lower than those in the other groups ($P < 0{\cdot}001$). A defective LOS, as evaluated by LOSP, LOS oesophageal length or LOS abdominal length, was found in 43 per cent of the patients with GORD. By using LOS-AUC or LOS-VV, the prevalence increased to 49 per cent and to 57 per cent using any of the above parameters. On the other hand, a LOS defective in LOSP, LOS oesophageal length or LOS abdominal length was detected in 11 per cent of patients without GORD, whereas a LOS defective in LOS-AUC or LOS-VV was seen in only 7 per cent.

To summarize, a defective sphincter is detectable in more than half of patients with pH-monitored proven GORD. Computer-aided evaluation of the LOS improves the sensitivity and accuracy of oesophageal manometry, and should be performed routinely in the evaluation of patients with GORD.

Laparoscopic Nissen fundoplication: rationale for a new approach

C. de Gheldere, J.M. Collard, J.B. Otte and P.J. Kestens, *Department of Digestive Surgery, Louvain Medical School, St Luc Hospital, Brussels, Belgium*

From September 1991 to January 1993, 57 adult patients underwent operation for gastro-oesophageal reflux disease (GORD) with ($n = 33$) or without ($n = 11$) sliding hiatal hernia, paraoesophageal hernia without reflux ($n = 4$) or failure of a previous antireflux operation ($n = 9$). The operation was completed by laparoscopy in 28, laparotomy in 25 or left thoracotomy in four. The major reason for using an open approach was a remedial operation in nine, abdominal wall-related problems in eight, a

0007–1323/93/S062–03 © 1993 Butterworth-Heinemann Ltd

shortened oesophagus in four, and the need for additional surgical procedures in the abdomen in two. Conversion of laparoscopy to open surgery was necessary in two patients owing to hard adhesions in one and liver parenchyma fragility in one. The fundoplication consisted of a subdiaphragmatic Nissen in 46, a supradiaphragmatic Nissen in three, a partial fundoplication in seven, or a duodenal diversion in one. Laparoscopic Nissen fundoplication consisted of a 360°, 2-cm long floppy wrap with division of the short gastric vessels, posterior crural approximation and intraluminal calibration.

Mean postoperative hospital stay was 6·7 days for patients undergoing laparoscopy, 8·6 days for those having laparotomy, and 13·6 days for those having thoracotomy. Of the patients having laparoscopy, 83 per cent resumed their occupational activity within 2 weeks of operation, while all patients but one having laparotomy or thoracotomy returned to work more than 6 weeks after the operation. At follow-up, none of the 57 patients had residual heartburn, and only one had dysphagia. At postoperative barium swallow study there was neither disruption of the wrap nor gastro-oesophageal reflux (GOR). In one patient having laparoscopy, the wrap was found to have partially herniated into the chest. Adequate lower oesophageal sphincter pressure ($\geqslant$6 mmHg) was restored in all patients having laparoscopy who underwent postoperative oesophageal manometry (16 of 16). Postoperative oesophageal acid exposure was normal in 13 of the 14 patients having laparoscopy who underwent 24-h oesophageal pH monitoring.

Laparoscopic fundoplication is effective on GOR. It is as easily feasible as open fundoplication. The factors that are most critical in choosing this approach are an unsuccessful previous antireflux operation, abdominal wall-related problems, a shortened oesophagus, abdominal adhesions and major concomitant surgical procedures. Prompt rehabilitation is the main advantage of laparoscopic over open surgery.

Changes in oesophageal motility following Nissen fundoplication for the cure of gastro-oesophageal reflux

N. Di Martino, G. Izzo, V. Maffettone, P. Zampiello, A. Cosenza and A. Del Genio, *School of Medicine, University of Naples, Italy*

The authors report their experience on the functional modifications of the high-pressure zone (HPZ) and of the oesophageal body induced by Nissen fundoplication performed for the cure of gastro-oesophageal reflux (GOR). In the past 7 years 80 patients underwent surgery by the open procedure and 12 by the laparoscopic route. Thirty-six patients underwent clinical and instrumental follow-up (manometry, combined 24-h gastro-oesophageal pH monitoring and endoscopy), and the results obtained were compared with those of a control group of 15 healthy individuals. Compared with the control group the patients showed a reduced lower oesophageal sphincter tone before surgery ($P < 0{\cdot}001$) and an increase in mean(s.d.) percentage of hypotonia (28·16(10·54)) ($P < 0{\cdot}01$) and multipeak (18·16(10·54)) ($P < 0{\cdot}05$) waves. All patients were submitted to a calibrated Nissen procedure with intraoperative manometry (mean(s.d.) 28·15(8·23) mmHg for 3·04(0·64) cm). At clinical and instrumental follow-up (mean(s.d.) 43·15(9·21) months) five patients complained of transient symptoms which disappeared in 3 months; one patient showed pyrosis and one had chest pain. The other 30 patients were asymptomatic. Measurement of pH revealed the presence of hypercompetence of the new HPZ in 35 patients while the patient with pyrosis showed GOR relapse because of a disrupted Nissen fundoplication. At endoscopy, first-degree oesophagitis was diagnosed in three patients and the presence of Barrett's ulcer, which was present before surgery in four patients, was confirmed. At manometry the new HPZ resting pressure was higher than the preoperative value ($P < 0{\cdot}001$) and lower than the intraoperative pressure ($P < 0{\cdot}001$), while it showed no difference compared with the control group. The dynamic study revealed a significant reduction of the postdeglutitive relaxation (mean(s.d.) 70(13·5) per cent) compared both with its preoperative value ($P < 0{\cdot}001$) and that of the control group ($P < 0{\cdot}001$). None of the parameters considered for the oesophageal body (percentages of hypotonic, hypertonic, repetitive and simultaneous waves, and wave duration) showed any significant difference compared with the preoperative values. The 19 patients with marked preoperative hypotonic peristalsis showed a certain increase of wave amplitude after surgery (mean(s.d.) 16·63(3·15) *versus* 25·45(5·24) mmHg). The patient with GOR relapse showed a marked hypotonia of the new HPZ.

In conclusion, Nissen fundoplication has proved effective for the cure of GOR. Moreover, it produces a hypercompetence which may be related to incomplete relaxation of the new HPZ. The procedure does not entail significant complications, nor does it inhibit oesophageal motility. In fact, postoperative motor disturbances are similar to those found before operation. Furthermore, an increase of peristaltic amplitude was observed in patients with preoperative hypotonia.

Long-term results of round ligament gastropexy in the treatment of gastro-oesophageal reflux disease

F. Docobo, C. Tejido, M. Dovale, M. Lozano and M. Fernandez, *Departamento Cirugia, Hospital Universitario V. Rocio, Sevilla, Spain*

Surgical indications in the treatment of gastro-oesophageal reflux disease (GORD) must be determined by demonstration of pathology with an early assessment of surgical results to obtain complete and permanent absence of symptoms without any surgical complications or medical treatment.

A prospective study was begun in 1973 of the treatment of GORD and its complications using the round ligament (ligamentum teres) for gastropexy. A total of 119 patients were operated on until 1986. Diagnostic procedures and surgical indications were evaluated and periodical controls were performed including clinical, radiographic, manometric and endoscopic evaluation.

The results obtained in the group of patients over a 5-year follow-up were satisfactory, with 93·3 per cent of results clinically favourable by 'Frenchay Hospital' criteria. A recurrence rate of 6·7 per cent was observed endoscopically. The overall mortality rate was nil and complications were minimal.

Round ligament gastropexy for the treatment of gastro-oesophageal reflux allows a return to normal physiological gastro-oesophageal junction activity. There are no troublesome side-effects of surgery and the symptoms of GORD are cured.

Significance of transmucosal potential difference after surgery for reflux oesophagitis

F.M. Gulino, A. Coglitandolo, M. Bottari, R.R. Pidoto and B. Micali, *General Surgery, University of Messina, Messina, Italy*

Transmucosal potential difference (TPD) represents a reliable index of mucosal integrity. A new technique that allows, under endoscopic vision, evaluation of TPD, pH and the degree of oesophagitis has been reported. The goal of this study was to establish the significance of TPD in the evaluation of surgical treatment of gastro-oesophageal reflux disease (GORD).

Fourteen patients with GORD (eight men, six women, mean(s.d.) age 39·3(3·4) years) were studied. Written informed consent was obtained from each patient. TPD was performed as previously described. Briefly, a pH glass electrode is assembled with a flexible Olympus GIF Q10 endoscope. The tip of the electrode is under direct vision of the endoscopist, ensuring contact with the oesophageal mucosa. A further reference electrode is inserted in a forearm vein to close the electric circuit. The values obtained are recorded with a pH-meter specific for the measurement of TPD. Four degrees of oesophagitis were classified endoscopically. All patients underwent fundoplication, either total (eight) or partial (six).

Before surgery there was a significant relationship between TPD and the degree of oesophagitis evaluated by linear regression analysis ($r = 0{\cdot}741$, $P = 0{\cdot}002$). The mean(s.d.) TPD value of $-0{\cdot}4(1{\cdot}98)$ mV before surgery was significantly different from that of 22·1(3·4) mV after operation ($P < 0{\cdot}001$).

The results suggest that TPD measurement is a safe, reliable and objective test of mucosal damage in patients with GORD. It is of value in the follow-up of such patients after surgical repair.

Anatomy of the cardia and gastro-oesophageal reflux

T. Ismail, J. Bancewicz, H. Kashiwagi, J. Barlow and A. Hobson, *Hope Hospital, Salford, UK*

It is unfashionable to consider the anatomy of the hiatal region as important in controlling gastro-oesophageal reflux. The anatomy of the cardia has been studied, with particular emphasis on its valvular structure at endoscopy, in 73 patients with and without gastro-oesophageal reflux. A further 25 patients were studied after Nissen fundoplication The yield pressure of the cardia was also measured and the lower oesophageal sphincter (LOS) assessed by conventional manometry and 24-h pH studies

There was a significant correlation between yield pressure and De Meester composite reflux score ($P < 0.05$), but no direct correlation between yield pressure and the pressure and length of the LOS. In an additional series of 49 patients there was no correlation between yield pressure and vector volume analysis of the LOS There was a close correlation between yield pressure and the anatomy of the cardia using two different grading systems ($P < 0.005$) Yield pressure allowed complete separation of successful and unsuccessful fundoplication and the distinction could also be made by endoscopic inspection.

The cardia is a complex structure Its competence in controlling reflux depends as much on its anatomical form as on its function After fundoplication, structural change is more important in controlling reflux than manometric LOS characteristics.

Evaluation of signs of cure after antireflux procedures

P Misiuna, G. Wallner, D. Chibowski, A. Dabrowski and M. Chmurzyński, *Medical Academy Lublin, Lublin, Poland*

The aim of this study was to find the criteria indicating cure in antireflux mechanism insufficiency after Nissen–Rossetti fundoplication A group of 40 patients (22 men, 18 women) undergoing Nissen–Rossetti fundoplication from 1981 to 1990 was studied. Follow-up ranged from 28 to 170 (mean 92) months The follow-up investigations were anamnesis according to Visick's scale, radiography, endoscopy, 24-h pH-metry, biopsy and isotopic scanning (^{99m}Tc) A total of 31 patients (78 per cent) were symptom-free. There were no abnormalities in endoscopy in 21 patients (52 per cent) and in 23 (58 per cent) 24-h pH-metry results were normal with DeMeester score < 14·75. In isotopic scanning reflux was reported in 29 (72 per cent). Biopsy revealed pathology in 37 patients (92 per cent) 16 had columnar-cell oesophagitis, 13 squamous oesophagitis and eight hyperplasia with abnormal keratosis Taking biopsy into consideration as the basis of cure, after operation microscopic pathology persisted even in those patients without symptoms The results of the diagnostic methods and anamnesis were different. Assessment of the results of endoscopy or isotopic scanning showed high conformity with biopsy (35 of 37, 95 per cent), sensitivity 95 per cent and efficacy 90 per cent, while the results of endoscopy, isotopic scanning or 24-h pH-metry confirmed higher conformity with biopsy (36 of 37, 97 per cent), sensitivity 97 per cent and efficacy 92 per cent

It is concluded that lack of reflux symptoms after the antireflux procedure cannot be the only criterion for cure, biopsy should be performed in all cases to confirm the cure and combining the postoperative results of endoscopy, 24-h pH-metry and isotopic scanning is of equally high value as biopsy in objective estimation of antireflux procedure efficacy

Treatment of reflux-induced oesophageal stricture

P. Parrilla, L. Martinez de Haro, A Ortiz, G. Morales, J. Aguilar and V Garay, *Department of Surgery, V. Arrixaca Hospital, University of Murcia, Spain*

Assessment of the long-term results of 90 patients with reflux-induced oesophageal stricture managed over a period of 16 years is reported. Thirty-seven patients received conservative treatment and 53 underwent surgery

Conservative treatment (drug treatment and dilatation) was indicated in patients who refused surgery and in those who had mild stenosis, were elderly and/or presented with a poor general status

The 53 patients undergoing surgical treatment received preoperative dilatation to determine which operation they were suitable for Nissen fundoplication was performed in cases of dilatable stenosis without oesophageal shortening ($n = 41$). The Collis–Nissen procedure was performed in patients with dilatable stenosis but with major oesophageal shortening ($n = 9$) Three cases with non-dilatable strictures and three with previous surgical failure (two patients from the Nissen and one from the Collis–Nissen groups) had resection of the stricture with colonic interposition ($n = 5$) or resection with gastric interposition ($n = 1$)

There were two postoperative deaths The remaining 88 patients were followed for between 1 and 16 (median 6) years Of the 37 patients receiving conservative treatment, 11 were asymptomatic, 17 required fewer than two dilatations per year and nine needed more than two dilatations per year The results after surgery were considered excellent to good in 34 of 41 patients who underwent Nissen fundoplication, three of nine of the Collis–Nissen group and four of six with oesophageal resection

Pitfalls of laparoscopic Nissen fundoplication

D.I. Watson, G.G. Jamieson, R Britten-Jones and P. Mitchell, *Department of Surgery, Royal Adelaide Hospital, Adelaide, Australia*

A total of 54 patients underwent attempted Nissen fundoplication using a laparoscopic technique The procedure was completed laparoscopically in 46 (85 per cent) Eight procedures were converted to open surgery because of difficulty with morbid obesity in two, large hiatal hernia in two, inability to ensure a loose fundoplication in two patients with oesophageal dysmotility, hypertrophied left lobe of liver in one, and inadequate oesophageal mobilization in one patient.

Mean follow-up has been 5 months, ranging up to 15 months. Postoperative complications have occurred in 13 patients. Three of the eight requiring conversion to open surgery suffered pulmonary embolism Five patients have undergone revisional surgery, one for a rolling hiatal hernia, one for recurrent reflux, one for dysphagia associated with oesophageal dysmotility, and two for gastric obstruction because of the inadvertent construction of a fundoplication using the distal body of the stomach.

Postoperative barium meal examination in 28 patients has also revealed that the fundoplication was fashioned using the gastric body rather than fundus in seven, creating a distorted, bilobular stomach Despite this, the five not requiring reoperation all have excellent clinical results

Difficulty may occur during laparoscopic Nissen fundoplication owing to the lack of a three-dimensional image and the altered angle of view, even when using a 30° laparoscope. Full mobilization of the intra-abdominal oesophagus, taking steps to ensure that the correct piece of stomach is utilized for the fundoplication, will lead to reduction of problems

Oncology

Carotid body tumours

I. Bellenis, A. Loutsidis, A. Chadjimichalis, P. Dedeilias and N. Exarchos, *Department of Thoracic and Vascular Surgery, 'Evangelismos' Medical Centre, Athens, Greece*

The aim of this study is to present experience in the treatment of carotid body tumours. It is based on four patients presenting with chemodectoma of the carotid body studied over a period of 5 years. There were three women and one man aged 35–64 years. In three patients the lesion presented as an asymptomatic mass of the angle of the jaw and in the fourth was accompanied by headache and dizziness. Diagnosis was suspected by the clinical findings and established by angiographic demonstration of neovascularity, which is pathognomonic of the tumour.

All patients were treated surgically. In three tumour removal was easy and total. In one patient a subadventitial plane was established and the removal was nearly total. This patient's treatment was completed by postoperative radiotherapy. All the patients are alive and well 5, 3, 2 and 1 year after operation.

Role of radioimmunoscintigraphy with labelled monoclonal antibodies in patients with gastrointestinal tumours

G. Conzo, S. Lastoria*, L. Pezzullo, C. Caracò*, C. Caracò Jr, E. Vergara*, L. Santini, P. Varrella*, P. Mezzaluna and M. Salvatore*, *Chair of Patologia Chirurgica I Fac Med. Napoli and *Nuclear Medicine Department, National Cancer Institute Napoli, Eurocetus Italia, Italy*

The staging of patients with gastrointestinal tumours is significantly improved by means of radioimmunoscintigraphy, especially using indium-111 labelled B72·3 monoclonal antibody (MAb), which recognizes a tumour-associated mucin-like antigen termed TAG-72. Twenty consecutive patients (16 with active disease and four disease-free) previously operated on for gastrointestinal adenocarcinoma were studied after administration of 3–5 mCi radiolabelled B72·3 MAb. Serum markers carcinoembryonic antigen (CEA) and TAG-72 were raised in seven of 20 patients (CEA, 21·5(13) ng ml^{-1}, TAG 72, 18(4·5) units ml^{-1}). Radioimmunoscintigraphy was positive in 13 patients, detecting 32 lesions, missing only hepatic metastases in two of them. In three patients no uptake was observed at tumour sites, while four disease-free patients were negative. The main clinical outcome of radioimmunoscintigraphy was the detection of unknown clinically silent distant metastases in five cases (two to lung, three to lymph nodes). These tumour sites were later confirmed by other imaging techniques. In conclusion, radioimmunoscintigraphy with B72·3 allowed better staging of patients previously operated on, showing in association with computed tomography (CT) an accuracy of 84 per cent *versus* 75 per cent for CT alone.

Hickman–Broviac or totally implantable systems for systemic chemotherapy

E. Cortesi*, L. Laurenzi†, P. Chirletti, A. Lembo*, I.A. Muttillo, R. Caiazzo and M. Cardi, **Cattedra di Oncologia Clinica, †Cattedra Anestesia and Ria, and I Clinica Chirurgica, Università di Roma 'La Sapienza', Rome, Italy*

Long-term venous access for systemic chemotherapy is of paramount importance in the management of patients with cancer. This study reports the results and complications of 93 patients having implantable systems for systemic chemotherapy in this institution. Forty men (43 per cent) and 53 women (57 per cent) of median (range) age 54 (16–76 years) underwent study. All systems were implanted in the superior vena cava via the right subclavian vein. For totally implantable systems, the port was located in a subcutaneous pocket made on the right anterior thoracic wall, and the catheter was pulled through to the puncture site. Group A ($n = 68$) had a fully implantable system, and group B ($n = 23$) had a Hickman–Broviac catheter inserted. The median (range) duration of chemotherapy was 6 (1–71) weeks in group A and 2 (1–13) weeks in group B. The median (range) duration of catheter patency was 139 (4–1003) days in group A and 66 (9–442) days in group B. Complications were observed in 11 (16 per cent) patients in group A and in four (17 per cent) in group B. Five systems (7 per cent) in group A and two (9 per cent) in group B had to be removed.

Prognostic factors and survival in lingual epidermoid carcinoma: analysis of 201 cases

R. de Paz, P. Ramírez, J. Moreno, M. Puche, A. Martínez and S. Mendez, *Virgen de la Arrixaca, University Hospital, Murcia, Spain*

Carcinoma of the tongue is the most frequent tumour of the oral cavity. A report is presented of 201 patients treated at one university hospital.

A study of survival has been carried out using actuarial analysis in relation to epidemiological, clinical, anatomical, pathological and therapeutic variables. These have been studied through a multifactorial test (Cox's proportional model of risk) of the prognostic factors which affect survival in tongue carcinoma in an independent way. From all epidemiological variables that had an influence on the probability of death a prognosis index (PI) has been defined. Through the PI, a prognostic classification for tongue carcinoma has been established. Patients were classified into four groups according to risk.

On global multifactorial analysis of the 146 patients undergoing operation, the presence of clinical signs (i.e. pain, haemorrhage and external form) which show tumoral dissemination and have an influence on the probability of death were observed. Perineural infiltration and the peritumoral inflammation reaction also have an independent influence on the probability of death.

According to the PI, calculations were made of the survival probability of each patient and it was observed that the higher the PI, the less the survival probability. Therefore, the patients with a PI higher than 63 have shown a survival of 5·41 per cent at 5 years, compared with 93·46 per cent in patients with a PI less than 32.

This study suggests that the classification using PI adjusts the survival in a more homogeneous way than classification in traditional stages.

Modulation of postoperative immune suppression by interleukin 2

O. Eremin, D.J. Deehan, S.D. Heys, C. Walker and R.A. Keenan, *Departments of Surgery and Clinical Biochemistry, University Medical School, Aberdeen, UK*

The cytokine interleukin 2 (IL-2) is known to stimulate the proliferation and tumoricidal activity of lymphokine-activated killer (LAK) and natural killer (NK) cells. Surgery (from the induction of anaesthesia) is known to be a potent suppressor of the immune system, including NK and LAK cell cytotoxicity, and this time period coincides with the risk of iatrogenic mechanical dispersal of tumour emboli at operation.

The aim of this study was to modulate NK and LAK cell function in patients with colorectal cancer undergoing curative surgery by the administration of perioperative recombinant interleukin 2 (rIL-2). Patients were randomized to receive rIL-2 or placebo for 3 days before (day −3 to −1) and after (day 0 to +2) operation.

NK and LAK cell activity (expressed as stimulation indices with reference to pretreatment values) was measured on days −3, −1, +1, +7 and +21. NK cell activity enhanced with rIL-2 on days +1 and +7 ($P < 0·05$, Mann–Whitney U test), LAK cell activity enhanced with rIL-2 on days +1, +7 and +21 ($P < 0·05$).

Flow cytometric analyses showed no significant differences in the phenotypic profiles (CD3, CD4, CD16, CD25 and CD56) of peripheral blood lymphocytes. These preliminary results suggest that rIL-2 enhances both NK and LAK cell function in the immediate postoperative period.

Meningioma *en plaque*: an aggressive approach

B.T Evans, G Neil-Dwyer* and D.A. Lang*, *Department of Maxillofacial Surgery and *Wessex Neurological Centre, Southampton University Hospital, Southampton, UK*

Extensive tumour removal in the region of the anterior skull base requires not only good exposure, but also acceptable reconstruction The objective when treating benign tumours in this region should be a radical resection, with good cosmesis, no visible scars and intact vision A multidisciplinary team is required and there is need for a flexible surgical approach and for a three-dimensional concept with reconstruction of the orbit Three patients with meningioma *en plaque* involving the orbit are presented to illustrate these concepts

Internal hemipelvectomy

M. Haamdi, M. Gebhart and M. Caldow, *Jules Bordet Institute, Brussels Free University, Brussels, Belgium*

Until recently, tumours involving the pelvis were usually treated by hemipelvectomy with hindquarter amputation A more recent approach to treatment of these tumours is 'conservative hemipelvectomy', which spares the lower extremity.

Three patients (21, 22 and 43 years old) underwent extensive hemipelvectomy for Ewing's sarcoma and chondrosarcoma The femoral head was fixed temporarily to either the remaining parts of the acetabulum or to the iliac wing by a Steinman pin which was removed 6 weeks after operation The patient was treated using traction for 3 months, and weight bearing was gradually allowed after 6 months.

All patients remodelled a neoacetabulum, which gave sufficient stability to the hip joint Walking without external help was possible in two patients and with a cane in the third The latter had also an external sciatic nerve palsy One patient had no limb shortening and the other two had limb shortening of 4 and 5 cm. No local recurrence was observed during a follow-up of 7–48 months

This small experience with internal hemipelvectomy shows encouraging results in terms of tumour control and gait function.

Serum neurone-specific enolase as a prognostic factor in non-small cell lung cancer

F. Hernando, A. Sánchez-Pernaute, M.L. Maestro, M. Díez, A. Gómez, S. Martinez, A.J Torres and J.L. Balibrea, *Hospital Clinico San Carlos, Madrid, Spain*

Serum neurone-specific enolase (NSE) levels were evaluated before surgery by enzyme immunoassay in 84 patients undergoing curative surgery for non-small cell lung cancer (NSCLC) The results were compared with similar estimations in 40 healthy subjects and 20 patients with non-malignant pulmonary disease

Mean(s.d.) NSE concentrations were higher in patients with lung cancer (11·7(10·8) ng ml^{-1} (median 9·7 ng ml^{-1})) than in patients with benign disease ($P < 0{\cdot}05$) or healthy controls ($P < 0{\cdot}01$) NSE levels were not related to tumour node metastasis stage nor to histological subtype. At a cut-off level of 15 ng ml^{-1}, NSE had a sensitivity of 27 per cent and a specificity of 96 per cent At this level there was a high likelihood of tumour relapse with a poor 24-month survival rate

These findings suggest that the measurement of NSE would be helpful in the management of patients with NSCLC

Perioperative interferon α administration in patients with advanced malignant tumours: immunological effect and clinical tolerance

G. Houvenaeghel, D Baume, J.L. Blache, D. Olive, J.R. Delpero and G. Guerinel, *Institut J Paoli-I Calmettes, Marseille, France*

Surgical procedures may be associated with an increased risk of tumour spread secondary to surgical mobilization of the tumour and transient postoperative immunosuppression Recurrence may result either from early growth of micrometastases already present at the time of surgery or from the seeding of malignant cells shed during the operation. Immunomodulators have been proposed to correct the immunological impairment induced by surgical procedures

Between January and July 1992, 23 patients with advanced cancer underwent surgical resection with perioperative interferon α administration Patients received interferon α_{2a} (Roferon-A), by subcutaneous injection daily for 14 days, starting 3 days before surgery Incremental doses were 2, 3, 5, 7, 9 and 12 × 10^6 units for four, four, three, three, three and six patients respectively Peripheral blood lymphocyte subset numbers were assessed using flow cytometric analysis the day before injection (day −3), before surgery (day −1). and on days 4 and 12 after operation. Absolute numbers of total T cells ($CD3^-$) and natural killer (NK) cells ($CD56^+$, $CD3^-$) were determined, as well as auxiliary T cells ($CD4^+$), activated T cells ($CD3^+$, Dr^+), and B cells ($CD19^+$) counts Short-term cytotoxicity of peripheral blood mononuclear cells against K562 and DAUDI target cells in a 4-h standard chromium-release assay was determined.

No World Health Organization grade IV toxicity was observed A significant postoperative fall of the total peripheral blood lymphocyte count, of $CD3^+$, $CD4^+$, $CD19^+$ and $CD3^-56^+$ occurred from day −3 to day 4. The decrease was not significant for $CD3^+$ Dr^+ Values were not significantly different between days −3 and 12, except for $CD3^+$ Dr^+ and $CD3^-$ 56^+ Cytotoxicity against K562 and DAUDI target cells was significantly increased from day −3 to day −1, and from day −1 to day 1, with a significant fall of cytotoxicity against DAUDI from day −3 to day 4

Perioperative interferon α administration is well tolerated even with the 12 × 10^6 unit doses. In spite of treatment and increasing cytotoxic activity, a postoperative fall was observed for the majority of the immunological parameters Further studies are necessary to make comparisons with a control group, to evaluate more patients treated with 12 × 10^6 units daily

Surgery-induced immunosuppression in advanced cancer: immunological parameters during the perioperative period

G Houvenaeghel, D. Baume, J.L. Blache, D. Olive, D. Francon, J.R. Delpero and G. Guerinel, *Institut J Paoli-I. Calmettes, Marseille, France*

The use of immunomodulators has been proposed to correct the immunological impairment induced by surgical procedures, especially in patients with cancer, in whom immunosuppression may favour early metastatic seeding To study further the mechanisms of postoperative immunosuppression, the evolution of various lymphocyte populations following surgery was analysed

Twenty-five patients with advanced cancer underwent surgical resection The mean duration of anaesthesia was 314 (range 90–540) min A total of 14 patients received packed red blood cells (mean 2 units). Peripheral blood lymphocyte subset numbers were assessed the day before surgery (day −1), and at days 4 and 12. Absolute numbers of total T cells ($CD3^+$) and natural killer (NK) cells ($CD56^+$, $CD3^-$) were determined, as well as auxiliary T cell ($CD4^+$), activated T cell ($CD3^+$, Dr^+), B cell ($CD19^+$) and other lymphocyte subsets as $CD3^+$, $CD25^+$, $CD3^+$, $CD8^+$ counts Short-term cytotoxicity of peripheral lymphocytes against K562 and DAUDI target cells was determined.

A significant postoperative fall of the total lymphocyte count occurred from day −1 to 4. The peripheral lymphocyte count subsequently increased and day 12 values were no different than the baseline value. A decrease of both T cell and NK cell populations accounted for the fall of the lymphocytes at day 4 A full recovery of NK cell number was observed at day 12 although T cells were still markedly reduced. $CD4^+$, $CD3^+$, Dr^- and $CD8^+$ lymphocytes decreased in proportion to T cells between days −1 and 4, and $CD4^+$ cells were still markedly reduced at day 12 In contrast, B cells did not undergo significant change during the perioperative period Cytotoxicity against K562 and DAUDI target cells was significantly decreased from days −1 to 4

The clinical significance of these immunological changes in the perioperative period has not been established. However, they provide a rational basis and a means of evaluation for immunotherapy trials in the perioperative period

Pelvic exenteration with low colorectal anastomosis for gynaecological cancer

G. Houvenaeghel, J.R. Delpero, F. Bladou, M. Resbeut and G. Guerinel, *Institut J. Paoli–I. Calmettes, Marseille, France*

Between January 1980 and December 1992, 97 pelvic exenterations were performed (36 anterior and ten atypical, 26 posterior and 25 total). Radiotherapy was performed before exenteration in 69 cases. Thirty-six low colorectal anastomoses were performed among 51 posterior and total exenterations. in 14 of 26 posterior and 22 of 25 total exenterations. Colorectal anastomosis was performed by hand suture in eight patients and by end-to-end stapling in 28. A protective transverse colostomy was fashioned in 22 patients (11 of 22 total exenterations, 11 of 14 posterior). Defunctioning colostomies were closed in only five cases (two of 11 after total and three of 14 after posterior exenteration).

Continence was achieved in 19 of 36 patients: these consisted of 13 of 22 total and six of 14 posterior exenterations with low colorectal anastomosis; nine achieved continence among 12 anastomoses performed without previous radiotherapy or after radiotherapy < 45 Gy, as did ten of 24 with anastomoses performed after previous radiotherapy or concomitant radiochemotherapy ⩾ 45 Gy. Continence was achieved after three of 14 pelvic exenterations performed between 1980 and 1984, five of 17 between 1985 and 1989 and 11 of 20 between 1990 and 1992.

In conclusion, although the type of anastomosis does not appear to be important, a complete lack of tension on the anastomosis seems vital.

Endosonographic staging of advanced gynaecological cancer: results of a prospective study

G. Houvenaeghel, M. Martino, R. Rosello, J.R. Delpero, M. Resbeut and G. Guerinel, *Institut J. Paoli–I Calmettes, Marseille, France*

Between January 1988 and December 1992, 106 patients with advanced gynaecological cancer were investigated before surgery by gynaecological examination and endosonography under general anaesthesia; abdominopelvic computed tomography (CT) was performed in 91 patients and magnetic resonance imaging (MRI) in 23. There were 61 primary tumours and 45 cases of recurrence. Aetiologies were as follows: 73 cervical cancers (49 primary, 24 recurrent), ten ovarian cancers (five primary, five recurrent), eight endometrial cancers (two primary, six recurrent), five uterine sarcomas (one primary, four recurrent), five vaginal cancers (four primary, one recurrent) and five others. All patients underwent surgery. This prospective study compared data from clinical and imaging examinations to that obtained from histological analysis of surgical resection margins.

According to anterior or posterior tumour extension, the accuracy of clinical evaluation and preoperative imaging were studied for (1) the posterior vesical wall and vesicovaginal septum and (2) the anterior rectal wall and rectovaginal septum. Histological examination revealed vesical involvement in 32 patients and vesicovaginal septum involvement in 35. The accuracy of clinical examination, endosonography, cytoscopy, CT and MRI for vesical extension was 79, 90, 82, 80 and 85 per cent respectively. Cytoscopy was not taken into account for evaluation of extension to the vesicovaginal septum: accuracy was 80, 92, 77 and 75 per cent for clinical examination, endosonography, CT and MRI respectively. Histological examination showed rectal involvement in 23 patients and rectovaginal septum involvement in 30. The accuracy of clinical examination, endosonography, CT and MRI was 93, 97, 89 and 70 per cent respectively for extension to the anterior rectal wall. Concerning the extension to the rectovaginal septum, accuracy was 85, 96, 85 and 60 per cent for clinical examination, endosonography, CT and MRI respectively.

In conclusion, endosonography appears useful in completing examinations for regional extension of advanced gynaecological cancers, with accuracy superior to that of other methods. Since it is performed under general anaesthesia, there is no discomfort for the patient during this low-cost procedure.

Multivisceral operations

F. Jakab, Z. Ráth and J. Faller, *Semmelweis Medical University, Budapest, Hungary*

A total of 141 (2·6 per cent) multivisceral operations were performed between 1987 and 1992 from a total of 5423 operations. They do not include radical surgery for lymphatic spread or extended surgery for technical reasons such as splenectomy for injury. These operations were performed for the surgical cure of two or more different diseases, or because of extension or complication of the basic surgical disease. The most frequent multivisceral operations were: resection of colonic cancer adherent to the small bowel and of metastases of the liver, gastrectomy, splenectomy, resection of the pancreas, colon and diaphragm; resection of the liver, gastrectomy, splenectomy and cholecystectomy, and pancreatoduodenectomy and hemicolectomy.

In the group of patients with two or more diseases the extrapolated morbidity rate increased by 8 per cent and the length of hospital stay by 32 per cent. In the group of patients with extended disease the morbidity rate increased by 19 per cent.

Multivisceral resection in treatment of pelvic tumours

K. Kett, *Medical University of Pécs, County Hospital, Pécs, Hungary*

Surgical intervention not only offers a chance of cure, but may add significantly to the quality of life when reconstructive techniques are employed. A total of 39 patients aged 42–79 years underwent multivisceral resection between 1988 and 1993. The initial diagnosis of rectal, urinary bladder and gynaecological tumours (uterus and ovarian) was made in six, 21 and 12 patients respectively. In two patients, radiation enteritis was present. Continent urinary function was achieved by constructing a Kock pouch. In two patients, partial resection of the bladder was followed by plastic repair and re-implantation of the ureters. Low anterior resection was performed whenever possible, to avoid a stoma. There were no operative deaths or serious complications other than in one patient with wound dehiscence.

Risk factors in elective general surgery for malignancy

H.P. Klotz, D. Candinas and F. Largiadèr, *Department of Surgery, University of Zurich Hospital, Zurich, Switzerland*

Since 1988 all patients undergoing elective surgery have been analysed in a prospective study with the aim of identifying and evaluating risk factors. The risk has been divided into the following groups of factors: the environment, the surgeon, the anaesthesia, the operative intervention, the disease and the patient independent of any current illness.

In 1990, 682 patients (male:female ratio 1·15:1) of mean age 51·6 (range 14–90) years entered the study. Of these, 225 patients (male:female ratio 1·62:1), mean age 59·1 (range 17–90) years, were operated on for malignant disease. Radical resection was performed in 136 cases (60·4 per cent), whereas 89 patients (39·6 per cent) underwent a palliative procedure.

Following operative procedures for malignancy, general complications occurred in 40 cases (17·8 per cent) and local complications were registered in 34 (15·1 per cent), compared with 23 (5·0 per cent) cases of general complications and 39 (8·5 per cent) cases of local complications in surgery for benign disease ($P < 0{\cdot}0001$). A total of five patients died within 30 days following surgery for a malignant disease. Of these, on three occasions the main risk factor was the disease, in one case the surgeon, and in the other, coexisting disease in the patient. There were no deaths in the patients undergoing surgery for benign disease.

Analysing the collected data, the authors could define variables with significant association to general and local operative and postoperative complications after elective surgery for malignancy: sex (male), arrhythmia, pathological electrocardiogram, platelet count $< 150\,\mu l^{-1}$ and duration of operation > 90 min ($P < 0{\cdot}02$).

In this series it is obvious that operative procedures for malignancy have an increased risk of complications and fatal outcome. To consider specific risk factors, radical treatment should be weighed against palliative procedures, especially minimally invasive surgery.

Surgery and brachytherapy in soft tissue sarcoma of the limb

J. M. Mendes de Almeida, M. Cândida Trindade, A. Aguiar Ferreira, P. David and J.C. Mendes de Almeida, *Instituto Português de Oncologia, Lisbon, Portugal*

Soft tissue sarcomas are tumours with a high risk of local recurrence if conservative surgery is performed in tumours larger than 5 cm in diameter. To prevent this problem these tumours are treated using interstitial brachytherapy in association with conservative surgery whenever possible.

Since April 1991, 13 such patients have been treated, with tumour diameters ranging from 10 to 24 cm. Histology of these lesions was. malignant histiosarcoma (four); myxoid liposarcoma (seven), and malignant schwannoma (two).

At the time of conservative surgery, plastic tubes were implanted in the tumour perpendicular to the wound. Seven to 13 tubes were used. Loading was performed 3–5 days later, using radioactive iridium. Brachytherapy dosage ranged from 2000 to 5000 cGy. External beam radiotherapy was used when necessary, to reach the ideal dosage of 5000 or 6000 cGy. Maximum follow-up was 18 months, with ten patients currently alive without disease. Two other patients have shown local recurrence, and were subsequently submitted for another conservative resection. One patient is alive with pulmonary metastases, and no signs of locoregional disease, and the other patient has died, with distant multiple metastases. The two patients that had recurrence locally following primary tumour excision were referred with recurrence after surgery.

Despite limited experience, the authors believe that soft tissue sarcomas larger than 5 cm in diameter are amenable to conservative surgery with an acceptable rate of local recurrence provided adjuvant brachytherapy is part of the treatment.

Detection and *in vivo* grading of soft tissue sarcoma by positron emission tomography

O.E. Nieweg, H.J. Hoekstra, J. Pruim, H. Schraffordt Koops, J. Oldhoff, A.M.J. Paans, A.T.M. Willemsen, W.M. Molenaar and W. Vaalburg, *University Hospital Groningen, Groningen, The Netherlands*

The purpose of this study was to investigate positron emission tomography (PET) with ^{18}F-fluorodeoxyglucose (FDG) as a means of visualizing primary and recurrent soft tissue sarcomas. Fourteen patients with various types of soft tissue sarcoma were studied: nine with a primary tumour, five with local recurrence. The tumours ranged from 1·0 to 20·0 cm in size. Four patients had a grade I tumour, four a grade II tumour and six patients had a grade III tumour. An intravenous dose of 370 MBq FDG was administered for PET. In all patients images were obtained, using a Siemens ECAT 951 positron camera. The glucose metabolic rate (MR) was calculated in ten patients. A grade I recurrent liposarcoma 9·5 cm in diameter was not visualized. All other tumours were clearly depicted on PET. Even a 1-cm local recurrence was distinctly visible.

Glucose consumption proved to be higher in poorly differentiated tumours. In grade I tumours the mean(s.d.) MR (μmol per 100 g per min) was 3·8(0·6), in grade II tumours 15·5(8·0) and in grade III tumours 27·8(11·3). The difference in MR between grade I and grade III sarcomas was statistically significant ($P < 0{\cdot}01$). It appears that the sensitivity of PET for detection of soft tissue sarcomas is high (93 per cent). PET may be of value for early detection of local recurrence. Other imaging techniques are often insufficient for this purpose because tissue planes may be distorted by previous surgery and radiotherapy. PET may also be able to provide an indication of the grade of malignancy *in vivo*.

Surgery after radiochemotherapy in treatment of advanced cervical carcinoma

T. Perez, G. Houvenaeghel, M. Resbeut, F. Granger, P. Viens and J.R. Delpero, *Institut J. Paoli–I. Calmettes, Marseille, France*

Between February 1988 and June 1992, 30 patients with advanced epidermoid carcinoma underwent surgery after radiochemotherapy. Initial FIGO stages were: IIIA, two patients, IIIB, four, IV, four, and bulky tumours (> 4 cm) stage IB (four) or IIB (16). Staging was checked under anaesthetic examination with endosonography. Radiochemotherapy was radiotherapy on the whole pelvis delivering 45 Gy over 33 days and chemotherapy on days 1 and 21 which delivered CDDP followed by 5-fluorouracil intravenous continous infusion for 96 h. Brachytherapy (15 Gy) and a parametrial boost (55–60 Gy) were performed after radiochemotherapy. The operations were colpohysterectomy with lymphadenectomy (22 cases), anterior pelvic exenteration (seven) and total pelvic exenteration (one). All but three were performed with curative intent.

No postoperative mortality was observed. The immediate morbidity rate was high: four severe short-term complications (digestive or urodigestive fistula) required a second surgical procedure and seven short-term complications were minor. Two long-term complications required reoperation and ten long-term complications were minor. Histologically complete excision was achieved in 14 cases. Actuarial survival rates at 1, 2 and 3 years were 77, 71 and 63 per cent respectively, with 21, 14 and five patients respectively at risk.

Postoperative morbidity rates can be reduced by the use of a non-irradiated bowel segment to perform urinary diversion after exenteration. Surgery after radiochemotherapy appears to be an important step to obtain local control. Although these results in the treatment of advanced cervical carcinoma are encouraging, prospective studies are needed.

Correlation between histological stage and preoperative levels of CA19.9 and CA195 in colorectal and gastric cancer

J.M. Ramia, A. Abad, C. Morales, R. Villeta, J.D. Sanchez, A. Ibarra, J.I. Landa, J. Alcalde and D. Ballesteros, *Servicio de Cirugia General, Hospital 12 de Octubre, Madrid, Spain*

A prospective study was planned measuring preoperative CA19·9 and CA195 levels in serum from patients with gastric and colorectal cancer. Before the surgical procedure, serum values of CA19.9 and CA195 were measured by immunoassay in 100 patients with colorectal and 50 with gastric cancer.

In colorectal cancer, distribution by Dukes' stage was 8, 25, 53 and 14 per cent for stages A to 'D' respectively. Preoperative tumour marker values for stages A to 'D' for CA19.9 were 12·1, 30·5, 65·4 and 200·4 ng ml^{-1} and for CA195 5·8, 10·4, 23·5 and 57·0 ng ml^{-1}. In patients with gastric cancer no statistical correlation was observed with respect to histological stage. Nevertheless, gastric cancer with severe lymphatic spread (more than five positive lymph nodes) or metastasis showed high levels of CA19·9 (275·8 ng ml^{-1}) and CA195 (134·2 ng ml^{-1}) compared with those without metastasis (31·4 and 20·1 ng ml^{-1} respectively). The predictive preoperative value (PPV) for CA19·9 was: A, 23 per cent, B, 37 per cent, C, 79 per cent, and 'D', 92 per cent for colorectal cancer. For gastric cancer without tumour extension the PPV was 34 per cent and with extension 79 per cent. The PPVs of CA195 in colorectal cancer of stages A to 'D' were 27, 36, 69 and 84 per cent. For gastric cancer without extension the PPV of CA195 was 22 per cent and with extension 72 per cent. CA19·9 and CA195 together had PPVs for stages A to 'D' of 31, 41, 84 and 93 per cent. For gastric cancer the combined PPVs for tumour with and without extension were 83 and 36 per cent.

In conclusion, the sensitivity of CA19·9 and CA195 seems to be high in Dukes' stages C and 'D' of colorectal cancer and in advanced gastric cancer. CA19·9 and CA195 together have a higher predictive value than separately.

Oncogenes and clinical outcome in lung cancer

A.J. Ritchie, C. Johnston, K. Buchanan, J. McGuigan and J. Gibbons, *Aberdeen Royal Infirmary, Aberdeen and Royal Victoria Hospital, Belfast, UK*

Fos and *myc* are oncogenes poised at a critical point in the pathways controlling gene expression and neoplastic transformation. Clinical stage of disease is perhaps the most important factor in determining an individual's outcome in lung cancer. Various claims have been made about the prognostic implications of oncoprotein expression. This study compared oncoprotein with clinical stage and expected outcome in 68 patients in each stage of squamous cell carcinoma of the lung. Overall survival rate in stage I disease, excluding patients who died in the perioperative period, was 84 per cent. *Fos* oncoprotein expression in early-stage disease was significantly greater in those who died ($P < 0{\cdot}02$) compared with those who remained alive. *Myc* expression was not significantly different in those who died compared with those who remained alive in either early- or late-stage disease. Overexpression of *fos* is a poor prognostic indicator in squamous carcinoma of the lung.

p53 tumour suppressor in squamous carcinoma, adenocarcinoma and adjacent lung

A.J. Ritchie, C. Johnston, J. McGuigan and J. Gibbons, *Aberdeen Royal Infirmary, Aberdeen and Royal Victoria Hospital, Belfast, UK*

Normal p53 acts as a tumour suppressor gene inhibiting other genes involved in neoplastic transformation. Mutations within this tumour suppressor gene lead to a loss of this function which then allows the neoplastic process to transform the cell. The accumulation of the defective p53 protein can be detected in individual cells using immunohistochemical techniques. This study assessed the accumulation of this abnormal product, and hence loss of the tumour suppressor function, in 68 patients undergoing surgical resection for squamous carcinoma and 41 undergoing resection for adenocarcinoma. Immunoreactivity to p53 was detectable in both diseases and in each stage of disease in tumour and peritumour areas but was usually confined to the lobe harbouring the tumour. These results suggest that loss of tumour suppressor function occurs at an earlier stage than has previously been thought in squamous carcinoma, and supports the concept of loss of function at the dysplasia stage before occult tumour development. It provides evidence for mutant p53 oncoprotein accumulation within a significant proportion of early and late stage adenocarcinomas, implicating loss of tumour suppressor function at an early stage of adenocarcinoma development

Clinical significance of oncogenes in malignant melanoma

D.A. Ross and G.D. Wilson, *Mount Vernon Hospital, Northwood, UK*

Malignant melanoma continues to pose an epidemiological and therapeutic challenge. However, the answers to outstanding questions will only be found with greater understanding of tumour biology. Considerable interest centres on the molecular genetics of cancer and, in particular, the behaviour of oncogenes p53 is the focus of increasing attention because it appears to be expressed in the majority of human cancers, including melanoma

Using flow cytometry, expression of the protein products of two nuclear oncogenes, p53 and *c-myc*, was studied in human melanoma. In addition, the proliferation kinetics of these tumours were measured using bromodeoxyuridine with an *in vivo* technique. These parameters were related to the clinicopathological features of each tumour

Both fresh and fixed material (in ethanol and paraffin-embedded) was investigated in prospective and retrospective studies. Results show both oncogenes to be frequently overexpressed in melanoma, p53 was expressed in 77 per cent of primary lesions and 83 per cent of metastases, while *c-myc* was found in 67 per cent of primary tumours and 88 per cent of secondary tumours. The level of expression of *c-myc* was associated with tumour proliferation and outcome. No such relationship was evident with p53.

Consideration of these markers may lead to improved tumour characterization and an objective platform on which to design future therapy.

Sacral resection and reconstruction with bone cement

Y. Sağlik, S. Koçak, N. Sengül and S. Eraslan, *Ankara University Medical School, Ankara, Turkey*

Sacral resection is sometimes the only way to effect palliation of severe pain in patients with tumours involving the sacrum However, many believe the operation to be unacceptable because of the reported operating time, blood loss and complications. A case of retrorectal leiomyosarcoma invading the sacrum with severe pain resistant to combined irradiation and chemotherapy is reported The tumour was removed, with resection of the right two thirds of S2, S3 and S4 The sacrum was reconstructed with bone cement. The operation lasted 3 5 h with a total blood loss of 700 ml. The postoperative course was excellent, with full continence of faeces and urine, complete spinal and pelvic stability, no motor deficiencies and complete relief of the preoperative pain.

In conclusion, complete sacral resection is unnecessary for sacral root pain palliation in unilateral tumour involvement of the sacrum. The sacrum should be reconstructed with bone cement rather than with muscle flaps, to prevent pelvic instability and herniation of the rectum through the sacral defect

Orthopaedics

Morphology of cortical bone revascularization after open tibial fracture and local muscle flap transposition

J Buchholz*, R. Schnabel†, K. Morgenroth†, W. Knopp†, A Ekkernkamp* and G. Muhr*, **Chirurgische Universitätsklinik Bergmannsheil and †Abteilung fur Pathologie, Ruhruniversitat, Bochum, Germany*

Open fractures of the lower limb are difficult to manage even under optimal conditions In addition to severe fragmentation of the bone, there is often avulsion and devascularization of soft tissues, extensive bacterial contamination, and a relatively poor local circulation All of these compromise sound healing. Recently, vascularized muscle grafts have been used to provide soft tissue coverage as well as to encourage early healing of the fracture through an increase in the local blood supply

In an experimental study with 80 New Zealand rabbits divided into four groups the time between the trauma and the soft tissue coverage and successful revascularization was investigated. During anaesthesia all animals had an open tibial fracture stabilized with two screws After 3 or 7 days a local muscle flap was transposed into the defect zone. Histomorphological examinations were conducted at time intervals up to 16 weeks after the transposition.

In the early group, 1 week after the muscle transposition a part of the bone showed necrosis In the next 4 weeks granulation tissue grew with new vessels The vessels then contact with the cortical bone The reintegration is complete after 8 weeks and the granulation tissue changes into a new periosteum In the group with a muscle flap after 1 week, the cortical bone completely necrosed and osteomyelitis resulted

Only an early muscle flap in the first 3 days will successfully revascularize cortical bone in the treatment of open fractures. A late transposition after 1 week will result in necrotic bone and osteomyelitis.

Three-dimensional computed tomography in the preoperative assessment of cementless hip reconstruction

P. Campbell, A.B. Nevelos and O.J. Follows, *Bradford Royal Infirmary, Bradford, UK*

Experience with multiplanar and three-dimensional computed tomography (CT) in the preoperative assessment of total hip reconstruction is reported and its usefulness compared with that of standard plain radiography. Twenty patients underwent 21 ceramic cementless total hip reconstructions for secondary degenerative arthropathy. In all 20 patients standard transaxial computed tomograms were taken initially. Using advanced software, these were reformatted to give both sagittal and coronal views in 17 patients, in eight of these three-dimensional images were produced. When transaxial images alone were used, further information was obtained in only two of four patients However, when these data were reformatted to give sagittal and coronal views, more accurate details regarding acetabular bone stock were found in 14 of the 17 patients. The use of a complete three-dimensional image gave useful information, additional to that from the multiplanar views, in half of the patients. Overall, the CT images gave additional information concerning femoral head uncovering, acetabular osteophytes, bone stock and orientation in 16 of 21 hips operated on

In conclusion, in routine total hip replacement, even advanced CT is unlikely to offer any advantages over plain radiography In more complex situations, however, this technology is a reliable method of obtaining more detailed preoperative information and its use is recommended in selected patients.

Distal radius fractures in arthroscopic procedures and transarthroscopic operations of the wrist

W.-R. Dingels and U. Schütz, *Sana-Krankenhaus, Hürth/Cologne, Germany*

Today's conservative or operative treatment of fractures of the distal radius is at best only satisfactory Even with better techniques of osteosynthesis (e g. external fixation) these fractures show unsatisfactory results in 20–30 per cent of cases in the literature and on follow-up Between 1979 and 1984, 956 fractures of the distal radius were treated conservatively The retrospective study of 548 cases by clinical and radiological means showed a severe reduction in function of the wrist and hand in 18 per cent. Another study of 84 operated cases in the years 1989–1990 indicated the same outcome as in the conservatively treated patients This should not be acceptable. Since 1991, in selected cases primary wrist arthroscopy of the fracture of distal radius and/or radiocarpal joint was performed The intra-articular fracture and depression are differentiated With transarthroscopic procedures the articular surface is reduced Subsequent stabilization of the fragments was obtained via percutaneous K wires and/or screws In some cases cancellous bone grafts were inserted percutaneously by distal portals of the radius shaft The management and also the operative procedure and results are presented.

Degenerative spondylarthropathy: treatment by lumbar arthrodesis

S.A. El Banna, O. Delahaut, F. Sabri, S. Boulvin and K. Hutsebaut, *Department of Orthopaedics, CHU Vesale, Charleroi, Belgium*

Between 1986 and 1991, 65 patients were operated on for lumbar osteoarthritis There were 33 women and 32 men, with a mean age of 52 (range 30–81) years All patients suffered from posterior lumbar arthropathy with possible degenerative discopathy and interbody osteoarthritis, 14 had lumbar stenosis. Twenty-one patients had grade 3 and 44 grade 1 or 2 disease, according to the classification of the American Society of Anesthesiologists. Symptoms were low back pain with or without sciatica.

Conservative treatment was unsuccessful Before operation clinical, neurological and radiographic investigations were performed At operation via a posterior approach, two plates were fixed with intrapedicular screws according to the Louis' technique. A posterolateral bone graft was performed, and spinous processes removed Laminectomy was carried out if there was lumbar stenosis. Arthrodesis was usually between L3 and S1 depending on the number of diseased vertebrae

Follow-up was 1–6 (median 3) years. One patient died 6 days after operation from a cerebrovascular accident Evaluation of patients was based on clinical assessment according to Cabot's scale, with radiography and electromyography if necessary In all. 59 patients had clinically good results and lumbar arthrodesis was successful in all patients in spite of some broken screws.

Day-case surgery of subcapital and cervical fractures of the femoral neck

D. Fahed, Y. Daoud, J.N. Kuhlmann and S. Baux, *Rothschild's Hospital, Paris, France*

The repair of femoral neck fractures is considered to be major surgery because of the operative procedure, complications and elderly target population (mean age 78 years) Total anaesthesia, the lateral position during operation and sometimes a long period of hospitalization may affect the clinical outcome. Local 'assisted' anaesthesia may allow a short hospitalization and immediate weight-bearing

Thirteen patients have undergone operation in our department between 1989 and 1992, with an average of 22 h of hospitalization and immediate weight-bearing The osteosynthesis by Knowle's pins with a short approach under local assisted anaesthesia and under radioscopic control was used for Garden I and II subcapital and cervical femoral neck fractures.

The results have been encouraging· neither secondary displacement, local or general complications, nor necrosis or non-union have been seen during a follow-up of 18 months. The shortness of the hospitalization period permitted patients rapid recovery

Day-case surgery may have a place in the management of femoral neck fractures.

0007–1323/93/S070–04 © 1993 Butterworth-Heinemann Ltd

Comparison between operative treatment of acromioclavicular dislocation using metal implants and augmentation fixation with Vicryl threads

R. Haaker, U. Eickhoff and H.-L. Klammer, *Department of Traumatology, Bundeswehrzentralkrankenhaus, Koblenz, Germany*

Different operative procedures exist for the treatment of ruptured acromioclavicular ligaments. In a retrospective study two different operative procedures were compared, according to their clinical and radiological results. In 36 patients, operative treatment of the ruptured ligament was performed by using Vicryl threads Augmentation of the coracoclavicular ligament was performed in six of these patients, whereas in four the acromioclavicular ligament was repaired Augmentation of both ligaments was performed in the remaining 24 patients using 5 mm Vicryl threads. Postoperative results were documented in 24 patients by clinical examination, ultrasonography and radiology. Dislocation of the acromioclavicular joint of more than 10 mm was found in five patients Using the TAFT score, in five patients an excellent result was achieved, 14 patients had a good result, four patients a satisfying result and one patient a bad result regarding clinical evaluation and ultrasonographic and radiological findings. Compared with 75 patients who were treated by implantation of metal fixators from 1980 to 1985, the same results were achieved by using augmentation with reabsorbable Vicryl In conclusion, operative treatment of acromioclavicular dislocation using Vicryl threads should be preferred, because of the same clinical and radiological results, but without the necessity for a second operative intervention for removal of the osteosynthetic material

Self-reinforced polyglycolide and polylactide rods and screws in the fixation of fractures and osteotomies

E. Hirvensalo, E.K. Partio, O. Böstman, E.A. Mäkelä, S. Vainionpää, P. Törmälä and P. Rokkanen, *Helsinki University Central Hospital, Helsinki, Finland*

Totally absorbable fracture fixation devices were introduced in the authors' department in 1984 A total of 2100 patients have been managed with these implants, mainly rods and screws made from polyglycolide (80 per cent) or poly-L-lactide (20 per cent). Indications for these implants included fracture of the ankle, radial head and olecranon, chevron osteotomy for hallux valgus, flake fractures in different joints and arthodeses of the ankle, foot and hand regions, as well as epiphyseal fracture in children. Recovery was uneventful in over 90 per cent of patients, the infection rate being 3 per cent The reoperation rate was 2 3 per cent. An inflammatory reaction against the polyglycolide material resulting in spontaneous sinus formation was seen in 2 8 per cent of patients, but not in children.

A 1-year analysis of 102 patients with unimalleolar and bimalleolar fractures treated with rods alone showed good radiographic results in 84 per cent (anatomical ankle mortise) and good functional results in 87 per cent. Fixation of ankle fractures with absorbable polyglycolide or polylactide screws was even more successful. In a study of 145 patients the radiographic and functional results were good in 89 and 98 per cent respectively.

The treatment of fractures of the radial head was highly successful in 20 of 24 cases, eight of whom had a severely comminuted fracture of the radial head before surgery. Fixation of 41 olecranon fractures was successful in all but two cases. There was no difference in success rate whether 3 2-mm rods or screws were used for fixation.

Absorbable rods and screws are now used routinely for fixation of different types of fracture and osteotomy of the cancellous bone in adults, as well as in children. The main advantage of the method is that removal of the implants is not needed, which is important when calculating the operative costs of the surgical unit. The good fixation properties and the low complication rate justify further development and use of absorbable polyglycolide and polylactide implants.

Impingement and the coracoacromial ligament

E.M. Holt and R. Allibone, *University of Liverpool, Liverpool, UK*

Anatomical dissection of 50 shoulders, with measurement and histological analysis of the coracoacromial ligament, was performed The results show that in persons > 50 years of age the coracoacromial ligament does not have a constant form. Three main types were found: quadrangular (48 per cent), Y shaped (42 per cent), and broad band (8 per cent) The Y form and the quadrangular type of ligaments had significantly larger attachments to the coracoid. The broad-band ligament was significantly correlated with height. In 80 per cent of the Y shaped ligaments, those with both medial and lateral bands, the lateral component had the largest attachment to the coracoid. The lack of uniformity of the ligament was emphasized by the absence of statistical correlation between the type of ligament and side, sex, age, midpoint thickness, acromial attachment or the minimum distance between coracoid and acromion.

A previously unreported type of coracoacromial ligament, the multiple-banded ligament, was found, which also had the largest coracoid attachment This multiple-banded version was similar to the Y form but with an additional band extending inferiorly and medially on the coracoid, increasing the likelihood of impingement by this type of coracoacromial ligament. Histological analysis of the ligaments, including the diaphanous section of the Y version, indicates that the multiple-banded type could be more common than this study suggests

Results of femoral fracture treatment

M. Holt, R. Evans, C. Hindley and J. Metcalfe, *Walton Hospital, Liverpool, UK*

A prospective study to determine factors affecting mortality, morbidity and postoperative mobility of 1000 patients with femoral neck fracture (525 subcapital, 475 intertrochanteric) admitted to a district general hospital over a 50-month period is described. A total of 25 fractures were treated conservatively with a mortality rate of 60 per cent. The hospital mortality rate of the 975 surgically treated fractures was 11 3 per cent. Discriminant analysis revealed that the best predictor of survival was mobility before injury. The effect of grades 1–6 of mobility before injury on mortality was progressive. The best predictor of operative survival was the mobility score Delay affected the results, but only 30 h after admission, a period in which 75 per cent of patients had undergone operation.

The best predictors of morbidity and discharge mobility were age and mobility before injury Specific attention was given to the results obtained by the 62 surgeons in this series. Experience affected the discharge mobility, but statistical analysis determined its effect to be small.

This study shows that, given a similar distribution of fractures of the femoral neck, surgeons of 1–5 years' experience in orthopaedics and those with greater than 5 years' experience can achieve comparable mortality and morbidity results in hemiarthroplasty and internal fixation.

Treatment of comminuted fracture of the distal end of the radius by ligamentotaxis

K. Huch, M. Huenerbein and P.J. Meeder, *Department of Surgery, University of Heidelberg, Germany*

Comminuted fractures of the distal end of the radius with involvement of the joint (C2–3 in the AO classification) are treated by osteosynthesis with Kirschner wires or external fixation. Particularly unstable fractures may be reduced and held by external fixation according to the principle of ligamentotaxis

A total of 73 patients (48 female, 25 male) with C2 (34 patients) and C3 (39) fractures (14 open cases) were treated by external fixation over a period of 4 years. In all, 40 patients (24 female, mean age 69 years, 16 male, mean age 42 years) were followed for a mean of 28 months

All fractures healed. Although the action of the wrist had been restricted for 6 weeks, all patients were able to carry out their usual activities frequently after 3 months In one patient the radius was fractured by a screw during surgery. Significant pin track infection and Sudeck's dystrophy were observed in one patient each.

The mean reduction of dorsiflexion, palmar flexion, abduction and adduction was 10° compared with that in the healthy wrist. Pronation was 3° and supination 12° less than on the unfractured side.

Radiography showed arthrosis of the wrist in three patients. The mean dorsal angulation was 3° (range −5°–15°); the mean angle between the shaft of the radius and the area of the joint was 23° (range 12°–34°). Discontinuity of the articular surface was found in five patients. Most patients with a good radiological result have a good clinical outcome.

Treatment of C2 and C3 fractures of the distal end of the radius by external fixation can be recommended because of the good clinical and radiological results. The technique can be regarded as an alternative to Kirschner wiring.

Factors affecting wear of polyethylene in retrieved total knee replacements

A. Joshi, G. Blunn, S. Sathasivam, P. Walker and K. Hardinge, *Centre for Hip Surgery, Wigan, Lancashire, UK*

Over 250 retrieved tibial polyethylene components have been analysed for wear of polyethylene. Duration of implantation varied from 7 months to 19 years. There were 106 unicondylar type prostheses, 85 total condylar replacements, 35 meniscal and 17 stabilized total-knee replacements. All prostheses were assessed for wear by scoring bearing surfaces on a scale of 0 to 5 for delamination, pitting abrasion, deformation, scratching and cement entrapment. Wear scores were correlated with duration of implantation, patients' activity and weight. Crystallinity and oxidation of polyethylene were measured by infra-red microspectroscopy. The tensile strength of polyethylene was determined.

Delamination of polyethylene occurred in some unicondylar designs and in long-term (>10 years) condylar replacement designs. In one design of a meniscal bearing total-knee replacement delamination occurred at the edges of the polyethylene runners due to misalignment of the surfaces resulting from rupture of the anterior cruciate ligament. Abrasion by cement particles occurred predominantly in stabilized and total condylar replacement designs. In all specimens examined crystallinity of the polyethylene decreased under the wear track. There was a significant difference in the ultimate tensile strength of polyethylene from different designs. One of the main factors associated with early delamination in one design was the presence of fusion defects in polyethylene which led to crack initiation and delamination.

Conformity of the articulation *per se* did not appear to be the major factor influencing delamination wear of polyethylene. The quality of polyethylene had a significant effect on wear. Even highly conforming bearing surfaces of the total condylar replacement design type delaminated after long durations (>10 years).

Effect of osteotomy performed by an oscillating saw on bone regeneration

J. Krajničák, *Department of Surgery, Hospital with Poliklinik, Košice-Šaca, Slovak Republic*

Bone regeneration may be improved if an Ilizarov osteotomy is performed by a chisel with fragment torsion which causes a spiral fracture. The defects of bone healing after using either a rotatory or an oscillating saw have been reported.

The regeneration of distracted bone was studied in 20 men with bone defects ranging from 4 to 14·5 cm. Five patients underwent osteotomy (after Ilizarov) and in 15 patients the transverse osteotomy was performed by an oscillating saw. In four patients the osteotomy was performed on both main fragments. Bone regeneration was observed in radiographs at regular 4-week intervals. The first signs of ossification appeared after 4 weeks. There were no differences in the bone regeneration between the Ilizarov osteotomy and the transverse osteotomy performed with an oscillating saw. The defects of bone healing after the osteotomy by rotatory or oscillating saw have not been observed in experiments with 30 rabbits.

Transverse osteotomy of long bones with an oscillating saw to produce bone elongation by the Ilizarov method has no effect on the regeneration of distracted bone.

Ionizing radiation and the orthopaedic surgeon

F.P. Monsell and K. Middlehurst, *Royal Preston Hospital, Preston, UK*

The orthopaedic surgeon is exposed to increasing levels of ionizing radiation due to the growing number of techniques that use perioperative radiographic imaging. To quantify this potential risk, a prospective survey was conducted to measure radiation levels in a designated trauma theatre.

The study was conducted for 1 calendar month with operative procedures carried out as normal. Measurements were performed using eight standard dosimetry badges, placed at a height of 1·4 m at set points around the theatre. This was designated to record maximum radiation levels given the direction of the primary X-ray beam. In addition, one badge was attached to the operating table and one to the anaesthetic trolley. During the study period 41 cases required X-ray screening, 19 (46 per cent) during internal fixation of femoral neck fractures, a further six cases required the production of nine hard-copy radiographs. Total screening time was 19·7 min, with a mean screening time of 29 (range 8–180) s per case.

At the conclusion of the study all badges were processed at the regional department of medical physics to an accuracy of 10 per cent. The maximum recorded dose was 0·2 mSv at the operating table, all other badges recorded a dose of 0·05 mSv. If these data are extrapolated for a period of 1 year, the maximum dose is in the order of 2·5 mSv, well within the maximum permitted whole-body dose for a member of the public (5·0 mSv per annum).

It is concluded that there is no significant risk associated with current working practice. This is partly due to the use of high-performance image intensifiers with image retention and pulsed fluoroscopy.

Adjuvant local antibiotic therapy: an analysis of 1085 open fractures

P.A.W. Ostermann, S.L. Henry and D. Seligson, *University of Bochum, Germany and University of Louisville, Kentucky, USA*

A consecutive series of 1085 compound fractures was treated between May 1983 and July 1992. There were 279 grade I, 364 grade II and 442 grade III open fractures (199 IIIA, 171 IIIB, 72 IIIC). A total of 240 open fractures (group 1) received systemic administration of broad-spectrum antibiotics alone whereas 845 compound fractures were managed with the supplemental local use of aminoglycosides (tobramycin-polymethylmethacrylate beads). All fractures underwent copious wound irrigation, meticulous radical debridement and fracture stabilization.

The overall infection rate in group 1 was 12·1 per cent (29 of 240) and 3·7 per cent (31 of 845) in group 2. The difference is statistically significant ($P < 0.001$). In the grade I category the overall infection rate was 3 per cent (two of 67) in group 1 and 0·5 per cent (one of 212) in group 2. In patients with grade II the overall infection rate was 8 per cent (six of 71) in group 1 and 2·7 per cent (eight of 293) in group 2 whereas the overall infection rate in those with grade III open fractures was 20·6 per cent (21 of 102) in group 1 and 6·5 per cent (22 of 340) in group 2. A statistically significant reduction of the infection rates was evaluated only for the IIIB types for wound infection (group 1 41 per cent (11 of 27), group 2. 6·9 per cent (ten of 144), $P < 0.001$) and for chronic osteomyelitis (group 1. 30 per cent (eight of 27), group 2 6·2 per cent (nine of 144), $p < 0.001$) as well as for the IIIC types for wound infection (group 1 25 per cent (eight of 32), group 2 5 per cent (two of 40), $P < 0.05$).

External fixation in the treatment of multiple fractures

A. Petrulis, S. Pranckevicius and V. Geiulis, *Kaunas Medical Academy, Kaunas, Lithuania*

In the orthopaedic clinic of Kaunas Medical Academy from 1987 to 1993, 18 patients with multiple fractures of long tubular bones were treated using an external fixation apparatus designed especially for such fractures (patent no 1338851). The portable unilateral apparatus contains a screwed bar, rod holders and repositioning devices for each dislocated fragment of bone. Six patients were treated for femur, seven for tibia and two for humerus fractures. Two patients suffered both a femur and a tibia fracture and one had a bilateral femur and unilateral humerus fracture. The apparatus was removed after an average of 5 months. All 18 patients were followed for 1–5 years.

Good results (no complaints, knitting of the bone fragments in good position, full range of motion of the joints) were achieved in 12 patients. Satisfactory results (complaints of mild pain, slight deformation, shortening of the limb by 1–2 cm, limited motion of the joints to up to one-third of normal) were observed in six patients.

Kienbock's disease: prognostic evaluation by magnetic resonance imaging

I. Pigeau, P. Dupuis, M. Ebelin, O. Clement, J. P. Lemerle and G. Frija, *Boucicaut Hospital, Necker School of Medicine, Paris, France*

The main difficulty in treating stage III Kienbock's disease (Decoulx's classification) is deciding between conservative and non-conservative surgery. This problem would be resolved if the osteogenic potential of bone medulla could be assessed before operation. Plain radiography and scintigraphy do not assess medullary bone potential. Magnetic resonance imaging (MRI) accurately assesses the state of bone medulla and its vascularization (using T2- and T1-weighted acquisitions, performed before and after intravenous injection of contrast) The most valuable technique performed on patients before and after conservative surgery or on non-operated patients appears to be MRI follow-up providing the basis for prognostic staging, which may guide surgical strategy

A prospective study of 25 consecutive patients presenting on plain radiography with stage III Kienbock's disease was conducted. Patients were included if MRI follow-up (two examinations at 6-month intervals) was available. Fifteen patients underwent radial-shortening osteotomy and were examined by MRI before and 1 year after the procedure. Five patients had only postoperative MRI at 3 months and 1 year after surgery Five patients, still non-operated, were examined when diagnosis was made and 6 months later.

MRI was performed using T2- and T1-weighted acquisitions. T1-weighted images were obtained before and after contrast injection A prognostic subclassification of stage III Kienbock's disease was established, depending mainly on the volume of the non-vascularized medullary bone, as depicted on postcontrast T1 images.

Results of operative treatment of large benign proximal femur tumours

S. Pranckevicius, A. Petrulis and V. Gerulis, *Kaunas Medical Academy, Kaunas, Lithuania*

In the orthopaedic clinic of Kaunas Medical Academy from 1987 to 1992, 11 children aged 5–13 years underwent operative treatment for large benign tumours of the proximal part of the femur. Seven had osteodystrophia fibrosa cystica and four had osteoblastoclastoma. Intralesional curettage and filling of bone cavities with small (0·05 × 1 cm) biocompatible osteoconductive polymer fibres was performed No post-operative immobilization was used. After lying in bed for 1 month, walking with a special functional device which decreases weight-bearing by two-thirds was allowed. and 4 months after operation full weight-bearing without any device was allowed Full consolidation was observed 5–6 months after operation

Self-reinforced tacks, pins and wires in the fixation of ligaments, osteotomies and fractures

K. Vihtonen, T. Juutilainen, H. Pihlajamäki, H Pätiälä, P. Törmälä and P. Rokkanen, *Helsinki University Central Hospital, Helsinki, Finland*

Seventy patients with total rupture of the ulnar collateral ligament of the first metacarpophalangeal joint were treated with a self-reinforced (SR)-PLLA mini tack The study comprised 23 women and 47 men of mean age 33·7 years A 1·1-mm channel was drilled in the base of the proximal phalanx at right angles to the axis of the bone through both cortices A 1·1-mm K wire was used to perforate the ligament. A PLLA tack (1·15 mm/15 mm) was placed through the ligament in the bone channel. The top 4 mm of the tack was pressed tightly against the cortex, and the device stabilized the joint immediately A dorsal plaster cast was used to immobilize the thumb for 4 weeks. Follow-up of 6–24 months showed 69 ligaments to have remained stable. The subjective result was good or satisfactory in 66 cases No inflammatory reactions were noticed. The mean time off work was 34·4 days. On the basis of these findings the new totally absorbable fixation method seems to be a reasonable alternative to metal wire fixation

A total of 27 patients with small-fragment osteotomies or fractures were treated by internal fixation with absorbable SR-PLLA pins. Follow-up was from 8 to 37 months. The two most common indications were chevron osteotomy of the first metatarsal bone for hallux valgus and displaced fracture of the radial head No redisplacement occurred and there were no signs of inflammatory foreign body reactions. Biopsies in two patients 20 and 37 months after implantation showed that no polymeric material remained. The results suggest that SR-PLLA pins are useful in small fragment fixations.

Finally, seven patients with a fracture of the olecranon and four with fracture of the patella had internal fixation with SR-PLLA pins combined with a SR-PLLA tension wire. The preliminary results seem to be good· one redisplacement of a patella fracture occurred. Further experience with these fractures is required before firm conclusions can be drawn

Biodegradable fixation in thoracic, vascular and craniofacial surgery

T. Waris, W. Serlo, I. Merikanto, J. Hukki, J. Ohman, T. Antikainen, M. Ruuskanen, M. Rantanen, K. Lassila, T. Pohjonen and P. Törmälä, *Töölo Hospital, Helsinki University Central Hospital, Helsinki, Finland*

Biodegradable osteosynthetic material made from self-reinforced polylactide has been used in ten craniofacial operations in Finland, in 14 such operations in Sweden (Clas Laurizen), and in six operations in Mexico (Antonio Fuente del Campo) without complication.

Biodegradable self-reinforced polyglycolide and polylactide has shown interesting possibilities when used experimentally to guide the regeneration of perichondrium to cartilage and for the fixation of experimental pectus excavatum in rabbits, this has led to successful clinical use of polylactide plates in three clinical pectus excavatum corrections.

In addition, the polylactide wire has successfully supported the healing of sternotomy in rabbits and pigs and has been used clinically to close median sternotomy in six patients Moreover, encouraging preliminary results have been obtained from the use of an extraluminal polylactide ring in supporting the healing of vascular anastomosis, namely aortoaortic anastomosis in the pig (This work was performed in collaboration with K. Verkkala and K Kyosola from Helsinki University Central Hospital.)

Limb exsanguination: comparison of three methods

V.J. Woolf and P.J. Warren, *Lister Hospital, Stevenage, UK*

The effect of limb exsanguination by elevation alone, Esmarch bandage and Rhys-Davies' exsanguinator on the quality of the operative field in patients receiving upper- and lower-limb surgery has been investigated.

Patients were allocated to one of three methods of limb exsanguination using a randomized double-blind procedure The operating surgeon graded the operative field, using a previously published scoring system, without knowledge of the method of exsanguination employed Statistical analysis was performed with Fisher's exact test.

Mechanical exsanguination of the upper limb provided a satisfactory operative field in 28 of 34 cases while elevation alone was satisfactory in eight of 15. Mechanical methods involving the lower limbs were satisfactory in 33 of 38 cases compared with 15 of 20 elevated cases In the upper limb, suboptimal fields were associated with too much residual blood. In the lower limb, suboptimal fields from elevation were underexsanguinated, whereas those from mechanical methods were as likely to be overexsanguinated.

The authors advocate the use of mechanical methods of limb exsanguination where possible, but the clinically discernible advantages over elevation were not statistically significant.

Otorhinolaryngology

Surgical treatment of the discharging mastoid cavity

R.W. Clarke and M.S. McCormick, *Royal Liverpool University Hospital, Liverpool, UK*

Persistent otorrhoea following mastoid surgery is a frequent cause of morbidity, a considerable drain on outpatient resources and a possible pointer towards residual cholesteatoma

In an attempt to obtain a dry cavity, the authors offer revision surgery to patients with troublesome postmastoidectomy otorrhoea In a 4-year period, 37 patients, 20 men and 17 women of mean age 37 years, had such surgery. In all cases the mastoid bowl was cleared of granulations and the bony contours smoothed Cavity obliteration was attempted using a variety of techniques, alone or more often in combination, as follows local muscle flap (25), thiosite implants (12), autogenous bone plate (nine) and hydroxyapatite crystals (eight). Twenty-two patients had temporalis fascia grafting of the mastoid bowl and 11 had fascial grafting of mesotympanic defects The fascial ridge was lowered in seven cases and a modified cavity converted to a radical in four. Six patients had cholesteatoma at the time of revision and one had a mesotympanic cholesterol granuloma

Of the 32 patients available for follow-up two reported that their symptoms had been made worse by surgery, seven had little change and 23 now have a smaller mastoid cavity that requires minimal supervision

Revision surgery for the discharging mastoid cavity is associated with low morbidity and a good prospect of a satisfactory outcome

Middle fossa approach for acoustic neuroma: residual tumour, recurrence and growth rates

M.E. Wigand and S. Wolf, *University Erlangen–Nuremberg, Germany*

Between 1980 and 1992 more than 250 acoustic neuromas of sizes between 5 mm (intrameatal) and 30 mm (measured within the cerebellopontine angle) were operated on by exposure via the enlarged mid-fossa approach. Postoperative surveillance of residual or recurrent tumour growth could be carried out by imaging techniques in more than 100 cases. Using computed tomography or magnetic resonance imaging measurements, the sizes of 20 tumours were monitored for more than 1 year before their complete removal or after partial resection

The recurrence rate of tumours after their virtual total removal was 1 0 per cent. Completeness of the excision can apparently be controlled by this approach in an excellent manner. Regrowth of residual tumours after deliberate partial resection did not follow firm predictions some remnants remained stationary over more than 6 years, others increased in volume, but with different rapidity, and some disappeared from the ordinary images. Furthermore, the tumour behaviour before surgical treatment cannot be predicted As a rough approximation, larger tumours grow more quickly than smaller ones Functional impairment of hearing did not correlate with an increase in tumour size

Paediatrics

Middle cyst and fistula of the neck: results from surgical treatment of 128 children

L.D. Atanassov, *Regional Hospital, Surgery Clinic, Haskovo, Bulgaria*

A total of 128 children with middle cysts and fistulas of the neck have been admitted to the regional Hospital of Haskovo, Bulgaria, between 1967 and 1992. Of these, 104 had an operation for middle cysts and 24 for middle fistulas; 51 (39·8 per cent) came with an uncertain diagnosis.

In all, 80 cases (62·5 per cent) had previously been treated in hospital, 33 by surgical operation. Recurrence occurred in 25 per cent of all cases.

Diagnosis was made by clinical examination supplemented by fistulography in 18 cases, cystography in 11, microbiological examination of secretions in 19, and ultrasonography in three. Histological examination was performed in all patients.

The patients were operated on by Sistrunk's method, 125 were cured and three had recurrence. The 30-day postoperative complications were: wound complications in 23 (18 per cent), paresis of the tongue in one, and cosmetic defects in three. Recurrence occurred in three cases within 1 year of surgery.

No complications were seen in 114 patients traced for up to 1 year, in 58 traced for 2 years, and in 13 traced for 10 years after surgery.

In summary, surgical experience indicates that the operation of Sistrunk appears to be the most successful approach to cure cysts and fistulas of the neck.

Diagnostic methods for functional disorders of the anorectum: suction biopsy, anorectal manometry, endoscopy and endoultrasonography

A. Kolberg-Schwerdt and G.H. Willital, *Paediatric Surgical University Clinic, Munster, Germany*

Functional disorders of the anorectum in children are a frequent cause of admission. Successful treatment is possible only when a reliable diagnosis has been established.

Since 1970 four types of investigation have been used: (1) double-suction rectal biopsy for the diagnosis of aganglionosis and disturbances of innervation; (2) anorectal manometry for the diagnosis of functional disorders of the anorectum and for incontinence grading, (3) endoscopy for the diagnosis of morphological abnormalities, and (4) endoultrasonography for localization of the perirectal muscle layers.

Rectal suction biopsy identified 425 children with aganglionosis and 75 with neural dysplasia. Anorectal manometry enabled grading of severity of incontinence and revealed 'paradoxical reflex mechanism of the internal sphincter' as a cause of idiopathic constipation. Endoscopy allowed observation of complete or incomplete sphincter function. Endorectal ultrasonography (310 patients) demonstrated symmetrical or asymmetrical anorectal muscle layers or scars various distances from the anal verge.

Biopsy, manometry, endoscopy and endoultrasonography are all safe diagnostic procedures for the assessment of functional disorders of the anorectum with minimal discomfort to children.

Mechanical airway obstruction in children

J. McCarthy, J. Hurley, M. Neligan and A.E. Wood, *Department of Cardiothoracic Surgery, Mater Hospital, Dublin, Ireland*

Airway obstruction in the paediatric population is an important cause of respiratory embarrassment and may be treated successfully with surgery if diagnosed early. A review was conducted of all 16 patients presenting to Our Lady's Hospital for Sick Children with airway obstruction since 1 January 1984 to the present to determine mode of presentation, demographic data, diagnosis, surgical procedure and outcome. All patients presented with stridor, 15 had recurrent respiratory tract infection and wheeze. The female:male ratio was 8:8. Mean age of onset of symptoms was 35·1 (range 0–90·4) months. Mean age at operation was 37·8 (range 1–112) months. Diagnostic tests included chest radiography, barium studies, angiography, bronchoscopy and bronchography. Airway obstruction was due to congenital tracheal stenosis (five patients), vascular ring (seven), bronchial stenosis (two) and vascular compression (two). Four of the patients with tracheal stenosis had congenital ring stenosis involving 50–70 per cent of tracheal length, and also had no major intracardiac abnormality. Surgical procedures included vascular ring division (seven), tracheal resection (six), sleeve resection of the bronchus (two), aortopexy (one) and lobectomy (one). All anastomoses were performed with absorbable polydioxanone sutures.

One patient died before surgery, 15 were operated on with two deaths (hospital mortality rate 13 per cent) both of whom had major intracardiac abnormalities corrected at the same time. Thirteen were discharged alive and well, one patient died 1 month after discharge from inoperable congenital heart disease and one patient has been lost to follow-up. The remaining patients are alive and well 1 month to 9 years after discharge with no respiratory symptoms and excellent growth of the tracheobronchial tree on bronchoscopy. In conclusion, all cases of persistent stridor should be investigated to rule out mechanical airway obstruction that is potentially amenable to surgical correction. Absorbable suture appears to allow excellent anastomotic growth.

Essentials of laparoscopic procedures in children

J. Schleef and G.H. Willital, *Paediatric Surgical University Clinic, Münster, Germany*

For >10 years different minimally invasive methods for diagnosis and therapy in children have been evaluated. Endoscopy and especially laparoscopy play an important role. For 2 years laparoscopic operations performed with special paediatric instrumentation were compared with conventional procedures.

A laparoscopic set, designed and available for babies and children, was used for abdominal laparoscopic surgery for the following procedures: pyloromyotomy, adhesiolysis, liver wedge resection, appendicectomy, abdominal staging of Hodgkin's disease, large bowel resection and inguinal hernia. In children undergoing pyloromyotomy an endoscope was placed in the stomach at the entrance of the pylorus to aid localization of the pylorus.

In 2 years, 41 children aged from 10 days to 14 years have been treated by laparoscopy. All procedures planned as minimally invasive were performed without conversion to laparotomy. No postoperative complications occurred. All procedures were successful.

In the authors' opinion laparoscopic large bowel resection with a stapled anastomosis fulfills the criteria of being minimally invasive and easy to perform with minimal risk of postoperative adhesions and short postoperative ileus.

Open reduction and internal fixation of distal humeral fractures in children

T. Zimmermann, C. Kelm and K. Flechsenhar, *University of Giessen, Giessen, Germany*

Fractures of the distal humerus are among the most common injuries in childhood. Accurate reduction is vital to achieve a satisfactory functional result and to avoid late complications. Therefore, the authors favour immediate operation with open reduction and internal fixation using two crossed K wires. Between 1979 and 1989, 72 children (mean age 9·6 years) underwent operation: 40 were treated for supracondylar fracture, 15 for unicondylar fracture, six for transcondylar fracture and 11 had complex fractures with dislocation of the elbow. The patients were examined at a mean of 53 months after injury. According to the classification of Morger, an ideal or good late result was found in 86 per cent. In none of these children did postoperative irritation of the ulnar nerve occur. It is concluded that open reduction and internal fixation of distal humeral fractures is superior to other methods; for example, the most commonly used methods of closed reduction and percutaneous fixation. Open reduction allows exact reduction, particularly correction of rotational displacement, and avoids varus deformity after trauma.

Pancreas

Five cases of colonic complications in acute pancreatitis

A. Alarcó, M. Meneses, V. Medina, J. Pérez Palma and D. Gil, *Hospital Universitario de Canarias, Tenerife, Canary Islands, Spain*

Acute pancreatitis may evolve locally, creating a series of complications such as pseudocyst of the pancreas, pancreatic abscess or obstructive icterus. Other complications include pancreatic ascites, intestinal obstruction and other colonic lesions

Between 1983 and 1986, 45 cases of acute pancreatitis have been treated, of which 14 (31 per cent) were necrohaemorrhagic. A significant group of our patients are holiday visitors with a high consumption of alcohol in a short time.

The diagnosis of colonic necrosis was on clinical and surgical grounds In three cases, an early radio-opaque enema with diluted water-soluble contrast was carried out, this showed colonic fistula clearly

The treatment of these cases was five necrosectomies with drainage of the transcavity and two transverse colon resections (Hartmann), two colostomies to the right and a colon segment resection with end-to-end fistula and protective colostomy to the right Colonic fistula as a late complication occurred in three cases

Colonic lesions due to pancreatitis are still a clinical rarity, but may be on the increase because of a better recognition Their aetiology is not certain but may include involvement of the portomesenteric axis by the pancreatic process through enzymatic, mechanistic and thrombotic effects.

Suppurative pancreatitis as a postoperative complication of acute necrotizing pancreatitis

P. Andronescu, A. Miron, C. Andronescu and A. Marcov, *Colentina Clinical Hospital, Bucharest, Romania*

Two consecutive series of patients with acute necrotizing pancreatitis, submitting to surgery from 1975 to 1985 and from 1985 to 1992, were analysed. The first 72 patients underwent necrosectomy, peritoneal lavage, pancreatic drainage and treatment of biliary aetiology, when present, by cholecystectomy and biliary drainage, or cholecystectomy alone or cholecystostomy. In 26 patients postoperative pancreatic abscess occurred and was noted by change of the pancreatic drainage, which became purulent. An urgent reoperation was necessary in 21 patients, with death in 13 In the second series of 43 patients, necrosectomy was performed with wide exposure of the pancreatic area by debridement of all surroundings of the lesser sac, exposing the retropancreatic space Pancreatic debris, exudate and blood can easily drain to the dependent areas of the peritoneal cavity Drainage of the pouch of Douglas may be placed away from the pancreatic area, avoiding external bacterial contamination Biliary pathology was not treated at the first operation In the past 2 years a pancreatic instillation catheter was added to provide local broad-spectrum antibiotic therapy Postoperative suppurative pancreatitis occurred in only nine patients, necessitating seven reoperations; five patients died.

In conclusion, immediate reoperation should be considered whenever postoperative suppurative pancreatitis occurs In addition, peritoneal drainage should avoid the pancreatic area to minimize external bacterial contamination

Study of the influence of fresh-frozen plasma on the serum level of antiprotease systems in patients with acute pancreatitis

G. Antsaklis, S. Pierrakakis, N. Economou, P. Karydakis and G. Sabalis, *Sismanoglion General Hospital, Athens, Greece*

Forty patients with acute pancreatitis were divided in two groups according to their mode of treatment. Both groups had standard treatment of acute pancreatitis but the patients in group 1 were given dried plasma while patients in group 2 were given fresh-frozen plasma (FFP) Serum levels of the antiprotease systems, α_1-antitrypsin and α_2-macroglobulin were measured.

α_1-antitrypsin was increased at a statistically significant level ($P < 0{\cdot}01$) from the first to the third day in both groups and remained high up to the seventh day The level of α_2-macroglobulin was low in both groups from the first to the third day. The α_1-antitrypsin level was not implicated in either prognosis or the severity of the illness

The α_2-macroglobulin level after 7 days of the disease was found to be statistically significant ($P < 0{\cdot}05$) in patients with severe septic complications compared with those given FFP, moreover, their disease course was very satisfactory It appears that administration of dried plasma does not alter the course of the disease

Role of cholecystectomy for microlithiasis in idiopathic acute pancreatitis

M. Armengol, B. Oller, N. Rodríguez, P. Humbert, J. Gener and A. Gallardo, *Department of Surgery, Hospital Germans Trias i Pujol, Autonomous University of Barcelona, Spain*

Gallstones and alcohol abuse are common causes of acute pancreatitis (AP), accounting together for 70 per cent of all cases in Spain. Other aetiologies include trauma, hyperlipidaemia, surgery, endoscopic retrograde cholangiopancreatography and drugs. The remaining cases can be considered as idiopathic, while microlithiasis of the gallbladder has been proposed as a possible cause.

The purpose of this study was to assess the incidence of microlithiasis or biliary sludge in patients with AP initially considered as having idiopathic causes, and to evaluate the role of cholecystectomy in the clinical evolution of AP

In a series of 241 patients with AP, 130 (54 per cent) were attributed to gallstones, 60 (25 per cent) to alcohol, and ten (4 per cent) to other specific causes. The remaining 41 (17 per cent) were considered to be idiopathic These patients were submitted to a study of gallbladder bile obtained by contraction of the organ with a perfusion of 2 units Crick–Harper–Raper kg^{-1} of cholecystokinin The bile was collected through a soft gastroduodenal tube placed into the duodenum and was then centrifuged for 10 min. at 2000 r p m and examined with a polarizing microscope for microlithiasis Cholecystectomy was proposed to patients diagnosed with microlithiasis

Microlithiasis was found in 33 of 41 (80 per cent) patients Bile was normal in eight (20 per cent) Cholecystectomy was performed in 14 patients who agreed to surgical management and 18 did not have operation In the mean (range) follow-up period of 25·7 (1–52) months only one of the patients having operation presented with a new episode of AP, recurrence was seen in four (22 per cent) of those not undergoing operation

Microlithiasis of the gallbladder is found in 80 per cent of cases of AP initially considered to be idiopathic Cholecystectomy can prevent new episodes of AP.

Treatment of acute pancreatitis with octreotide

N. Beechey-Newman, W. Lee, J. Grogono and G.A.D. McPherson, *Wycombe General Hospital, High Wycombe, UK*

Octreotide prevents the onset of acute pancreatitis (AP) and reduces the mortality rate from established AP in rats, but no convincing study in humans has been published The present study was designed to determine whether octreotide improves the course of AP in man Nineteen consecutive patients with AP (amylase level > 1000 units l^{-1}) were allocated to receive octreotide 250 μg subcutaneously and 0·5 $\mu\mathrm{g\,kg}^{-1}\,\mathrm{h}^{-1}$ by intravenous infusion ($n = 9$), or to be controls ($n = 10$) In all other respects treatment was standardized and identical Analgesia was by patient-controlled continuous infusion The groups did not differ with regard to Ranson or Glasgow scores on admission Clinical course was assessed by monitoring blood gases, haematology, biochemistry, clinical signs, radiology including computed tomography (CT) morphology and clinical milestones Although no severe cases of AP were admitted during the study period, prognostic falls in serum calcium (to $<2{\cdot}00\,\mathrm{mmol\,l}^{-1}$), albumin (to $<32\,\mathrm{g\,l}^{-1}$) and haematocrit (>10 per cent), and falls in

0007–1323/93/S076–06 © 1993 Butterworth-Heinemann Ltd

haemoglobin (of $>2\,g\,dl^{-1}$) and oxygen saturations (to <10 kPa) were significantly less frequent in the octreotide-treated group ($P < 0{\cdot}05$, Fisher's exact test). Analgesic requirements were also significantly less ($P < 0{\cdot}05$, Mann–Whitney U test). Every other variable without exception including CT morphology showed a non-significant improvement in the octreotide-treated group. No deaths occurred in either group. These preliminary results suggest that octreotide may beneficially affect the course of AP.

Expression of gastrointestinal antigens and survival in resected pancreatic cancer

L. Colombo, G. Carcano, L. Dominioni, A. Benevento, A. Chiappa and R. Dionigi, *University of Pavia in Varese, Varese, Italy*

Recent immunohistochemical and ultrastructural studies[1] have demonstrated that exocrine pancreatic tumours represent a heterogeneous cytological population with different immunophenotypic expression. Histological heterogeneity might be responsible for the different biological behaviours; this could account for the local recurrent disease in cases treated by radical excision and expected to have a better prognosis according to tumour node metastasis staging.

The expression of gastrointestinal antigens Du-Pan-2, M1 glycoprotein antigen, cathepsin E, pepsinogen II (PG II) and CAR-5 antigen has been retrospectively assayed by immunohistochemical methods in 70 cases of pancreatic cancer (66 ductal carcinoma, four cystadenocarcinoma) radically operated on. The antigenic expression has been correlated with tumour grading and survival.

Statistical evaluation was possible only for CAR-5 and PG II antigens. CAR-5 antigen was not found in any cystadenocarcinoma, and was expressed more frequently in G_3 (63 per cent) than in G_1 and G_2 carcinoma (40 per cent). PG II was expressed in all cases of cystadenocarcinoma, and was present in 43 per cent of ductal carcinoma. Mean survival correlated with antigen expression was 17·7 months in ductal carcinoma positive for PG II and 10·3 months in ductal carcinoma negative for PG II ($P < 0{\cdot}01$).

In conclusion, the data show that patients undergoing surgery for resection of ductal pancreatic carcinoma expressing PG II antigen have a more favourable prognosis. This information could be of value in planning treatment of pancreatic cancer.

1. Sessa F *et al.* Ductal cancers of the pancreas frequently express markers of gastrointestinal epithelial cells. *Gastroenterology* 1990; **98**: 1655–65.

Abdomen left open in severe acute pancreatitis

A. Cucu, N.G. Ionescu, I. Szabo, C. Gombosiu and A. Oancea, *University of Medicine and Pharmacy, Cluj, Romania*

Leaving the abdomen 'open' was undertaken in 64 patients with severe acute pancreatitis. The achievement of a 'stoma' between the outer space and the pancreatic bed was made possible by circumferential suture of the access slit in the gastrocolic omentum to the parietal peritoneum, with or without plication of the greater omentum at the inferior pole of the wound. Attachment of the omentum prevents leakage of the pancreatic fluid into the lower quadrants. Patients with an open abdomen did not require classic pancreatic bed drainage reoperation. Wide and constant access over the pancreas allows drainage of the pancreatic fluid and sequestrations, thus preventing retention problems as well as the hazards of repeated anaesthesia and operative procedures.

The open technique does not require special instruments, is technically easy to perform and lowers the mortality rate in acute pancreatitis.

Adjuvant external and intraoperative radiation therapy in resectable pancreatic cancer

G.B. Doglietto, M. Bossola, D. Frontera, R. Bellantone, M. Ippoliti, D. Borzomati and F. Crucitti, *First Clinica Chirurgica, Catholic University, Rome, Italy*

Prognosis after curative resection of carcinoma of the head of the pancreas is poor. Recurrence around the coeliac axis and mesenteric vessels occurs with high frequency. To improve local control a combined multimodality approach was started in January 1990 that includes surgical resection, intraoperative radiation therapy (IORT) and external beam radiation therapy (ERT). So far 12 patients have been treated in this way. In 11 cases subtotal pancreatectomy was performed, in one total resection. IORT has always been delivered to the tumour bed including the coeliac axis, portal vein and origin of the superior mesenteric vessels. Postoperative ERT of the tumour bed (dose 50 Gy; three-box technique) alone has been used in six patients (group 1), in six cases a preoperative treatment (the day before surgery, liver and pancreas irradiation, dose 5 Gy) was added (group 2). Mortality and postoperative major complications were absent, six wound infections occurred.

In group 1, five patients (stage I, two; stage III, three) died after a mean of 11·4 months: four from liver metastases (occurring after a mean of 6 months) without evidence of local disease and one from local recurrence outside the ERT/IORT field. One patient is disease-free at 3 months from surgery. All six patients in group 2 (stage I, one; stage III, five) are alive after a mean follow-up of 9·3 months without evidence of local recurrence, two have developed liver metastases.

Combination of ERT and IORT in the surgical resection of pancreatic cancer appears safe, tolerated and seems to offer a good local control. The high frequency of liver metastases suggests that more aggressive treatments (e.g. preoperative ERT, as in group 2) and/or chemotherapy need to be evaluated.

Predictive value of systemic manifestations in acute pancreatitis

Cr. Dragomir, M. Stoian, C. Diaconu and C. Dolinescu, *Third Surgical Unit, Iasi, Romania*

Organ and regional disorders in acute pancreatitis are connected with various clinical manifestations. Furthermore, when acute necrosis of the pancreas (ANP) occurs the pancreatic broth is responsible for some distinct systemic manifestations. From the records of 42 patients admitted with pathologically demonstrated ANP, 23 (55 per cent) were selected for a retrospective study on the basis of systemic manifestations. Initial shock was present in all 23 patients, acute respiratory distress syndrome (ARDS) in 14 (61 per cent), acute renal failure in seven (30 per cent), toxic psychosis in eight (35 per cent) and hypocalcaemia in one (4 per cent). Fourteen patients had three systemic manifestations, five patients had two and one patient had a single systemic manifestation. The most frequent and serious combination was initial shock and ARDS, occurring in 13 patients with eight deaths. Early surgical treatment for unmanageable initial shock was necessary in 11 patients (all presenting with ARDS as well) with five deaths. The overall mortality rate was 61 per cent, as nine of the remaining 18 patients died from septic complications. The statistical analysis of these data allows some conclusions: systemic manifestations occur early in about half of patients with ANP, and are associated with a poor prognosis which is even worse when a triple or double association occurs; patients developing systemic manifestations are candidates for early surgical treatment even though mortality is high and the outcome is complicated in patients who develop systemic manifestations following ANP.

Surgical internal drainage in pancreatic pseudocyst

Gh. Funariu and V. Munteanu, *Fourth Surgical Clinic, Cluj–Napoca, Romania*

To evaluate the indications for and effectiveness of surgical cyst–enteric anastomoses, 70 patients with postnecrotic pancreatic pseudocyst were reviewed retrospectively. Elective internal drainage operations alone were carried out in 34 patients (49 per cent). Surgical procedures performed were pseudocystogastrostomy in six patients and pseudocystojejunostomy in 28 (Roux-en-Y limb in 27 and ω limb in one). The indications for elective surgery included persistent pseudocyst mass 4–6 weeks from the onset of pancreatitis, an uncomplicated course, mature pseudocyst wall detected by ultrasonography or computed tomography, ineffectiveness of other drainage procedures and minimal operative risk.

Postoperative complications requiring reoperation occurred in four patients (6 per cent) (intestinal obstruction in one case and suppuration of the residual cavity in one case). Pseudocyst recurrence was noted in two patients in whom the previous drainage procedure had failed because of stenosed anastomoses. They were cured by a second operation. There were no operative deaths.

It is concluded that pseudocyst–enteric anastomosis is the treatment of choice for persistent pancreatic pseudocyst with a mature wall. The appropriate surgical procedure is selected according to the site and anatomical relationships of the pseudocyst. The various procedures offer the same good results if the anastomotic diameter is more than 6 cm.

Allotransplantation of pancreatic embryonic tissue culture in treatment of complex diabetes

A.G. Grintsov and A.A. Alexejenko, *Donetsk Medical State Institute, Ukraine*

Patients of age 15 to 46 years with a labile course of a severe form of diabetes complicated by microangiopathy and polyneuropathy, and in two cases also by retinopathy, were examined. All patients had disturbances of the immune system, whether a decrease in the absolute number of T lymphocytes, an imbalance in their subpopulations, the relationship between T helpers and T suppressors, high levels of the circulating immune complexes (up to 180 optimal units l^{-1}), or high plasma toxicity as assessed by the paramesial test.

Organospecific floating cultures of pancreatic cells of human embryos aged 16–24 weeks were used for transplantation. Cultures were transplanted into a large epiploon to all patients according to presently used methods. Maximal functional efficiency of the transplantate was observed at 16–20 days after surgery. Control examinations were made at 3, 6, 9 and 12 months after transplantation, at which times it was observed that the disease had clearly stabilized. Moreover, the postoperative ultrasonographic investigation of the transplantate morphofunctional state developed has shown the transplantate to remain highly effective for more than 1 year.

Comparison of two techniques of duodenum-preserving resection of the head of the pancreas in treatment of chronic pancreatitis

J.R. Izbicki, C. Bloechle, W.T. Knoefel and C.E. Broelsch, *University Hospital Eppendorf, Hamburg, Germany*

This study compared two surgical techniques for treatment of chronic pancreatitis, both involving duodenum-preserving resection of the head of the pancreas. In a randomized controlled study, 12 patients underwent subtotal resection of the head of the pancreas as described by Beger[1] and 13 underwent resection of the head of the pancreas leaving a small remnant of pancreatic tissue combined with a longitudinal pancreatojejunostomy as described by Frey[2]. The time interval between onset of symptoms due to pancreatitis and surgery varied from 12 months to 12 years, with a mean of 4·6 years. Preoperative assessment of all patients included abdominal ultrasonography, computed tomography, digital subtraction angiography, blood chemistry, a pain score and quality-of-life index. Outcome measures were mortality, early and late morbidity, pain score, quality-of-life index and occupational rehabilitation.

The resected tissue showed a diameter of more than 5 cm in 76 per cent of patients. No postoperative mortality was observed in either group. Postoperative stenosis of the common bile duct in one of the patients in the 'Beger' group was the only complication that occurred, and was successfully treated using an endoscopically placed pigtail drain. When the Frey procedure was performed, the mean duration of operation was significantly shorter ('Beger' group 308 min *versus* 'Frey' group 194 min) and mean blood loss tended to be less ('Beger' group 1500 ml *versus* 'Frey' group 900 ml). In a mean follow-up of 12 months currently all patients reported substantial relief of the vast majority of symptoms. Evaluation of the quality-of-life index showed an overwhelming increase in patient contentment in both groups, in this aspect no significant differences were observed.

Both duodenum-preserving techniques of resection of the head of the pancreas resulted in alleviation of symptoms, including relief of pain, and caused a substantial increase in quality of life. In long-term follow-up, recurrence of symptoms and pain, alteration of glucose metabolism, as well as occupational rehabilitation will be assessed to determine the late results.

Characterization of the procoagulant activity of human pancreatic carcinoma cell lines

A.K. Kakkar, M.F. Scully, S. Tebbutt, M. Sugimura, V.V. Kakkar and R.C.N. Williamson, *Department of Surgery, Royal Postgraduate Medical School and Thrombosis Research Institute, London, UK*

Carcinoma of the pancreas has long been known to be associated with a high incidence of thrombotic complications. Perhaps this ability of cancer cells to generate a procoagulant activity not only predisposes to thrombosis but plays an important role in tumour invasion and metastasis, as antithrombotic therapy at the time of implantation of certain experimental tumours reduces metastatic potential. The procoagulant activity of eight human pancreatic carcinoma (HPC) cell lines was studied 48 h after passage but before cells reached confluence. Tissue factor (TF) was measured in whole plasma by an amidolytic assay and recorded as thromboplastin units (TU) from a standard curve prepared using rabbit thromboplastin. Phosphatidylserine, considered to be responsible in part for monocyte adhesion and platelet activation by tumorigenic cells, was measured by prothrombinase activity (PA).

Cell line	TF dependent (TU per 10^4 cells)	TF independent (TU per 10^4 cells)	PA (pmol thrombin per min per 10^4 cells)
CaPanc 2	6560	100	22·9
Panc 1	60	10	23·6
BxPC 3	3450	50	14·4
MiaPanc	110	10	36·0
PT 45	2450	20	13·8
818·1	1400	0	17·2
818·4	14	0	14·7
818·7	4000	0	10·5

This study demonstrates for the first time that (1) the procoagulant activity of HPC is primarily dependent on expression of TF, (2) HPC cells vary considerably in the level of TF activity, and (3) PA is constant and independent of TF expression. These findings may explain the wide variation in thrombotic complications seen in patients with pancreatic carcinoma.

Mucinous cystadenoma and cystadenocarcinoma of the pancreas: a clinicopathological study

H. Levard, L. de Calan and H.C. Hennet, *French Association for Surgical Research, Colombes, France*

Mucinous cystadenoma of the pancreas is a rare cystic neoplasm that can change into pancreatic cystadenocarcinoma. This retrospective multicentre study (reviewing data from January 1978 to December 1987) reports the clinicopathological features and results of treatment of 27 patients with mucinous cystadenoma and 19 patients with cystadenocarcinoma.

There were 27 women with mucinous cystadenomas. The median age was 45 (range 23–72) years. Two patients each had two tumours. Twenty-five patients had a single tumour of mean size 9 cm, located in the head of the pancreas (three patients), body (four) or tail (18). One patient had a biopsy of the tumour only and one underwent cystojejunostomy. The tumour was completely excised in 25 patients; there were 22 distal pancreatectomies, one Whipple's procedure and two tumorectomies. There was no postoperative death, but two patients died from unrelated causes. The remaining 25 were alive and well at follow-up (median 20 months).

There were ten men and nine women with cystadenocarcinomas. The median age was 62 (range 49–82) years. The entire pancreas was involved in two patients, 17 patients had a single tumour located in the head (ten patients), body (six) or tail (one). Seven patients underwent curative resection and four palliative resection, eight patients had no resection and were treated by internal drainage and/or palliative bypass. There were two postoperative deaths. Twelve patients died from their tumour with a median survival of 10 months. Five patients were alive at 2, 3, 7, 26 and 62 months, two of whom had a recurrence.

The results strongly suggest that any mucinous cystadenoma of the pancreas, being a potentially malignant tumour, should be excised completely whenever possible. Moreover, pancreatic cystadenocarcinoma has a very poor prognosis which is similar to that of adenocarcinoma of the exocrine pancreas.

Microcystic adenoma of the pancreas (glycogen-rich cystadenoma): a clinicopathological study

H. Levard, L. de Calan and H. Hennet, *French Association for Surgical Research, Colombes, France*

Microcystic adenoma of the pancreas is a rare cystic neoplasm that is benign. This retrospective multicentre study (reviewing data from January 1978 to December 1987) reports the clinicopathological features and results of treatment of 20 patients with microcystic adenoma of the pancreas.

There were four men and 16 women of median age 62 (range 31–82) years. The tumour was found incidentally in ten patients (during an operation for other disease in three and during abdominal investigation for other disease in seven) Ten patients had a palpable abdominal mass with or without abdominal pain One patient had two tumours; 19 patients had a single tumour of mean diameter 7 cm, which was located in the head of the pancreas (six patients), body (five) or tail (eight). Two patients underwent a tumour biopsy only The tumour was completely excised in 18 patients, a Whipple procedure was performed in four and distal pancreatectomy in 12 There were two postoperative deaths, of patients operated on for carcinoma of the colon or rectum. One patient was lost to follow-up. The remaining 17 were alive and well, without evidence of recurrence at follow-up (median 16 months)

The present results confirm that microcystic adenoma of the pancreas is benign and can be managed conservatively For tumours in the body or tail of the pancreas distal resection can be carried out However, surgical removal of tumours in the head of the pancreas may not be necessary if a diagnosis can be made by biopsy and examination of frozen sections, especially in elderly patients If there is gastrointestinal or biliary obstruction, bypass can be performed.

Surgery of acute alcoholic and biliary pancreatitis

J. Männiste and J Tälli, *Tallinn Kivimae Hospital, Tallinn, Estonia*

For necrotic alcoholic pancreatitis (group 1), surgery was carried out 10 days to 2 months from the onset of symptoms Treatment aimed to eliminate the various complications and included necrosectomy and treatment of pseudocysts. Of 123 patients, 48 required reoperation; 24 of these died

For acute biliary pancreatitis (group 2), in addition to procedures on the biliary tree, surgical intervention on the pancreas was used in 47 patients, of whom seven died

In group 1, treatment was successful in 85 per cent of cases, with a late mortality rate for necrotic pancreatitis of 18 per cent. In group 2 the mortality rate was 5 per cent. Life quality after 3 years was satisfactory in 91 patients (49 per cent) in group 1 and 189 (91 per cent) in group 2

Selective indications for total parenteral nutrition in patients with acute pancreatitis

Th. Montariol, Ph. Marre, J.C. Seguier, P. Philippe and H. Ramirez, *General Hospital, Saint-Germain-En-Laye, France*

Between 1988 and 1992, 44 consecutive patients with acute pancreatitis received nutritional support consisting of total parenteral nutrition (TPN) within 48 h of admission Of these, 24 patients had one or two Ranson's criteria and 20 had three or more. Sixteen patients required operation and two died TPN duration was 3–52 days and 22 patients developed sepsis· 12 had intraperitoneal abscesses and ten had catheter-related sepsis with positive blood culture for *Staphylococcus epidermidis* In patients with sepsis, the mean number of Ranson's criteria was 3 4 and the mean duration of TPN 23 7 days. In non-septic patients these values were 2·0 and 12·5 days respectively In patients with one or two Ranson's criteria the mean duration of TPN was 11·8 days, the overall rate of septic events was 42 per cent (ten of 24) and the rate of catheter-related sepsis was 20 per cent (two of ten). In patients with three or more Ranson's criteria, mean duration of TPN was 24·3 days, overall sepsis was seen in 60 per cent (12 of 20), and catheter-related sepsis in 25 per cent (three of 12).

It appears that septic events are directly related to the number of Ranson's criteria and to the duration of TPN If TPN is necessary in severe acute pancreatitis, there is no evidence that it is useful in mild pancreatitis, because of the risk of catheter-related sepsis.

Serious factors in necrotizing pancreatitis

S. Neagu, F. Costandache and A. Priscu, *University Hospital, Bucharest, Romania*

Of 235 cases of necrotizing pancreatitis treated, there were 70 deaths (29 8 per cent) Analysis of the whole sample group enabled identification of significant factors that should be considered in establishing prognosis and appropriate therapeutic measures. These factors are as follows First, aetiology; necrotizing pancreatitis of alcoholic origin and that developed postoperatively and post-traumatically have a higher rate of mortality than that of biliary origin Second, being male, extremes of age and the presence of chronic disease (e.g. diabetes mellitus, pulmonary, liver or renal disease) show a higher mortality. Third, local and regional extension; the highest mortality rate is found in patients who develop extensive or total necrosis of the gland, peripancreatic necrosis, retroperitoneal extension and haemorrhagic ascites Fourth, sepsis; in cases of generalized sepsis within the peritoneum, necrotizing pancreatitis was associated with a higher mortality rate than in patients with an aseptic course Sepsis is implicated in the pathogenesis of multiple organ failure. Finally, clinical factors: refractory shock with early renal failure, neurological phenomena from extreme agitation to coma, and diffuse gastrointestinal haemorrhage are poor prognostic features.

Comparison between transplantation of pancreatic islet cells into liver subcapsularly and via the gastroduodenal vein in diabetic rats

K. Ozkan, Z. Malazgirt, E. Ersözlü, N. Ozen and B. Kandemir, *Ondokuz Mayis Universitesi, Tip Fakültesi Samsun, Turkey*

A total of 50 isogenic albino rats were use in this experimental study. Groups A, B and C each consisted of ten rats, group D, which consisted of 20 rats, underwent operation and total pancreatectomy was performed to obtain islet cells Groups A, B and C were rendered hyperglycaemic with streptozotocin (275 mg kg^{-1}), and islet cells were passed intraperitoneally into the liver via the gastroduodenal vein in group A rats, subcapsularly in group B rats, while group C was studied as the control group. The high blood sugar levels of the diabetic rats in group A started to decrease by the seventh day and after the tenth day they stayed at normoglycaemic levels ($P<0{\cdot}01$). In group B rats, islet cells were passed into the liver subcapsularly but blood sugar levels of this group of diabetic rats remained high throughout the study ($P < 0{\cdot}01$). Histological examination showed that viable islet cells were present in liver when islet cells were given via the gastroduodenal vein. When islet cells were injected under the liver capsule, in spite of detection of viable islet cells in liver on the first day by histological examination, significant lymphocyte infiltration under the liver capsule, and necrosis and abscess formation without any viable islet cells were noted on the 21st day.

In conclusion, isolated islet cells given via the gastroduodenal vein remain viable in liver and function well, regulating blood sugar levels effectively In contrast, no viable islet cells were demonstrated when the same islet cells were injected into liver subcapsularly, as blood sugar levels remained high in this group of rats

Endocrine tumours of the head of the pancreas and periampullary area

C. Pasquali, C. Sperti, M. Guido*, A. Alfano D'Andrea,
C. Filipponi and S. Pedrazzoli, *Semeiotica Chirurgica, University of Padua and *Department of Pathology, Cittadella, Italy*

Endocrine tumours of the periampullary area and the head of the pancreas may require an extended surgical procedure for cure. Since 1968, 37 patients have been observed with proven pancreatic endocrine tumours (PET). 19 insulinomas, nine Zollinger–Ellison syndrome (ZES) and nine non-functioning tumours.

Of the 19 insulinomas, 18 were typical single adenomas of the head of the pancreas and ranged in size from 1·0 to 4·0 cm. Fourteen were treated by local excision, two by pancreatoduodenectomy (PD) and two by subtotal resection of the head of the pancreas; all patients were cured. One patient had a multiple endocrine neoplasia syndrome (MEN I) and four adenomas were excised from the head of the pancreas, this patient is still normoglycaemic 8 years later.

Five of the nine patients with ZES had multiple tumours (two had MEN I) and three patients had microadenoma (< 0·5 cm). Five patients were treated by PD and four had excision of duodenal adenomas. In two cases ZES was not cured by surgery with one recurring 14 years after surgery. Five patients had normal gastrinaemia 5–16 years after operation. Six of eight patients with non-functioning tumours underwent resection: two PD, one partial pancreatic head and body resection, two local excisions and one partial duodenal resection. One died after 6 months from tumour progression, and four remain disease-free 1–11 years after operation. One of three patients with liver metastases was still alive 5 years after diagnosis.

While preservation of disease-free pancreas is generally the rule with insulinomas (extended procedures being reserved for technical problems) in the present series four of 19 patients had resection of the pancreatic head. Since long-term survival in non-beta PET is frequent, these tumours require an aggressive surgical approach even if advanced, as cure or long-term palliation can frequently be achieved.

Predictive factors in acute pancreatitis

V Păunescu, St Răgălie and M Tudor, *Carol Davila University of Medicine, Bucharest, Romania*

An attempt is made to identify the predictive factors of morbidity and mortality in acute pancreatitis. Data from patients with severe ($n = 75$) and mild ($n = 46$) pancreatitis were handled separately. The initial functional signs of predictive value ($P < 0{\cdot}01$) were predominantly epigastric pain, vomiting, fever, signs of peritoneal irritation, obstruction, jaundice, respiratory distress and encephalopathy. Initial leucocytosis, but principally its persistence, suggests the serious nature of the disease ($P < 0{\cdot}001$), as does the presence of hyperbilirubinaemia ($P < 0{\cdot}05$). Serum amylase levels can increase during the evolution of acute pancreatitis, but do not predict the prognosis. Among the associated lesions that suggested a poor prognosis were biliary lithiasis ($P < 0{\cdot}05$), pancreatic necrosis ($P < 0{\cdot}01$) and the appearance of a peritoneal inflammatory exudate ($P < 0{\cdot}001$).

Surgical treatment was addressed mainly to the pancreas and the biliary system, there was no significant statistical difference between the procedures. Reoperation was an unfavourable prognostic factor ($P < 0{\cdot}001$). There were 51 (42 per cent) deaths overall, 42 of which were among the 75 patients with severe pancreatitis. The highest frequency of death is during the first 4 days (56 per cent) due to shock (100 per cent), peritonitis (67 per cent), and intraperitoneal extension of cystonecrosis (31 per cent). Death in the second phase of acute pancreatitis was due to sepsis (77 per cent). Age over 55 years, hyperbilirubinaemia, peritonitis, leucocytosis, aetiology and shock were found to have a positive predictive value of death $>0{\cdot}5$.

This study, carried out in 121 patients operated on for acute pancreatitis, showed that morbidity and mortality rates depend on the severity of the disease and its complications.

Major haemorrhage from the pancreatic duct complicating chronic pancreatitis

S. Pedrazzoli, P. Petrin, C. Sperti, C. Pasquali, C. Longhini,
D. Zaramella and C Da Lio, *University of Padua, Padova, Italy*

Acute haemorrhage is the most rapidly lethal complication of chronic pancreatitis (CP). If the pancreatic duct communicates with a pseudo-aneurysm, a haemorrhage into Wirsung's duct (HW) may occur. Diagnostic procedures, therapy and long-term results are still the subject of controversy.

Eleven cases of HW observed among 220 patients with CP are reported. Hospital mortality rate was zero, five patients died between 4 months and 8 years after treatment. In one case, total pancreatectomy was performed because of a histological diagnosis of diffuse pancreatic cancer after suture ligation and pancreatojejunostomy. Arterial embolization was attempted four times and was successful on three occassions. Three patients died from haemorrhage 2–8 years after successful treatment.

In conclusion, it is believed that embolization is the treatment of choice for HW, long-term results being satisfactory in three of four patients treated by this method. Subsequent gastrointestinal haemorrhage developed in one embolized and two surgically treated patients; only in one case was it documented as pancreatic. Emergency surgery can be performed with low risk for the patient if the correct diagnosis is timely or suspected. Left pancreatectomy or right pseudocystojejunostomy with wide drainage of the pancreas are preferred. External drainage provides inadequate drainage and usually requires further surgery.

Pancreatoduodenectomy and local excision in the operative treatment of ampullary carcinoma

J. Poulantzas, R Nafas, S. Stylogiannis, S. Prigouris and M Lorentziadis, *'Evangelismos' Hospital, Fourth Department of Surgery, Athens, Greece*

Carcinoma of the ampulla of Vater is a relatively rare tumour but represents 10–36 per cent of all surgically operable pancreatoduodenal tumours. Despite the fact that pancreatoduodenectomy (PD) continues to be considered as the operation of choice for resectable ampullary carcinoma, recent experience indicates that local excision (LE) of the tumour may be an acceptable alternative in selected cases. Reported are 23 patients with ampullary carcinoma who were treated by PD (pylorus-preserving in seven, standard in four), and LE of the tumour (12) during the past 14 years. The diagnosis of vaterian tumour was made by hypotonic duodenography (four), endoscopy with or without biopsy (11) or at operation (eight). Macroscopically the tumour was polypoid in 17 patients and ulcerating in the remaining six. None of the patients died in hospital. One died 9 days after discharge from cerebral haemorrhage. In the group of patients subjected to PD, five major complications were observed (pancreatic fistula, four; biliary fistula, one) compared with two (biliary fistula, one; rupture of duodenotomy, one) in the group with LE of the tumour. The 3- and 5-year survival rates were 57 and 40 per cent following PD compared with 50 and 50 per cent after LE.

Despite the limited size of the present series and the shortcomings of a retrospective review, it appears that LE of the tumour in selected cases of ampullary carcinoma of the polypoid type may offer results comparable to those of PD.

Recurrent pancreatitis in 160 patients

M.A. Secchi, E. Tagliaferri and G. Raimundo, *Surgical Division, Italian and Provincial Hospital, Rosario, Argentina*

Recurrence of acute pancreatitis ranges from 10 to 20 per cent in patients treated specifically, and from 20 to 40 per cent in those not treated. A total of 160 consecutive patients presenting with acute pancreatitis were studied and treated prospectively between April 1987 and January 1993. Of these patients, 110 had gallstones, 15 had had one or more attacks before undergoing treatment and one had had recurrence after treatment. Patients were divided into three groups according to the severity of the prognostic index, 0·0–0·2 being mild, 0·21–0·4 moderate and >0·41 serious.

In this series 34 recurrences were recorded in 16 patients (10 per cent) (more than two attacks per patient), 24 in patients with biliary lithiasis, eight in patients with idiopathic pancreatitis and three in patients with hyperlipidaemia. While 144 patients had only one attack of acute pancreatitis, 46 (29 per cent) had had a similar attack to the present one, but acute pancreatitis had not been proven. The first attacks ranged from mild to moderate (mean(s.e.m.) 0·20(0·05)) but there were three serious cases from the second to the third attack (0·27(0·06)) ($P < 0{\cdot}05$).

In our experience, biliary lithiasis is the most frequent cause both of acute pancreatitis (69 per cent) and of recurrence (71 per cent). Since the second and third attacks are more serious ($P < 0{\cdot}05$), no patient with acute pancreatitis and biliary lithiasis should be denied an operation and every case of acute pancreatitis should be considered to be caused by gallstones until proved otherwise.

Influence of DNA ploidy, pathological factors and serum CA19-9 on the prognosis of resected pancreatic carcinoma

C. Sperti, C. Pasquali, A. Piccoli*, A. Perasole† and S. Pedrazzoli, *Semeiotica Chirurgica, *Medicina Interna, University of Padua and †Department of Pathology, Montebelluna, Italy*

It has recently been suggested that DNA content may provide significant prognostic information about pancreatic cancer. Serial CA19-9 assays have been studied and also found to be related to prognosis after excisional surgery. Twenty-six consecutive specimens of resected pancreatic carcinoma have been analysed to assess the rate of aneuploidy and the relationship between survival, DNA pattern and histopathological features. All patients had serial CA19-9 assay before and after surgery.

Sections (50 µm) of primary tumours were prepared and analysed by fluorescence-activated cytometry. All patients had a ductal adenocarcinoma, 21 pancreatoduodenectomies and five left pancreatectomies were performed, 15 being radical operations and 11 with microscopic residual tumour. Twelve patients had a well differentiated tumour and 14 a moderately or poorly differentiated tumour. Ten patients were in stage I, four in stage II and 12 in stage III according to Union Internacional Contra la Cancrum staging. Twelve of 25 patients had lymph node metastases. In eight cases the primary tumour was aneuploid. Excluding three patients with preoperative low CA19-9 levels, ten of 23 had a fall of CA19-9 levels to normal range after surgery.

No relationship was found between size, stage, lymph node status or tumour grading and DNA ploidy. A postoperative fall of CA19-9 was significantly related to survival (P = 0·001), only one of ten patients with a low postoperative CA19-9 survived less than 12 months and only two of 13 with high CA19-9 survived more than 12 months. No relationship was found between ploidy and postoperative fall of CA19-9. Lymph-node status (P = 0·02) and stage (I *versus* II–III, P = 0·04) were found to correlate with survival.

Despite preliminary findings suggesting that DNA ploidy may have prognostic value in pancreatic cancer, a relationship between ploidy of the primary tumour and survival after surgical resection has not been confirmed. DNA ploidy is unrelated to the metastatic potential of the tumour, CA19-9, lymph node status and stage are the main factors influencing prognosis.

Radical resection for ampullary carcinoma: long-term results

C. Sperti, C. Pasquali, A. Piccoli, C. Sernagiotto and S. Pedrazzoli, *Semeiotica Chirurgica, Medicina Interna, University of Padua and Surgery C H. Montebelluna, Italy*

Cancers arising from the region of the ampulla of Vater have a better prognosis than tumours originating from the periampullary area. Several factors are known to affect survival after radical resection for ampullary carcinoma, but conflicting results have been reported. Experience with ampullary carcinoma is reviewed to identify pathological factors influencing survival after resection.

From 1970 to 1990, 30 patients underwent potentially curative resection for adenocarcinoma of the ampulla of Vater (25 pancreatoduodenectomy, one total pancreatectomy, four local excision). According to the Union Internacional Contra la Cancrum staging system 19 patients were stage I or II and 11 stage III–IV. Tumor size ranged from 1·1 to 5·2 cm, seven patients had lymph node metastases, nine pancreatic invasion. The tumour was well differentiated in 19 cases and moderately or poorly differentiated in 11. One patient died in the perioperative period (3 per cent). Overall 5-year actuarial survival rate was 37 per cent, 45 per cent in the absence of lymph node involvement *versus* 0 per cent with nodal metastases (P=0·03). Estimated 5-year survival rate was 51 per cent for well differentiated tumours (P = 0·001) *versus* 0 per cent for moderately or poorly differentiated tumours. Survival was significantly better (P = 0·0002) in patients with tumour of stages I or II than in those with disease of stage III–IV. Tumour size, pancreas invasion and jaundice did not correlate with survival. After local excision, two patients developed local recurrence after 6 months and 3 years. Among the 15 patients without nodal metastases and treated by pancreatoduodenectomy, local and hepatic recurrence were found after 3, 3, 4, 5, and 9 years respectively.

In conclusion, long-term survival may be obtained by radical resection in patients with ampullary carcinoma, but the risk of late tumour recurrence requires long and careful follow-up. Lymph node involvement, tumour differentiation and stage are the most important factors influencing long-term survival.

Adenocarcinoma of the head of the pancreas: importance of selection for curative resection

H. Tevaearai and J.-F. Cuttat, *University Hospital, Lausanne, Switzerland*

Adenocarcinoma of the head of the pancreas still has a very poor prognosis since adjuvant therapy has not proved efficacious and surgical resection remains the only chance of cure. Despite progress in surgical technique and perioperative management, the mortality and morbidity rates associated with pancreatoduodenectomy (Whipple's procedure) are significant. Criteria for curative resection must therefore be clearly defined to select patients who could benefit from pancreatoduodenectomy.

Between 1 January 1981 and 31 December 1990, 80 patients were operated on for histologically proven adenocarcinoma of the head of the pancreas, periampullary and endocrine tumours were not considered. Twenty patients underwent pancreatoduodenectomy, 14 procedures could be considered macroscopically curative (wide *en bloc* resection with local lymph node dissection and no distant metastases). Histological examination confirmed that resection was curative in eight patients (margins were free of tumour and there was no vascular or lymphatic vessel invasion). The survival rate of patients in this latter group (group 1) was compared with that of those who underwent palliative pancreatoduodenectomy (group 2) or a primarily palliative procedure (biliary diversion and/or gastroenteroanastomosis) (group 3).

The median survival time of patients in group 1 was significantly higher (14·6 months) than of those in groups 2 (6·7 months) or 3 (7·1 months). Moreover, the 1-year survival rate for patients in group 1 was 50 per cent compared with 17 per cent in group 2 and 16 per cent in group 3. In group 1, 38 per cent of patients survived for > 24 months compared with none in group 2 and 7 per cent in group 3. The mortality rate was significantly higher in patients who underwent pancreatoduodenectomy (25 per cent) compared with those who underwent palliative diversion (8 per cent).

It is concluded that pancreatoduodenectomy is the only surgical procedure with curative potential, although significant mortality and morbidity rates limit its value. Staging of adenocarcinoma of the head of the pancreas should be more precise to select patients who will benefit from pancreatoduodenectomy and to avoid palliative resection. Preoperative laparoscopic examination with biopsies and peritoneal cytology, and routine peroperative ultrasonography should be evaluated as a means of achieving better staging.

Place for gastroenterostomy in patients with advanced cancer of the head of the pancreas

G.P. van der Schelling, R.P. van den Bosch, J.H.G. Klinkenbijl, P.G.H. Mulder and J. Jeekel, *Department of Surgery and Institute of Biostatistics and Epidemiology, Erasmus University Hospital, Rotterdam, The Netherlands*

There remains doubt about the need for gastroenterostomy in patients with advanced cancer of the pancreatic head, performed either prophylactically or when passage of food becomes impossible. The records of 142 patients admitted to the Erasmus University Hospital over a period of 11 years for advanced pancreatic cancer were reviewed. Preoperative and postoperative intake of food in cases involving gastroenterostomy and the morbidity and mortality rates associated with abdominal surgery in these patients were considered. Of 129 patients without symptoms of gastric outlet obstruction at the time of diagnosis, 31 underwent prophylactic gastroenterostomy. The procedure did not prevent gastric outlet obstruction in four patients. Of the remaining 98 patients, 15 developed gastric outlet obstruction. Cox proportional hazards analysis showed no significant difference in the interval to the occurrence of a symptomatic obstruction between these two groups, taking into account other covariables. Postoperative complications and mortality rates after gastroenterostomy were high, ranging from 9 to 41 per cent and 11 to 33 per cent respectively. These results do not indicate that prophylactic gastroenterostomy significantly prevents future gastric outlet obstruction; therefore, as it also increases morbidity rates, it should not be performed. Gastroenterostomy to relieve symptoms should be considered carefully, as the success rate is low and the procedure is accompanied by considerable morbidity and mortality rates.

Peptic ulcer

Restoration of nightly spontaneous alkalinization in duodenal ulcer using ranitidine

M. Cagossi and A. Bianco, *Department of Internal Medicine, Catholic University, Rome, Italy*

The effect of a 2-week administration of ranitidine (150 mg twice daily) on 24-h pH profiles in eight patients with duodenal ulcer is described Healthy volunteers demonstrated spontaneous nightly alkalinization.

Patients with duodenal ulcer before treatment had a mean(s.d.) nightly period at pH > 4 of only 68·5(65·7) s This value increased to 114·07(39·43) min after treatment The mean(s e m.) proportion of the night with pH > 4 before and after treatment was 0·5(0·3) per cent and 27·6(10·0) per cent respectively, with a significant increase ($P = 0·05$) Ranitidine was able to induce ulcer healing even when used for only 2 weeks. Complete healing of the ulcer was seen in patients whose overall acidity time was reduced to almost 40 per cent of the value before treatment

Intravenous omeprazole *versus* ranitidine in bleeding duodenal ulcer: a prospective randomized trial

M. Cardi, I.A. Muttillo, V. Petrozza*, L. Amadori, A. Stasio, R. Maira and A. Bolognese, *Istituto di Clinica Chirurgica and *Università di Roma, Rome, Italy*

Omeprazole is a potent inhibitor of H^+–K^+-ATPase activity, and provides a more effective treatment for acid-related diseases of the upper gastrointestinal tract than H_2 blockers. However, there are few reports of its use in emergencies This study reports the results of a prospective randomized trial of intravenous omeprazole *versus* intravenous ranitidine in bleeding duodenal ulcer

All patients were admitted as emergencies for upper gastrointestinal tract bleeding; diagnosis of bleeding duodenal ulcer was confirmed endoscopically in all cases After diagnosis, 21 patients (group 1) were randomly assigned to receive omeprazole (40 mg, bolus) followed by 80 mg day^{-1} as continuous infusion for the next 48 h. Twenty-four patients (group 2) received ranitidine (400 mg day^{-1}) as continuous infusion

Bleeding was stopped in 20 patients in group 1 (95 per cent) and in 17 in group 2 (71 per cent) ($P < 0·01$) Of seven patients in whom ranitidine treatment failed, subsequent omeprazole therapy stopped bleeding in five Operation was necessary in one patient in group 1 and in two in group 2 Control endoscopy performed at 15 and 30 days after bleeding showed complete healing of the ulcer in all patients given omeprazole and in 14 (82 per cent) of those given ranitidine Serum gastrin levels were not significantly increased after treatment. It is concluded that omeprazole seems to be effective in the control of bleeding duodenal ulcer.

Thoracoscopic truncal vagotomy

G. Champault, N. Rizk, J. Lauroy and P. Boutelier, *Department of Surgery, Hôpital J. Verdier, Bondy, France*

A total of 15 men and seven women (mean age 40·2 (range 26–79) years) diagnosed with duodenal ulcer were treated by truncal vagotomy (TV) via left thoracoscopy over a period of 18 months Except for a woman of 43 years who was hospitalized 10 days earlier for a perforated ulcer that was treated by laparoscopic suturing, the diagnosis was made endoscopically Some 18 ulcers were located in the bulb and four in the first part of the duodenum, with 12 of these lesions penetrating deep posteriorly. The mean duration of the ulcer disease was 7·2 (range 3–13) years Four patients had a history of perforation. Of 13 patients who had experienced haemorrhage, eight had had a recent massive bleed.

TV was performed by left thoracoscopy through four cannulas (Half the patients had selective tracheal intubation and one-third required pleural drainage.) The mean operating time was 46·5 (range 30–115) min. Feeding was started on average 1·6 (range 1–3) days after operation. The mean hospital stay was 4·6 (range 2–9) days but only 3·6 days for the last ten patients. There was no mortality or morbidity. Return to work was achieved around day 15 (range 4–34) after surgery. All patients were seen between 30 and 45 days after operation. Some 20 patients had Visick 1 and two Visick 2 (slowing of gastric evacuation ameliorated by dietary modifications). No diarrhoea was noted Follow-up endoscopy confirmed healing of the duodenal ulcer in all cases. An upper gastrointestinal series showed good gastric emptying in 20 of 22 patients and slight stasis in two asymptomatic patients The mean follow-up was 6·8 (range 1–12) months. TV is a simple, fast and efficient procedure with minimal side-effects. The technique offers a credible alternative to initial medical management in terms of efficiency and cost.

Bleeding duodenal peptic ulcer: injection *versus* operation

M Dobosz, A. Babicki, R. Marczewski, P. Juszkiewicz and Z. Wajda, *Department of Surgery II, Medical Academy of Gdańsk, Poland*

Duodenal peptic ulcer was recognized as the cause of bleeding in 98 patients presenting with signs of upper gastrointestinal bleeding and who underwent emergency endoscopy In 95 per cent of the patients bleeding was stopped by injection of thrombin, while five (5 per cent) required surgery due to failure of the injection procedure Of 93 patients previously injected, 16 (17 per cent) rebled The highest rebleeding rate was in the Forrest IA group (40 per cent), rates were lower in Forrest IIA (12 per cent) and Forrest IB (7 per cent) patients Of the rebleeding cases, 11 were successfully reinjected, while five underwent emergency surgery In general, injection sclerotherapy was sufficient in 81 per cent, but was successful in only 69 per cent of patients with visible vessel/Forrest IA and IIA bleeding. Spurting bleeding was confirmed in ten bleeding patients who required emergency surgery Nine patients in whom injection was successful underwent elective operation without active bleeding, the indication for surgery being localization of the ulcer and the calibre of visible vessel in the ulcer base

The mortality rate of all bleeding patients was 4 per cent. No patient died following endoscopic treatment alone Among patients undergoing elective surgery one died (10 per cent), while three of ten undergoing emergency surgery died.

It is concluded that injection sclerotherapy is a valuable method to arrest bleeding from duodenal ulcers. Patients with large visible vessels of the posterior duodenal bulb wall should be considered as candidates for elective surgery after successful primary injection

Perforated peptic ulcer

G. Errazti, L. Pérdigo, J. Pereira, A. Valdivieso, E. Tobalina, S. Mateo and S Sarabia, *Hospital Galdakao, Bilbao, Spain*

A total of 109 patients, 82 men and 27 women, were surgically treated for perforated peptic ulcer between 1987 and 1991. The mean age was 47 (range 18–89) years The mean interval between the first symptoms and surgery was 18 h (range 3 h to 7 days). According to their previous history, patients were divided into acute (56) and chronic (53) perforations. Twenty cases were related to non-steroidal anti-inflammatory drug use.

Some 45 patients underwent a simple closure technique plus treatment with H_2 inhibitors. In the other 64 patients, truncal vagotomy with a drainage procedure was performed

The overall mortality rate was 3·6 per cent (four patients) All four patients were elderly with high-risk factors (American Society of Anesthesiologists grade IV) and long-standing perforations (more than 72 h). Although morbidity rates were similar in both surgical groups (10 per cent), there were four cases of postoperative bleeding in the simple closure group and three of postoperative gastric retention. One of the latter required reoperation.

A mean follow-up of 42 (range 15–72) months was performed in 78 patients, 27 simple closures and 51 vagotomies. According to the Visick scale, five simple closures (19 per cent) and nine vagotomies (18 per cent) were included in grades 3–5, with no statistically significant difference even when divided into acute and chronic perforations

Mortality is confined to high-risk patients The morbidity and recurrence rate were similar in both groups Either surgical technique is suitable for perforated peptic ulcer, as long as simple closure is followed by H_2 inhibitor treatment

0007–1323/93/S082–02 © 1993 Butterworth-Heinemann Ltd

Combined endoscopic and surgical management in the therapy of acute and severe gastroduodenal haemorrhage

G.W. Lexer, W. Pimpl, M. Heinerman, H.W. Waclawiczek and O Boeckl, *Surgical Department and Ludwig Boltzmann Institute for Gastroenterological Surgery, Salzburg, Austria*

A benefit of emergency endoscopy is that active gastroduodenal bleeding can be treated by sclerotherapy This decreases the rate of emergency surgery with its related high mortality rate The aim of this study was to evaluate whether early elective surgery can decrease the number of patients undergoing emergency surgery.

From 1983 to October 1992, 535 patients were admitted with signs of acute gastroduodenal haemorrhage Each underwent immediate emergency gastroduodenoscopy to identify the site and extent of bleeding

The patients comprised two treatment protocols· I, 1983–1985, 116 patients, II, 1986–1992, 419 patients. In both protocols haemostasis of actively bleeding sources was by injection of adrenaline alone or with polidocanol (1 per cent). Vital signs, age, concomitant disease, blood count, transfusion of blood (units per 24 h), site and activity of bleeding (Forrest classification) were documented. In protocol I, patients were treated either with emergency or elective surgery, or conservatively. In protocol II, patients were categorized after successful haemostasis as high or low risk for recurrent bleeding after endoscopy High-risk patients underwent early elective surgery within 12 h of emergency endoscopy High-risk parameters were defined as: chronic or acute ulcer with active Forrest IA, Forrest IB or Forrest II bleeding with visible vessel on the posterior wall of the duodenum or lesser curvature of the stomach within the blood supply of the gastroduodenal and left gastric artery. In protocol I, 32 patients (28 per cent) were classified as high risk and 84 (72 per cent) as low risk for recurrent haemorrhage In protocol II, 122 patients (29 per cent) were high risk and 297 (71 per cent) low risk

Due to early elective surgery after emergency endoscopy, emergency surgery rates were reduced from 12 9 to 7·6 per cent, and the mortality rate from 53 to 38 per cent. The overall rate of surgery increased from 31 per cent in protocol I to 37 per cent in protocol II, whereas the overall mortality rate fell from 12·1 to 5 5 per cent Mean age and numbers of patients with Forrest IA and IB bleeding, in shock, with concomitant disease or who needed >5 units of blood after emergency endoscopy were similar in both groups.

In conclusion, management of acute gastroduodenal haemorrhage with combined endoscopic sclerotherapy and early introduction of elective surgery (by classifying high- and low-risk parameters during emergency endoscopy for recurrent bleeding) may significantly reduce the rates of emergency surgery, rebleeding and overall mortality

Results of a coordinated medicosurgical approach to peptic ulcer haemorrhage

X Mueller*, J.M. Rothenbuehler, A. Amery and F. Harder, *Departement Chirurgie, Kantonsspital, Basel, Switzerland and *Department of Surgery, Frimley Park Hospital National Trust, Surrey, UK*

Haemorrhage from a peptic ulcer is a medical as well as a surgical emergency A coordinated approach to the management of this condition has been established. Suitable candidates for surgery were selected at an early stage on the basis of haemodynamic and endoscopic criteria, a definitive operation was performed as soon as the haemodynamic situation was stable and within the first 48 h after admission The results in terms of rebleeding at > 48 h and mortality rate were analysed.

A total of 157 consecutive patients (mean age 67 (range 16–89) years) were admitted with a bleeding peptic ulcer over a 2-year period Thirty-one patients (20 per cent) underwent early operation Some 149 patients (95 per cent) were followed for a mean of 44 (range 35–58) months

	<30 days	≥30 days
Rebleeding	10 (6)	13 (9)
Death	11 (7)	54 (36)

Values in parentheses are percentages

Four patients who rebled at <30 days and two at ≥30 days were in the surgical group Six of the deaths at <30 days and two at ≥30 days were related to peptic ulcer disease. Only one death in the surgical group related to peptic ulcer

A mortality rate of 7 per cent at <30 days was achieved with a coordinated approach, with only two deaths (1·3 per cent) related to peptic ulcer at follow-up of 44 months However, a significant risk of rebleeding of 8·7 per cent persisted during this period.

Factors predisposing to further haemorrhage and mortality after bleeding from a peptic ulcer

X. Mueller*, J M. Rothenbuehler, A. Amery and F. Harder, *Departement Chirurgie, Kantonsspital, Basel, Switzerland and *Department of Surgery, Frimley Park Hospital National Trust, Surrey, UK*

The mortality rate of haemorrhage from peptic ulcers has remained unchanged This is mainly attributed to rebleeding in an increasingly elderly population with more coexisting systemic disease. The value of clinical factors and endoscopic findings in predicting rebleeding and death was analysed

Some 157 consecutive patients with a bleeding peptic ulcer were admitted over a 2-year period. Of these patients, 19 died and 37 had further bleeding. The predictive value of each factor was determined by the χ^2 test with Yates' correction.

Significant predictive factors of further bleeding were shock (15 of 25 patients), a transfusion requirement of 4 units during the first 48 h (19 of 46) and endoscopic signs of recent haemorrhage (29 of 79) The combination of these factors was of no better predictive value than shock alone The number of coexisting illnesses per patient was strongly related to the mortality rate ($P < 0\,001$). Other significant factors indicative of increased mortality included being on steroids (six of 16 patients), onset of bleeding during hospital stay (ten of 31), alcohol (eight of 32), further bleeding (nine of 37) and more than 4 units transfused over the first 48 h (seven of 46).

Shock remains the most valuable sign in predicting further bleeding and is superior to endoscopic stigmata. The close relation between mortality rate and coexisting illnesses underlines the fact that many deaths result from non-peptic ulcer disease

Plastic and reconstructive surgery

Transpositional finger replantation in children

P. Brenner, A. Berger and B. Reichert

Multidigit amputations, especially in children, still represent a challenging problem with regard to restoring optimal sensorimotor hand function Often either the orthotopic finger stump or the separated digits is unfit for conventional replantation This condition makes transpositional reattachment imperative.

Heterotopic finger replantations are a seldom performed procedure in current replantation centres. The incidence in this institution is approximately 1 per cent. The survival rate among children in this study was over 80 per cent, better than the conventional 'take' rate The favourable finger transfer in our closed series of eight children was the D2-stump, followed by a substitution of the middle finger and, finally, creation of an expanding opposite grip on the ulnar side of the hand. Secondary corrective procedures have been performed in one-third of patients. To evaluate global hand function, score systems according to Millesi or Tamai were applied Over 65 per cent presented a 'good' subjective and objective hand function according to Tamai.

Transoral approach to the cranial base

A. Crockard and D. James, *The National Hospital for Neurology and Neurosurgery, London, UK*

Access to midline lesions (such as tumours and congenital malformations) of the skull base, particularly those of the clivus and craniovertebral junction, may be obtained by a variety of techniques through the mouth. The authors' experience of over 280 cases has enabled them to formulate certain guidelines A direct midline approach is occasionally used for intradural tumours and mid-basilar aneurysms The advantage of this technique is that a pathological process will laterally displace the cranial nerve and the major vessels The disadvantage is the depth at which one is working and thus special bayonetted instrumentation of sufficient length is required, as well as illumination and magnification of the operating microscope

Abnormalities at the craniovertebral junction may be dealt with simply by upward retraction of the soft palate For lesions at the anterior foramen magnum, a midline split of the soft palate provides access The authors have developed the extended (open door) maxillotomy consisting of a Le Fort I maxillotomy combined with a midline soft and hard palatal split. This provides access to the skull base from the sphenoid and ethmoid sinuses down to the second or third cervical vertebral body. If the dura is penetrated, a wide bore lumbar drain is inserted for 5 days, to be converted into a lumboperitoneal shunt.

Cheek–temporal flap in reconstructive surgery of the head

C. D'Aniello, A Barbato, L. Grimaldi, A Guarnieri and C. Uhdris, *Istituto di Scienze Chirurgiche, Siena, Italy*

The cheek–temporal flap is useful for the reconstruction of skin deficit in the lateral and upper cephalic regions, and in particular in the fronto-temporal region. The limits are: superiorly, the upper temporal line; anteriorly, the temporal crest of the frontal bone and the lateral orbital margin, and posteriorly, a vertical line that passes immediately under the skin. The preparation of the flap does not create particular difficulties and its versatility allows large variation in size depending on the need Preparation takes place from above up to the zygomatic arch and can be extended to the cheek region to extend skin mobility The flap, which in the temporal region can be cutaneous or fasciocutaneous, can now be advanced or rotated depending on the case; the mobilization permits it to reach the frontolateral, parietal and occipital regions easily with satisfactory results regarding skin continuity and scarring, which remains nearly completely masked by hair The authors' experience regarding reconstruction after trauma or oncological excision is described, and the results are satisfactory both aesthetically and functionally.

Prosthetic reconstruction after chest wall resection for cancer

D. D'Ugo, P. Granone, G. Cardillo, P Perrotti, S. Margaritora, P. Bonatti and A. Picciocchi, *Catholic University Medical School of Rome, Rome, Italy*

A series of 20 consecutive chest wall resections with immediate prosthetic reconstruction has been performed in 19 patients over a 6-year period (1987–1992)

T_3 lung cancer (eight cases), local recurrence of breast cancer (seven cases) and primary tumours originating in the chest wall (five cases in four patients) were the indications for surgery Reconstruction was performed only for chest wall defects of more than three ribs not located in the scapular region Prosthetic materials were either Silastic sheeting (1·016-mm thickness) or GORE-TEX soft tissue patch (2-mm thickness)

There was no operative mortality. Postoperative complications were negligible and satisfactory respiratory function was preserved in all cases Complete control of preoperative pain was achieved in all patients. Six cancer deaths resulting from metastatic spread have been reported at follow-up, in one case a chest wall recurrence occurred at a site distant from the prosthetic implant

Reconstruction of external cervicofacial defects

Ch Ioannides, E. Fossion and W. Boeckx, *University Hospital St Rafäel, Leuven, Belgium*

Reconstruction of large cervicofacial defects requires a lot of tissue, which local flaps often cannot offer One solution is the use of distant pedicled or free revascularized composite flaps Between January 1982 and July 1992, 142 large head and neck defects were closed in 139 patients A pectoralis major osteomyocutaneous flap was used in 86 patients (17 women, 69 men) and a free latissimus dorsi flap in 53 (18 women, 35 men) Most of the defects resulted from cancer resections. The pectoralis major was used for the chin, neck and parotid area and the latissimus dorsi for the area of the midface and orbit, and for combined craniofacial defects. The failure rate of procedures using the pectoralis major was about 7 per cent and of those using the latissimus dorsi 2 per cent. There were no serious postoperative complications or long-term sequelae from either donor site The most important advantage of the pectoralis major was the shorter operation time and that of the latissimus dorsi the unlimited range of motion. The disadvantage of using the pectoralis major was a higher failure rate and that of the latissimus dorsi the necessity for microsurgery

Mandibular rotation and radial free flap for oropharyngeal tumours

A.M. Jortay, B. Coessens and P. Bisschop, *University Hospital Brugmann, Brussels, Belgium*

Buccopharyngectomy by segmental mandibular resection and myocutaneous pectoral flap reconstruction is associated with swallowing and chewing problems A new approach is proposed using mandibular rotation and radial free flap. During 1990–1991, seven patients underwent surgery for carcinoma of the tonsillar region (four), base of the tongue (two) and posterior wall extended to the pyriform sinus (one), in the range T_2–T_3, N_0–N_1 by TNM UICC classification Three patients presented with recurrent disease after a full dose of radiotherapy (60 Gy), three had had no previous treatment and one had received adjuvant chemotherapy (bleomycin and 5-fluorouracil) Radical neck dissection was performed in three cases and suprahyoid dissection in the other four. All patients underwent tracheostomy and gastrostomy There was one bone necrosis at the site of mandibulotomy. Cosmetic results were good in all seven patients One patient had salivary incontinence, one was unable to swallow and five patients had no trouble swallowing Chewing capacity was absent, poor in another and good in the other five cases The tracheostomy was closed on the 13th and the gastrostomy on the 18th day after surgery

0007–1323/93/S084–02 © 1993 Butterworth-Heinemann Ltd

The present results are compared with a series of patients previously treated by segmental mandibulectomy and myocutaneous pectoral flap reconstruction. Mandibular rotation provides excellent access for lesions of the posterior oral cavity and oropharynx. Immediate restoration of mandibular continuity and use of the radial free flap allows improved chewing and swallowing functions with satisfactory cosmetic results

Denatured muscle autografts in peripheral nerve repair in patients with leprosy

J.H. Pereira, J. Curtis, J.L. Turk, D.D. Palande*,
A. Subramanian* and T.S. Narayanakumar*, *The Royal College of Surgeons of England, London, UK and *Sacred Heart Leprosy Centre, Kumbakonam, India*

Autologous muscle grafts were used to repair 41 mixed peripheral nerves (eight median, at the wrist, 33 posterior tibial, at the ankle) in 32 patients with leprosy who had total anaesthesia and analgesia of the area supplied by the nerve. The aim was to assess the effectiveness of this technique at restoring protective sensation to such patients. The study has been in progress since November 1989, and the clinical results to date will be presented. Follow-up ranging from 3 to 36 months indicates that the progress of sensory recovery after grafting is slow but encouraging, particularly in the recipients of grafts to the median nerve.

Long-term results of blood flow and sensitivity of flaps used for the reconstruction of facial soft tissues

H. Schliephake, R. Schmelzeisen, F.W. Neukam and C. Reiche, *Medical University of Hannover, Hannover, Germany*

The aim of the present study was to determine the blood flow and cutaneous sensation of flaps after the repair of tumour-related defects of facial skin The mean postoperative interval was 62 months. A total of 50 restorations (27 local flaps, seven free skin grafts, six island flaps and ten microvascular grafts) were examined using laser Doppler flowmetry, two-point discrimination and a pain and thermal sensation threshold Measurements were performed on the flap surface, the donor site and the contralateral areas corresponding to the donor site and the former defect. Paired *t* tests were employed to assess statistically significant differences between the sites of measurement Results showed restoration of both blood flow and the two-point discrimination on the surface of local flaps, island flaps and free skin grafts to a level not statistically different from that of the corresponding area of the side not operated on. Only the pain and thermal sensation thresholds exhibited a significant increase in the group of local flap restorations. Large myocutaneous flaps showed complete loss of cutaneous sensation in seven cases, while partial restoration without normal two-point discrimination was found in the remaining three patients after a mean interval of 44 months. Flowmetry rates of myocutaneous flaps corresponded to those of the donor site and were significantly lower than those of the recipient site in the head and neck area

Microsurgically revascularized scapula grafts for midface/maxillary reconstruction

R. Schmelzeisen, J.-E. Hausamen and F.W. Neukam, *Medical University of Hannover, Hannover, Germany*

In complex midface/maxillary reconstruction, microsurgically revascularized scapula flaps have proved to be very useful. Since 1988, seven osteocutaneous scapula flaps have been used for maxillary/midface reconstruction in the head and neck area in this clinic.

The vascular anatomy of the scapula region allows for many combinations of isolated or combined bony and soft tissue reconstructions In particular, perforating maxillary defects can be reliably closed in separate layers, for example in patients with hemifacial microsomia, and orthognathic surgery principles can be combined with microsurgical tissue transfer from the scapula region. Special problems regarding recipient vessels and insertion of dental implants in vascularized scapula grafts are discussed.

Surgical treatment of Fournier's gangrene: a study of 15 patients

C. Serna Ballester and S. Pous Serrano, *Department of Plastic Surgery, La Fe Hospital, Valencia, Spain*

Fournier's gangrene is a synergistic infection that produces necrosis of the subcutaneous tissues of the external genital organs and perineum It is associated with severe systemic toxicity and a high mortality rate It requires early diagnosis and aggressive emergency surgical treatment

A series of 15 patients treated between 1983 and 1992 is reviewed All patients underwent urgent debridement and treatment with broad-spectrum antibiotics. A colostomy was formed in three patients, a suprapubic cystostomy in two cases and reconstructive procedures in eight The aetiology was long-term urethral catheterization (nine patients), perianal abscess (five patients) and urethral obstruction (one). The most frequently associated disease was diabetes mellitus (eight cases).

The treatment of the open area and the healing times were recorded.

	No. of patients	Duration of hospitalization (weeks)
Healing by secondary intention	7	6–8
Interment of the testicles	3	3–4
Gracilis muscle flap	2	3–4
Scrotal skin approximation and a graft on the penis	2	3–4
Split skin graft	1	2–3

There were no hospital deaths Urgent and aggressive surgical treatment, broad-spectrum antibiotics and advances in reconstructive procedures account for the excellent results of this series.

Reconstructive surgery has decreased mean healing times by half, and also the mean duration of hospitalization and morbidity.

Reconstructive and voice-formation operations in the treatment of malignant laryngeal tumours

N.P. Trofimenko and O.V. Maleev, *Donetsk Medical State Institute, Ukraine*

A complex set of operations for recovery of the above functions has been established and widely used. The principal distinction of the proposed methods is as follows: the tracheo-oesophageal shunt method uses the topographoanatomical and physiological approach to protect the upper respiratory tract from the contents of the oesophagus, and for functional larynx resections the remaining larynx–gullet structures are used in the recovery of the separate functions. Apart from this the usual methods of functional larynx resection and tracheo-oesophageal shunt in patients with total larynx removal have been used

In all, 420 of the above operations, including 167 reconstructive subtotal operations on the larynx and gullet, were performed according to the methods proposed, 127 voice-formation operations after complete larynx removal according to the methods proposed and 126 analogous operations according to common methods.

Analysis has shown that the total oncological survival rate was 73 5 per cent. Moreover, the use of these methods of surgical rehabilitation of the impaired functions is 7 2 per cent more effective than traditional approaches.

Portal hypertension

Evaluation and long-term results of mesocaval interposition shunts

J.P. Arnaud, C Casa, V. Serra-Maudet and J. Ronceray, *Department of Visceral Surgery, CHU Angers, Angers, France*

The ideal therapy for variceal haemorrhage would eliminate this life-threatening complication of portal hypertension and have no adverse effects on hepatic physiology. Mesocaval interposition shunts preserve hepatopetal blood flow

Thirty-five shunts were performed as an elective procedure from 1982 to 1992 in patients with cirrhosis and variceal bleeding. There were 24 men and 11 women, with a median age of 51 7 years The underlying aetiology of the varices was alcoholic cirrhosis in 31 patients and postnecrotic cirrhosis in four. The criteria of Child and Pugh were used to evaluate all patients. 21 were in grade A and 14 in grade B. All patients had had two or more episodes of acute variceal haemorrhage. The mean diameter of the knitted Dacron graft used was 14 (range 10–16) mm

Intraoperative portal pressure measurements showed satisfactory pressure reduction (mean 40 per cent) There were no deaths after operation Eight patients had postoperative complications, an overall morbidity rate of 23 per cent. two ascites, four temporary encephalopathy and two recurrent bleeding. At 3 months, angiographic (five cases), ultrasonographic (six) or scan (17) studies evaluated shunt patency. In one case an occluded graft was observed The actuarial survival rate was 82 per cent at 2 years and 66 per cent at 5 years It is concluded that the interposition mesocaval shunt appears to be an effective technique for the control of variceal haemorrhage, has important haemodynamic advantages and can be used in most patients for the control of variceal bleeding caused by portal hypertension. Moreover, this procedure can be considered as a solution before transplantation

Experience with distal splenorenal shunt in treatment of bleeding oesophageal varices

A. Edo, J L Lázaro, E. Murio, J Balsells, R. Charco, E. Gifre, and C. Margarit, *Liver Transplant Unit, Hospital General Universitario Vall d'Hebrón, Barcelona, Spain*

In recent years the introduction of endoscopic sclerotherapy, transjugular intrahepatic portasystemic shunting and liver transplantation have changed the role of surgery in the management of bleeding oesophageal varices. Surgery is indicated in this unit only when there is a failure of sclerotherapy and the patient is not considered a candidate for liver transplant

During the past 6 years 61 patients underwent a surgical procedure in this unit, 24 per cent being admitted for bleeding oesophageal varices during this period In 31 cases a Warren shunt was performed The mean age of these 31 patients was 52 years. The aetiology of portal hypertension was: liver cirrhosis in 27 patients, liver fibrosis in one, and portal thrombosis in three. Emergency operations were undertaken in ten patients (32 per cent), whereas 21 (68 per cent) underwent elective operation

The operative mortality rate in the elective group was 6 per cent, two patients dying from hepatorenal syndrome and sepsis Postoperative mortality rate, when other techniques were used, was 41 per cent Postoperative recurrent bleeding was observed in five cases (16 per cent); two were treated medically and three needed reoperation (two underwent modified Sugiura technique and one had a portocaval shunt) without mortality Actuarial survival was 86 per cent, 64 per cent and 43 per cent at 1, 4 and 6 years after operation.

A significant number of patients still need a surgical procedure for bleeding oesophageal varices. The Warren shunt could be performed in half of these patients, even in urgent situations In the authors' experience the splenorenal shunt gives the best results regarding postoperative death and patient survival

Selection of patients for peritoneovenous shunting in therapy-refractory ascites by a reinfusion test

A Lazar, K.-J. Paquet, J.-Fr. Kalk and R. Kuhn, *Heinz-Kalk Hospital, Bad Kissingen, Germany*

A prospective study with a newly developed preoperative ascites reinfusion test (ART) as a selection criterion for peritoneovenous shunts (PVSs) in the treatment of therapy-refractory ascites is presented A total of 457 patients with massive ascites were studied (January 1984 to January 1990). After a period of 3 months with conservative management including water and salt restriction, diuretics and paracentesis, 69 patients (15 1 per cent) were considered for a PVS Severe disseminated intravascular coagulation, bloody and infected ascites, and severe heart and renal insufficiency were contraindications in some and reduced this number to 51 (11 2 per cent) selected for ART

After placement of a caval and peritoneal catheter connected by a peristaltic pump, reinfusion began at $100\,\mathrm{ml\,h^{-1}}$, was increased to $400\,\mathrm{ml\,h^{-1}}$ and was carried out for 3–5 days Thereafter, 16 further exclusions were necessary, resulting mainly from coagulopathy In all, 39 PVSs were placed in 35 patients over a period of 6 years (18 Cordis Hakim, 21 Denver). Twenty-one patients were Child–Pugh grade C. All had liver cirrhosis. Two (5 per cent) minor operative complications (bleeding) were observed. Operative mortality rate was 11 per cent Coagulopathy developed in one case (3 per cent) with a fatal outcome. Sepsis related to the device was observed in one case (3 per cent) The patient survived after removal of the PVS. In four cases (11 per cent) a shunt malfunction occurred requiring revision. At the time of review (January 1992), 15 patients were alive, 14 of them with a patent shunt and ten with no ascites The 5-year survival rate according to Kaplan–Meier was 41 per cent

In conclusion, the ART is a cornerstone for the selection of patients with refractory ascites for PVS. Careful implantation technique, and pre-operative and postoperative management, in addition to ART preoperative selection criteria, are good methods for improving postoperative results The final goal is to improve the quality of life of these patients who have predominantly end-stage disease

Mesocaval interposition shunt with narrow-lumen polytetrafluoroethylene prosthesis in cirrhotic patients with recurrent variceal haemorrhage: a prospective study

K.-J. Paquet, A. Lazar and B. Hotzel, *Heinz-Kalk-Hospital, Bad Kissingen, Germany*

In 1972, Drapanas introduced a mesocaval interposition shunt to treat bleeding oesophageal varices using an 18–20-mm Dacron prosthesis

Since January 1987, a narrow-lumen 8–10-mm polytetrafluoroethylene prosthesis has been used in 56 patients with failed sclerotherapy In 93 per cent of cases liver cirrhosis, mostly alcoholic, was the underlying disease, 26 patients were Child–Pugh classification grade A, 25 grade B and five grade C. Thus, 51 patients were treated electively and five as emergencies There were five hospital deaths (9 per cent), two in the emergency group due to liver failure The hospital mortality rate for the elective shunt was 6 per cent One postoperative shunt thrombosis developed. The post-operative resting portal perfusion was shown to be preserved in all cases The encephalopathy rate was 11 per cent There were five late deaths, thus the 5-year survival rate according to the non-parametric estimation of Kaplan–Meier is > 80 per cent

These results show that a narrow-lumen mesocaval interposition shunt has a place as a treatment of portal hypertension in patients with recurrent haemorrhage after endoscopic sclerotherapy and that it is an alternative to the distal splenorenal shunt

Non-shunting surgery in portal hypertension

A. Popovici and Anca Petca, *Fundeni Hospital, Bucharest, Romania*

Because of high postoperative morbidity and mortality rates of shunting procedures, ligation of oesophageal varices and oesophagogastric resection, the non-shunting type operation devised by Hassab and Sugiura was adopted. The operation is performed through an abdominal incision with the devascularization of the abdominal oesophagus and of the proximal half of the stomach, splenectomy and transgastric ligation of oesophageal varices are also performed. Surgical control of the source of bleeding and correction of hypersplenism and of the mechanical effects of splenomegaly are achieved, as is the maintenance of good portal perfusion of the liver Portal encephalopathy is avoided.

During 1980–1991, 231 patients with portal hypertension underwent operation, 36 by the method described Fourteen patients had cirrhosis and 22 had presinusoidal disease (85·7 per cent of patients with cirrhosis, Child B and C stages). Four of the 36 underwent operation while bleeding

There was neither iterative bleeding nor portal encephalopathy Postoperative mortality rate was 19·4 per cent, whereas the mortality rate after shunting surgery was 39 2 per cent.

Rectum and anal canal

Plasty of the greater omentum and rectosigmoidectomy for treatment of rectal prolapse

A Koussidis and M. Apsokardou-Koussidou, *General Hospital of Chios, Greece*

The aim of this surgical technique is to recover good function of the large intestine and to reconstruct the permanent continence of the internal sphincter mechanism of the anal and perianal area. With the combination of rectosigmoidectomy and plasty of the greater omentum, excision of the whole rectal prolapse and the rectosigmoid, lifting of the whole of the anal- and perianal area and support of the pelvic floor is achieved

The surgical technique is done on a wide rectosigmoidectomy and end-to-end anastomosis between the ends of the descending colon and rectum. This is followed by mobilization of the greater curvature of the stomach from the pylorus to short gastric arteries The long stem of the greater omentum is brought down to the pouch of Douglas This stem is secured to the left lateral abdominal peritoneum. This securing begins from the upper left lateral abdomen Each stitch sews together deeply the lateral abdominal peritoneum, the middle taenia of the descending colon and this stem from the greater omentum After all these separate stitches have been placed, using 2/0 silk threads, they are carefully tied individually The end of the stem of the greater omentum is secured on the anterior wall of the dissected rectum, as well as on the anastomosis of the descending colon and rectum. After draining the pouch of Douglas the incision is closed in layers In May 1991, operation using this method was carried out on a 65-year-old woman who had been suffering for 3 years from a complicated rectal prolapse. The function of the sphincter mechanism of the rectoanal area as well as of the large intestine has fully recovered

A perineal approach to disabling rectocele: a series of 20 patients

P.A. Lehur, J. Moyon, S. Bruley and J. Le Borgne, *Clinique Chirurgicale II, Nantes, France*

Rectocele is a common rectal disorder, its usual clinical presentation is a distressing outlet obstruction. Surgical treatments usually proposed are based on transanal procedures However, we believe that such an approach does not treat all the abnormal components found in a rectocele.

This study evaluated a perineal approach to rectocele: 20 consecutive female patients (mean age 52 years) have been operated on Outlet obstruction was present in 17 cases, with vaginal digitalization in nine Minor faecal incontinence coexisted in five cases Surgical procedures involved: (1) complete mobilization of the rectal wall, (2) careful concentric folding of the rectocele, (3) stitching of the rectal fascia, and (4) preanal levatorplasty.

Care was taken not to reduce the vagina, therefore no colpectomy was performed. Results of this approach have been clinically and radiologically evaluated with a mean follow-up of 16 months Morbidity was minimal, anatomical correction was obtained in 18 cases and one pre-existing dyspareunia was aggravated. Normal rectal evacuation was restored in 16 patients, while four had functional failures Associated anorectal disorders (anismus, colonic inertia) were identified in each of these four cases.

This study showed that the perineal approach to rectocele has specific value It corrects the different components of the rectocele, avoiding anal dilatation, restoring a more stable pelvic floor, without creating significant sexual discomfort It compares favourably with other proposed techniques

Smoking impairs wound healing and increases risk recurrence in both Crohn's and non-specific fistula *in ano*

J.-P. Puts and J.A. Gruwez, *Catholic University Hospitals, Leuven, Belgium*

Between 1984 and 1992, 295 patients were treated for either fistula *in ano* or rectovaginal fistula. These patients presented with 526 fistulas, 375 of which were treated by the authors There were 141 smokers, of whom 43 (30·5 per cent) had a postoperative recurrence of their fistula and 154 non-smokers of whom 23 (14·9 per cent) had a recurrence ($P < 0{\cdot}005$). There were 236 patients without evidence of Crohn's disease, 125 were smokers Thirty (24·0 per cent) of these patients had a recurrence Of the 111 patients without Crohn's disease who did not smoke, only 14 (12·6 per cent) had a recurrence ($P < 0{\cdot}05$) Only 16 of 59 patients with Crohn's disease (27 per cent) were smokers. There were 13 recurrences in this group Nine recurrences occurred among the 43 patients with Crohn's disease who did not smoke ($P < 0{\cdot}0001$) The mean(s.d.) delay in complete healing was 3·8(5·4) months for patients without and 10·9(12·2) months for patients with Crohn's disease ($P < 0{\cdot}0005$). In patients without Crohn's disease, healing was delayed by a mean(s.d.) 5·1(7·2) months in smokers *versus* 2·4(1·8) months for non-smokers ($P < 0{\cdot}05$) However, for patients with Crohn's disease the delay in healing was 15·4(13·9) months in smokers *versus* 3·8(2·1) months in patients who did not smoke ($P < 0{\cdot}05$) It is concluded that smoking increases the risk of recurrence and delay in healing after an operation for fistula *in ano*.

Late results of postanal repair: a retrospective study

W.R. Schouten and J.W. Briel, *University Hospital Dijkzigt, Rotterdam, The Netherlands*

In 1975 Parks described postanal repair (PAR) in the treatment of idiopathic faecal incontinence Although the short-term results are quite promising, the long-term outcome is still unknown. The aim of this study was to evaluate the long-term results after PAR During the time period 1984–1992, 38 patients underwent PAR (eight men and 30 women, median age 62 (range 17–77) years. Twelve patients presented with idiopathic faecal incontinence. Eight patients underwent PAR for persistent incontinence after rectopexy for rectal prolapse. The history of the remaining 18 patients revealed obstetric trauma without clinical sphincter defect ($n = 4$), rectocele repair ($n = 2$), surgical trauma ($n = 9$), traumatic injury ($n = 1$), anorectal malformation ($n = 1$) and low anterior resection ($n = 1$) Postoperative complications (<30 days) occurred in six patients (urinary tract infection, four; wound infection, two) The median duration of follow-up was 39 (range 4–94) months During the first year of follow-up PAR was successful in 24 patients In 22 patients this beneficial effect was observed soon after the operation (< 6 months) In seven of the 24 patients incontinence recurred after a mean duration of 16 months In 14 patients continence was never regained The final outcome was therefore good in only 45 per cent of the patients. No correlation was found between the history of the patient and the final result. Therefore, it has to be questioned whether other treatment modalities such as biofeedback are not more favourable.

Relationship between anal pressure and anodermal blood flow: the vascular pathogenesis of anal fissure

W.R. Schouten, J.W Briel and J J.A Auwerda, *University Hospital Dijkzigt, Rotterdam, The Netherlands*

The poor healing rate of anal fissures and their predilection for a posterior midline location have been attributed to insufficient blood supply at the posterior commissure It has been suggested that the increased activity of the internal anal sphincter further decreases the arterial supply The aim of this study was to investigate this hypothesis by evaluating the relationship between anal pressure and anodermal blood flow

In 148 consecutive patients (M:F 67:81, median age 50 (range 18–87) years) with various colorectal disorders, maximal resting anal pressure (MRAP) was recorded. Laser Doppler flowmetry was performed simultaneously to assess perfusion of the anoderm at the posterior midline using a Periflux PF2B laser Doppler flowmeter A significant correlation was found between MRAP and perfusion of the anoderm ($r_S = 0{\cdot}61$, $P < 0{\cdot}001$) Both measurements were also performed in controls ($n = 12$), patients with faecal incontinence ($n = 22$) and those with anal fissure ($n = 7$). Mean(s.d.) MRAP was significantly higher in patients with anal fissure (125(24) mmHg) than in controls and those with faecal incontinence (60(18) and 42(14) mmHg respectively, $P < 0{\cdot}001$ and $P < 0{\cdot}001$, Student's *t* test), whereas perfusion at the base of the anal fissure was significantly lower (0·43(0·11), 0·70(0·17) and 1·02(0·34) V, $P < 0{\cdot}005$ and $P < 0{\cdot}001$)

0007–1323/93/S088–02 © 1993 Butterworth-Heinemann Ltd

In six patients with anal fissure both measurements were performed before and 6 weeks after lateral internal sphincterotomy. This procedure resulted in a significant decrease of mean MRAP (46 (range 33–63) per cent), which was associated with a consistent increase of anodermal blood flow (54 (range 20–125) per cent). These findings strongly support the hypothesis that anal fissures are ischaemic ulcers.

Surgical treatment of rectal prolapse: a randomized study

F. Selvaggi, E. Scotto di Carlo, A. Silvestri, L. Festa and V. Piegari, *Università degli Studi di Napoli, Naples, Italy*

Rectal prolapse (RP) is often associated with a functional outlet obstruction. There is some evidence that division of the lateral ligaments (LL) during rectopexy, performed for rectal prolapse, results in a higher incidence of constipation than if the LL are preserved.

Twenty patients with RP were randomized to undergo anteroposterior Marlex rectopexy with either division of the LL (group 1, n = 11, nine women, mean age 60 (range 52–71) years) or sparing of the LL (group 2, n = 9, seven women, mean age 64 (range 58–69) years). Preoperative and postoperative assessment was made of frequency of defaecation, straining, tenesmus, continence, anal pressure, anorectal sensation, balloon expulsion and evacuation proctography. The mean follow-up was 14 (range 6–24) months.

Continence improved in both groups. Postoperative symptoms improved significantly in group 2 ($P < 0.01$) compared with group 1. There was no statistical difference between preoperative and postoperative anorectal sensation or balloon expulsion test. All patients showed resolution of prolapse by proctography. These data suggest that division of the LL is followed by a higher incidence of constipation than if they are preserved.

Spleen

Conservative approach to post-traumatic spleen injuries

C. Diaconu, C. Dogaru, D. Arvătescu and M. Diaconescu, *St Spiridon Hospital, Third Surgery Clinic, Iasi, Romania*

This paper presents a retrospective study comparing the results of conservative treatment with those of splenectomy. A total of 29 post-traumatic spleen injuries were treated in this clinic. The diagnosis of rupture with intrasplenic haematoma was formulated clinically with ultrasonography in 13 cases; there were three ruptures with haematoma of the spleen and 13 spleen ruptures with haemoperitoneum. The mean period of hospitalization for the patients not having splenectomy was 19 days, and for those undergoing splenectomy 15 days Three of the 16 patients who underwent operations had complications Conservation of the spleen after abdominal trauma must be used whenever the local and general conditions of the patient allow. The immediate postoperative complications, as well as the later ones that result from depressed immunological status after splenectomy, are arguments in favour of the conservative attitude in splenic trauma

Role of splenectomy in the management of splenic trauma

O. Fercocq, P. Petrequin, M. Soler and P. Verhaeghe; *Université de Picardie, Hôpital Nord, Amiens, France*

Ninety-four cases of splenic trauma (blunt, iatrogenic and penetrating) presenting between 1981 and 1991 were reviewed retrospectively The overall splenic conservation rate was 55 per cent, including cases managed conservatively and surgically The literature has been reviewed with the aim of determining why the rate was so low and recommendations for improvement are made.

It is believed that the most effective way to obtain a greater conservation rate is an early laparotomy with the surgeon performing splenic repair and avoiding splenectomy for most patients Only life-threatening associated injury requires splenectomy.

The success rate for splenorrhaphy should be very high if early operation is undertaken If there is prolonged conservative management before operation the success rate is much lower

The criteria for conservative management should be. (1) isolated abdominal or extra-abdominal injury with haemodynamic stability (no blood transfusion requirement of > 2 units), (2) absence of peritoneal fluid at repeated examination by computed tomography; and (3) observation of patients in an intensive care unit for the first 72 h If these conditions are not applied then early laparotomy is the only safe and effective alternative.

Partial splenectomy in children: an alternative to splenectomy in the pathological staging of Hodgkin's disease

H.J. Hoekstra, *Division of Surgical Oncology, University Hospital, Groningen, The Netherlands*

The key to staging laparotomy in children with clinically staged I or II Hodgkin's disease is to identify the extent of disease and therefore the radiation field required The staging laparotomy consists of coeliac, portal, aortic, mesenteric and inguinal lymph node biopsies, wedge and needle biopsy of both lobes of the liver and splenectomy After splenectomy in children there is an increased risk of overwhelming postsplenectomy infection (OPSI). To reduce the risk of OPSI and ensure an adequate staging of Hodgkin's disease in children, partial splenectomy may be an alternative, since the risk of understaging is less than 1 per cent.

Twelve patients, median age 12 (range 7–16) years, with clinically staged IA or IIA Hodgkin's disease underwent a staging laparotomy with lymph node and liver biopsies and partial splenectomy in which the lower part of the spleen was resected. All patients were treated with involved field radiation therapy: three patients received only 44 Gy radiation and nine received 25 Gy and two cycles of mitoxin, Oncovin, procarbazine, prednisone–Adriamycin, bleomycin, vinblastine, decarbazine.

The median postoperative stay was 7 (range 5–23) days. Morbidity consisted of a small bowel obstruction requiring relaparotomy in one patient. The clinical stage changed from IA to IIIA in three patients The final pathological stage was IA in five patients, IIA in four and IIIA in three During a median follow-up of 6 (range 4–10) years, one patient died from secondary leukaemia after 4 years The remaining 11 patients have no evidence of disease and none developed OPSI.

Partial splenectomy is a reasonable alternative to total splenectomy for Hodgkin's disease. In the future, laparoscopy with laparoscopic lymph node biopsy, liver biopsy and partial splenectomy may replace staging laparotomy in Hodgkin's disease in children.

Conservative treatment of the spleen: a review of 168 cases

M. Kehila, M. Bentiress, A. Mselmi and T. Abderrahim, *Surgical Service, CHUF Hached–Sousse, Tunisia*

From 1983 to 1992, 168 cases of total or partial conservative treatment of the spleen were practised (92 for splenic trauma, 54 for splenic haematological disease and 22 for splenic cysts).

For splenic trauma, the indication for operation was haemoperitoneum For splenic haematological disease, the operation was indicated for splenomegaly and/or the increasing transfusion needs and hypersplenism Conservative treatment for splenic trauma included 66 partial splenectomies, ten electrocoagulations, ten autotransplantations and one gastric transposition of the spleen. Haematological splenic disease involved subtotal splenectomy keeping the lower pole in 53 cases and the higher pole in one case Splenic cysts involved 11 partial splenectomies resecting the lower pole in two cases, the upper half-spleen in two cases, the lower half-spleen in two others, the upper two-thirds in two cases, and three total pericystectomies keeping the lower pole in one case and the upper in two others. In the ten other cases there were seven cyst dome resections, one splenotomy and drainage for a central spleen cyst, two electrocoagulations and one case was sutured Two patients required reoperation, one for bleeding and the second for necrosis. No death was reported in relation to the conservative techniques. The efficacy of partial splenectomy in the postoperative period was confirmed by Jolly's bodies measurements (absent in 122 cases), platelets increasing (negative in 123 cases), spleen homogeneity on ultrasonography (131 cases) and scintigraphy (fixed in 124 cases)

In conclusion, conservative treatment has proved to be a safe technique with definite benefits.

Splenectomy and haematological disease

A. Montvidas, P. Metrikas and R. Jurgutis, *City Hospital, Klaipeda, Lithuania*

The purpose of this study was to evaluate splenectomy in patients with haematological diseases Between 1976 and 1992 a total of 35 patients underwent splenectomy for the following haematological diseases. thrombocytopenic purpura (12), haemolytic anaemia (five), chronic lympholeukaemia (seven), chronic myeloleukaemia (five), chronic monocytic leukaemia (one), Hodgkin's disease (four) and hypoplastic anaemia (one) There were 21 men and 14 women with a mean age of 33 (range 13–71) years All patients were treated by haematologists before operation for periods ranging from 1 week to 13 years. Indications for splenectomy were the failure of conservative treatment or cytopenia.

Midline laparotomy was used in 24 cases and oblique incision in 11 cases Two patients died (6 per cent) during the immediate postoperative period because of coagulation disorders with diffuse bleeding Five patients (14 per cent) had postoperative complications (pneumonia in three, wound infection in one, and superficial vein thrombosis in one) After splenectomy all patients' general and haematological states improved and haematologists continued their treatment

In conclusion, splenectomy has an important role as palliative management in patients with haematological diseases

0007–1323/93/S090–02 © 1993 Butterworth-Heinemann Ltd

Results of splenectomy for idiopathic thrombocytopenic purpura: a review of 72 cases

A.R. Naouri and E.R. Tissot, *E Herriot Hospital, Lyon, France*

Seventy-two patients underwent splenectomy for idiopathic thrombocytopenic purpura (ITP) between 1979 and 1990. There were 14 men and 58 women. Mean age at splenectomy was 36·4 (range 11–73) years. Indications for splenectomy were steroid dependence in 21 cases and resistance to steroids in 44 cases. Thirty-five patients underwent platelet kinetic studies by ^{51}Cr-alloplatelets; 22 had splenic sequestration. Haematological results were evaluated on discharge, at 3 months and in the long-term (median follow-up 5·4 years) There was no mortality; morbidity was observed in 7 per cent. None of the patients experienced secondary infectious complications; 89 per cent had good results on discharge (platelets $> 120 \times 10^9 l^{-1}$), 73 per cent at 3 months and 90 per cent on long-term follow-up. Factors associated with a good response to splenectomy included a high postoperative platelet count ($> 120 \times 10^9 l^{-1}$ on discharge), younger age (under 30 years) at the time of surgery, preoperative steroid dependence and splenic sequestration. It is believed that splenectomy is the best treatment for ITP when a durable response with steroid therapy cannot be achieved.

Results of spleen conservation during distal pancreatectomy

R. Van Hee, D. Ysebaert and L. Verbist, *Department of Surgery, University of Antwerp, UIA and Department of Gastroenterology, Palfijn Hospital, Antwerp, Belgium*

Resection of the body of the pancreas for chronic pancreatic disease generally includes splenectomy. In this series of patients the results of splenic conservation were studied, with a 1–3-year follow-up. Five patients underwent distal pancreatectomy for chronic pancreatitis, insulinoma or solid papillary tumour In all cases the main splenic vessels were ligated The spleen was preserved and remained vascularized through the gastroepiploic and short gastric vessels. Postoperative studies included blood count, ultrasonography and scintigraphy of the spleen, computed tomography (CT) of the upper abdomen, as well as Doppler investigations of the spleen.

All patients showed a peroperative blue-purple discoloration of the spleen. Postoperative ultrasonography and CT revealed swelling of the spleen with heterogeneous zones; blood investigations showed neither increased cytological breakdown nor any rise in thrombocytosis or leucocytosis. Vascular duplex scan showed increased flow in the short gastric vessels and virtually normal intrasplenic vascularization. In the long run, no clinical abnormalities were related to the main arteriovenous devascularization of the spleen.

In this small series of patients operated on by means of distal pancreatectomy with ligation of the main splenic artery and vein, no clinical effects were noted due to the devascularization Radiological, cytological as well as duplex parameters after operation showed no apparent deleterious effects in splenic function, as well as maintenance of adequate blood flow to the spleen.

Thoracic surgery

Surgical treatment of pulmonary metastases: experience with stapler and laser in the treatment of 100 patients

G Antypas, C. Potaris, D Karayiannis, N. Bolanos, G. Kantidakis and S. Bathrelou, *Metaxa Cancer Hospital, Piraeus, Greece*

Between 1983 and 1993, 100 patients with metastatic neoplasms of the lung underwent a total of 129 operations. The primary lesions were malignant neoplasms of the colon, breast, soft tissues, bones, epidermis (melanoma), uterus, ovaries, thymus and lung Surgery was performed using staplers or the neodymium–yttrium–aluminium garnet laser. There was no mortality related to the surgical procedure.

A prerequisite for surgery was the absence of other metastases and adequate pulmonary and cardiac reserve In some patients more than one thoracotomy was performed, up to a maximum of eight Postoperative chemotherapy was generally given

Long-term results of operation for non-small cell cancer of the lung

V. Beltrami, *Clinica Chirurgica dell'Università degli Studi di Chieti, Italy*

Up to 1992, 1059 patients, selected from a total of 2614 observed cases, underwent surgery for lung cancer There were 278 pneumonectomies and 525 lobectomies and minor resections, the number of exploratory operations was 30 per cent before 1981, 21 per cent from 1982 to 1986 and less than 10 per cent from 1987 Mortality rate was around 5 per cent; 16 patients were lost to follow-up Long-term survival was considered for patients operated on within 1982 (184) and 1987 (263). More than 73 per cent of those with T_1N_0 disease fared well after 5 years, the figure was 57 per cent after 10 years Survival with T_2N_0 disease was respectively 50 and 27 per cent; T_3N_0 patients survived to 5 years in 34 per cent of cases, but after 10 years only 11 per cent of them survived A high percentage of the late deaths (around 50 per cent) was related to the development of metastases. Local recurrences were not frequent, a second primary carcinoma was observed five times The results of surgical resection could improve in coming years, due to the increasing number of patients subjected to neoadjuvant therapy.

Resection of pulmonary nodules using video-assisted thoracic surgery

A. Bernard, B. Benhamiche, P. Goudet and H Viard, *Hôpital du Bocage, Dijon, France*

The aim of the study was to assess the limits and complications of video-assisted thoracic surgery (VATS) Twenty patients (16 men, four women, mean age 57 (range 17–80) years) underwent a total of 21 VATS procedures Indications for surgery were· primary malignant tumour (11 patients), benign lesion (five patients), and metastasis (four patients). A thoracotomy was performed twice after failure of VATS (one central pulmonary nodule and one pleural adhesion) One patient underwent two consecutive VATS procedures because the first removed insufficient tissue. The nodule was difficult to localize in 12 patients

Mean diameter of the resected nodules was 2 3 (range 1·5–5) cm. In total, 13 wedge resections, two segmentectomies and five lobectomies (two through a thoracotomy and three through a small 'utility' thoracotomy) were performed Among 11 patients operated on for a primary malignant tumour, seven had severely impaired lung function with a mean forced expired volume (FEV) of 1 litre Of these, five underwent wedge resections, one segmentectomy and one lobectomy through a 6-cm thoracotomy.

No death occurred There were two complications one persistent pulmonary fistula and one pneumonia Mean duration of chest drainage was 2 9 (range 0–10) days Mean duration of hospital stay was 5 5 (range 1–12) days

In conclusion, VATS is advised for benign pulmonary lesions and for frail patients.

Spontaneous pneumothorax: video-assisted thoracic surgery *versus* thoracotomy

A. Bernard, P. Goudet and H. Viard, *Hôpital du Bocage, Dijon, France*

The aim of this study was to compare video-assisted thoracic surgery (VATS) with thoracotomy in the treatment of spontaneous pneumothorax. Thirty patients underwent VATS Pleurodesis was carried out using a 'scotch brite' swab. Blebs were stapled and resected

Thirty patients (23 men, seven women, mean(s.d.) age 37(18) years) previously having had open thoracotomy for pneumothorax were selected at random from the hospital files Patients were matched for age, sex, profession, smoking habits and disease aetiology

Eighteen middle-sized and five large-sized blebs were resected An independent physician telephoned the patients to assess postoperative pain and time off work. Mean(s d) chest drainage time was 6 7(4) days for thoracotomy and 5(2) days for VATS (t = 1·74, 29 d.f., P = 0 13) Mean(s d) duration of hospital stay was 11(5) days for thoracotomy and 7(2) days for VATS (t = 3 47, 29 d.f , P < 0 003). From day 30 to day 60 after surgery, pain was moderate in 28 patients in the VATS group and intense or acute in 21 of those in the thoracotomy group ($\chi^2 = 26$, 2 d.f , P < 0 001). Mean(s.d.) resumption of working was 2 6(0·8) months in the thoracotomy group' *versus* 1(0 8) months in the VATS group (t = 7 78, 29 d.f , P < 0 001). One persistent and partial pneumothorax was noted in each group and one relapse occurred in the VATS group ·5 months after surgery In conclusion, VATS produces a better quality of life and is as efficient as thoracotomy in treatment of pneumothorax

Adjuvant therapy in lung cancer after cytological and immunocytological detection of tumour cells by intraoperative pleural lavage

J. Buhr*, K.H. Berghäuser†, T. Zimmermann*, Ch Kelm*, H. Morr‡, J Dobroschke§, W.M. Padberg*, K Henneking* and K. Schwemmle*, **Klinik fur Allgemein- und Thoraxchirurgie and †Institut fur Pathologie, Justus-Liebig-Universität, Giessen, ‡Klinik fur Lungen- und Bronchialerkrankungen, Greifenstein and §Krankenhaus der Barmherzigen Brüder, Regensburg, Germany*

According to the tumour node metastasis (TNM) classification, a malignant pleural effusion equals a T_4 spread of lung cancer The criterion is the cytological demonstration of tumour cells The results of a prospective study are presented in which pleural lavage was performed with 300 ml physiological saline solution after opening the chest to discover whether tumour cell dissemination into the pleural cavity had occurred in the early stages of lung cancer (lavage 1). A second lavage after resection of lung cancer (lavage 2) showed whether surgical manipulation of the lung parenchyma led to tumour cell contamination of the pleural cavity

A total of 205 patients (159 with the first manifestation of lung cancer, 46 with non-neoplastic lung disease) underwent pleural lavage The lavage fluid was prepared for cytological examination The sediments from the lavages were studied immunocytologically with the alkaline phosphatase–anti-alkaline phosphatase method Antibodies against keratin (Kl 1), vimentin (V 9), the endothelial marker BMA 120 and HEA 125, the B 72 antibody, polyclonal antibody against carcinoembryonic antigen (CEA) and a monoclonal antibody against CEA (BMA 130c) were used.

Tumour cells were found in lavage 1 in 65 patients and in 58 of them also in lavage 2. Among those previously classified as stage I ($pT_1 N_0$, $pT_2 N_0$), lung cancer-positive tumour cell detection was possible in 38 5 per cent of cases All controls were negative, i e there were no false-positive findings Immunocytological examinations found co-expression of Kl 1 and BMA 120 in squamous cell carcinoma and co-expression of Kl 1 and BMA 130c in adenocarcinoma of the lung, if pleural lavage was positive. The cumulative 4-year survival rate for curative resected non-small cell lung cancer of stage I (n = 78) was 22 1 per cent if lavage was positive (n = 30), and 64·3 per cent if lavage was negative (n = 48) (P < 0 05)

Detection of tumour cells in pleural lavage before resection proves that tumour cells have spread into the pleural cavity Therefore adjuvant therapy is necessary for patients with positive intraoperative pleural lavage in lung cancer

0007–1323/93/S092–04 © 1993 Butterworth-Heinemann Ltd

Combined videothoracoscopy and limited thoracotomy

M. Di Bisceglie, P. Paladini, M.M. Haid, L. Voltolini, G. Biagi and G. Gotti, *Istituto di Chirurgia Toracica e Cardiovascolare, University of Sienna, Sienna, Italy*

The superiority of videothoracoscopy over standard thoracotomy in the treatment of small lesions of the pleura and the lung is now well accepted because it offers a short period of surgical drainage, minimal postoperative pain and early recovery In addition, videothoracoscopy often obviates the need for thoracotomy Nevertheless, in some cases it is still necessary to perform a standard thoracotomy, especially to manage any intraoperative complications.

Between September 1990 and February 1993, 15 wedge resections and two lower lobectomies were performed by videothoracoscopy In the latter two patients, however, it was necessary to perform a small incision (7 cm) on the route of the grasping forceps to have more control on the inferior pulmonary vein and to have an adequate exit for the resected lobe

In summary, it is believed that the combined videothoracoscopic procedure with a limited thoracotomy incision offers an excellent view of intrathoracic structures, and enables avoidance of the use of a rib spreader.

Diagnostic and therapeutic open lung procedures in patients with leukaemia and severe aplastic anaemia

J.M. Habicht, A Gratwohl, P. Stulz, B. Speck and E. Grädel, *Kantonsspital, Basel, Switzerland*

Pulmonary complications often occur in patients with leukaemia and severe aplastic anaemia (SAA). Such complications account for a significant number of deaths, especially in patients having undergone bone marrow transplantation (BMT). A retrospective study is presented of experience with 27 consecutive patients (17 men, ten women, mean age 30 years) operated on between 1980 and 1992 Twelve patients underwent open lung biopsy (OLB) and 16 lung resection (LR), one patient was operated on twice Results of surgical procedures are shown.

	BMT (*n* = 12)	Leukaemia (*n* = 8)	SAA* (*n* = 7)
Radiologically diffuse disease	5 (42)	3 (38)	0 (0)
Non-specific histology	10 (83)	4 (50)	1 (12)
Proof of causative micro-organisms	1 (8)	3 (38)	6 (75)
Ratio of OLB to LR	8 4	4:4	0.8
Mortality (30 days)†	6 (50)	3 (38)	0 (0)

Values in parentheses are percentages *Eight operations, †no death due to operative procedure

In conclusion, when considering an open lung procedure in patients with haematological dysfunction it is helpful (for prognostic reasons) to distinguish between the categories BMT, leukaemia and SAA. Based on present findings open lung biopsy is no longer advocated in patients undergoing BMT with (acute) diffuse lung disease, as diagnostic yield is limited and seems to have little or no influence on outcome. Lung resection in localized disease, especially in patients with SAA, is beneficial in most cases.

Indications and results of operation for small cell lung cancer

C. Kelm, W. Padberg, T. Zimmermann, M. Hurtgen and J. Bühr, *Klinik fur Allgemein- und Thoraxchirurgie der JLU Giessen, Giessen, Germany*

Between 1982 and 1991, 31 operations were performed for small cell lung cancer. The mean age was 57·3 years Patients were operated on with a preoperative diagnosis of bronchogenic cancer (small cell cancer, ten; undifferentiated carcinoma, four, adenocarcinoma, one). Only four patients were treated before operation by chemotherapy or radiation. At diagnosis 23 patients were classified as stage I, two as stage II, four as stage IIIA and two as stage IV On five occasions only a diagnostic exploration operation was possible Resections included 16 lobectomies, four wedge resections, three pneumonectomies and three bilobectomies After operation only 14 patients were stage I, two were stage II, 12 were stage IIIA and three were stage IV Three postoperative deaths occurred: one as a result of cardiovascular failure, one because of lung embolism and one because of bronchial fistula after pneumonectomy. Postoperative treatment in 21 patients consisted of either chemotherapy (ten), radiation (one) or both (ten) Until now after a mean follow-up of 27 months, 14 patients have died between 3 and 25 months after operation, in 11 cases because of tumour progression, and ten patients are alive with a maximum survival of 72 months Three patients were lost to follow-up It is concluded that resection of small lung cancer is indicated as primary management for all patients with a tumour in stage I and II, and as secondary therapy for all patients with a tumour in stage IIIA and good remission after chemotherapy and/or radiotherapy

Experimental study of tracheal anastomosis

L. López, J. López Pujol, S. Quevedo, J. Freixinet and A. Salvatierra, *Hospitales del Pino y Reina Sofía, Las Palmas and Córdoba, Spain*

Revascularization of tracheal segment implants with omentum is possible. Previous trials by the authors have proved that the best results are achieved when the trachea is kept distended, its lumen drained, and the recipient receives immunosuppressive therapy with antibiotic prophylaxis.

The purpose of this trial was to test the different types of anastomosis using this experimental model A total of 50 Sprague–Dawley rats were used, and tracheal extraction from the donors performed by median sternotomy. The trachea was divided in two parts, performing anastomoses of hemitracheas from two different donors The implant was distended by traction from its zenith, its lumen was drained, and it was implanted into the omentum of the recipients via a laparotomy. Three groups were studied. end-to-end anastomosis group (*n* = 20); telescoping group (*n* = 20), and the control group with normal tracheas (*n* = 10) Groups 1 and 2 received immunosuppressive therapy (cyclosporin and azathioprine) and antibiotic prophylaxis (cefonicid). After 14 days the animals were killed and tracheal anastomotic segments studied and histologically graded according to a previously established scoring scheme (0, normal, 9, necrosis) Non-parametric statistical analysis was performed using the Kruskal–Wallis test

No statistically significant difference was found when the groups were compared The transplanted and anastomosed tracheas of group 1 had a normal microscopic appearance, even at the site of anastomosis However, group 2 showed moderate necrosis of the telescoped cartilage, whereas the anastomoses appeared normal

It is concluded that omentum promotes complete revascularization of anastomoses of transplanted trachea when its collapse is avoided, the lumen is drained, and the recipient receives standard immunosuppression, regardless of the type of anastomosis used

Intrathoracic muscle transposition in the treatment of chronic postpneumonectomy bronchopleural fistula

J. López Pujol, L. López Rivero*, C. Baamonde Laborda, S. Quevedo*, F. Cerezo Madueño and A. Salvatierra Velazquez, *Reina Sofía Hospital, University of Córdoba and *Pino Hospital, University of Las Palmas, Spain*

The management of postpneumonectomy empyema (PE) associated with bronchopleural fistula (BPF) remains controversial The aim of this study was to assess the effectiveness of a sequential procedure Twelve men (mean age 57 (range 40–65) years) with PE and BPF were treated. The initial diagnosis was bronchogenic carcinoma in seven patients, TBC in four and bronchiectasis in one All patients were managed initially by the Eloesser procedure When the cavity was sterilized, as judged by serial cultures, a muscle transposition was performed to close the fistula and obliterate the pleural cavity

In total, 25 myoplasties were performed. The latissimus dorsi was employed in ten cases, the pectoralis major in eight, the serratus anterior in four, the pectoralis minor in two and the intercostal muscles in one. In four patients, a partial thoracoplasty was added No major complications or postoperative mortality occurred. Mean follow-up was 28·6 (range 11–60) months. There has been no recurrence of infection or fistula and the only late death was unrelated to BPF

It is concluded that this 'two-stage procedure', which includes initial thoracostomy and delayed intrathoracic muscle transposition, is a safe and effective treatment of chronic BPF associated with PE.

Carcinoma of the lung with chest wall involvement

J. Loscertales, J Ayarra, F. Garciá, R. Jiménez, C. Arenas, A. Rico, J. Cuaresma and J.C. Girón, *Hospital Universitario Virgen Macarena, Sevilla, Spain*

Of 868 patients operated on for lung cancer, 132 (15 per cent) presented with invasion of the chest wall on clinical and surgical criteria. Of these, 15 (14 per cent) were not resected. The average age of the patients was 64 (range 48–64) years. The male:female ratio was 10:1 The histologically predominant type was squamous cell cancer in 73 per cent of cases followed by adenocarcinoma in 17 per cent The surgical operations performed were 44 pneumonectomies, 11 bilobectomies and 56 lobectomies, all of them extended (to the chest wall on 36 occasions, to the pleura on 72 and, to the diaphragm on five)

The mortality rate was 12 patients (11 per cent), caused by respiratory insufficiency five times, by sepsis three times and in the rest by other causes. It was necessary to reoperate in 14 cases (12 per cent) eight thoracostomies, three clearings of the pleural cavity with pneumonectomies; on two occasions it was necessary to complete the pneumonectomy and on one occasion to make a secondary closure of the bronchial stump with a myoplasty procedure. The survival rate of the patients in this series was 68 per cent at 1 year, 49 per cent at 2 years and 21 per cent at 5 years. The prognosis is influenced by the tumour and ganglionic state and by the extent of pneumonectomy

Video-assisted thoracic surgery

J. McCarthy, J. Hurley and A.E. Wood, *Department of Cardiothoracic Surgery, Mater Hospital, Dublin, Ireland*

Videothoracoscopic techniques have been used over a 12-month period in 41 patients to perform 44 procedures. The applications of the procedure are diverse, the approach having been used diagnostically in 23 cases and therapeutically in 21. The diagnostic procedures included lung biopsy (11), intrapulmonary masses (nine) and pleural effusion (three), and were associated with a high diagnostic yield; accurate staging of lung cancer was possible, in particular nodal status in stage III disease This technique also allows assessment of the disease process in patients with malignant pleural effusion. The therapeutic procedures included pleurectomy and blebectomy (six), excision of emphysematous bulla (one), trauma (three), lung resection (five), pericardial window (one), ligation of patent ductus arteriosus (one), closure of bronchopleural fistula (one), drainage of empyema space (two), and repair of paraoesophageal hernia (one) These procedures were associated with minimal morbidity and a short hospital stay There were no intraoperative complications in either group and we did not have to revert to formal thoracotomy in any case This experience indicates an established and an expanding diverse role for video-assisted thoracic surgery

Recurrent pneumothorax: endoscopy *versus* open thoracotomy

J.A. McKeever, Y. Ellias, M. Stokes and V. Lynch, *St Vincent's Hospital, Dublin, Ireland*

Endoscopic blebectomy (EB) is advocated as the treatment of choice for recurrent pneumothorax. A group of 28 consecutive patients who had received previous EB was compared with 157 patients who had undergone open thoracotomy (OT) to perform blebectomy during the previous 10 years

Both groups were comparable in age, sex, smoking habits and underlying pathology. Hospital stay, operative time, and recurrent morbidity and mortality were studied. Comparison was by means of Student's t test or χ^2 test as appropriate.

	EB	OT	*P*
Hospital stay (days)	4·5(2·3)	11(2·8)	0·05
Operating time (min)	31(9·9)	66(10·5)	0·05
Recurrence rate (%)	2	2	n.s.

Values are mean(s.d.). n.s., Not significant

In conclusion, endoscopic blebectomy has a shorter operative time and hospital stay. The difference in recurrence rate is not statistically significant.

Thoracoscopy in patients with thoracic trauma

R. Radev, J Kuzmanov, R. Nenkov and G. Slavov, *Department of Surgery, Medical University, Varna, Bulgaria*

Experience proves that thoracoscopy is valuable for the diagnosis of organic injuries after severe thoracic trauma. Thoracoscopy was performed for exact diagnosis in 79 patients with severe thoracic trauma and the results analysed. A rigid thoracoscope and Storz procedure was performed with local anaesthesia, combined with neuroleptic analgesia The mean age was 35·6 years, and 72 were men Blunt thoracic trauma was found in 37 (47 per cent) and, of these, 31 (84 per cent) had lung injuries, ranging from single lesions to massive intrapulmonary haematoma and parenchymal damage Pneumothorax or haemothorax was diagnosed in 35 (95 per cent) of patients with blunt trauma

Penetrating trauma was found in 42 (53 per cent). The most common injuries were to the lungs – 39 (93 per cent) patients had haemorrhage and pneumohaemothorax of differing extents Diaphragmatic lesions were found in nine patients and lesions of the heart and pericardium in five.

In conclusion, thoracoscopy enables early and exact diagnosis of patients with severe thoracic trauma, as well as giving correct indications for operative treatment Complications after thoracoscopy were not observed.

Indications for major videothoracoscopic resection: lobectomy or pneumonectomy

G.C. Roviaro, F. Varoli, C. Rebuffat, C. Vergani, S.M. Scalambra, F Grignani and M. Maciocco, *Department of Surgery, S Giuseppe Hospital, University of Milan, Italy*

A series of 21 major pulmonary resections performed between October 1991 and November 1992 is reported. The series included two left pneumonectomies, 18 lobectomies and one segmentectomy This experience represents part of a large series of 157 thoracoscopic interventions performed in the same period

The criteria for major videothoracoscopic pulmonary operations were limited to three indications

1. Benign pulmonary diseases requiring lobectomy, e.g localized purulent bronchiectasis (four patients) and an arteriovenous fistula causing severe haemoptysis (one patient)
2. Endobronchial pulmonary metastases which were removable by classic wedge resection and therefore requiring lobectomy (two patients), when the primary extrapulmonary neoplastic site was under control.
3. Primary lung cancer at stage I ($T_1N_0M_x$) requiring lobectomy (12 patients). Lymphadenectomy was performed in each case In two cases pathology revealed stage II ($pT_1N_1M_x$) disease

Left pneumonectomy was performed videothoracoscopically in two cases of small tumour involving the distal end of the left main bronchus and not susceptible to sleeve lobectomy

There were neither major operative complications nor any deaths. Five further patients intended to undergo videothoracoscopic resection were converted to open procedure because of intraoperative technical problems.

Evaluation of extended mediastinal lymphadenectomy in 5-year survival of patients undergoing resection for bronchial carcinoma

I. Troján, K. Kovács, L. Veszprémi and A. Szent-Györgyi, *Medical University Szeged, Hungary*

In the 3-year period 1985 to 1987, a randomized study was performed on 288 lung resections carried out for non-small cell pulmonary carcinoma. Alternate patients were operated on conventionally with local lymphatic resection, or received in addition extended mediastinal lymphadenectomy. Of the patients undergoing conventional surgery, two died (1·6 per cent). In this group 43 pulmonectomies and 81 lobectomies were performed. Of the group undergoing extended lymphadenectomy, three patients died (2·5 per cent); in this group there were 46 pulmonectomies and 76 lobectomies There was no significant difference in the 5-year survival rate between the two groups In cases of squamous cell carcinoma, the 5-year survival rates were 58 and 42 per cent, in favour of extended mediastinal dissection. Considering stages II and IIIA lymph node-positive squamous cell carcinoma, the 5-year survival rates were 40 and 26 per cent in favour of extended mediastinal lymphadenectomy. In adenocarcinoma the 5-year survival rates of N_1 and N_2 patients were 34 and 22 per cent; here too extended lymphadenectomy was better In large cell carcinoma the rates were 30 and 20 per cent.

On the basis of these data, lymph node sampling is performed from the upper mediastinum, the subcarinal region and the pulmonary ligament. If the cytological results are positive, extended mediastinal lymphadenectomy is performed

Operative treatment of erythrophobia

R. Wepf, *Hospital Engeried, Bern, Switzerland*

The morbid flush of the face is a most disturbing condition in adults Curative measures are inadequate. Considering erythrophobia as an organic disturbance, in 1985 systematic treatment by thoracoscopic sympathectomy under local anaesthesia was started. The sympathetic trunk was divided in thoracic segments 2, 3 and 4 on both sides over a period of 2–3 days. In all, 47 patients have undergone operation Of these, 43 were followed: 24 men and 19 women, aged from 18 to 54 years.

The results have been established by a postoperative check between 1 and 8 years However, 67 per cent (29 patients) were checked 5–8 years after transpleural neurotomy (TPN). Excellents results (no blush at all) were attained in 32 patients (74 per cent), good results (rare blush in situations of high mental tension) was seen in five patients (12 per cent) and satisfactory improvement (occasional blush, but without causing psychological problems) occurred in three (7 per cent). Relapses after 1–3 years occurred in three patients (7 per cent) These were corrected by successful reoperation. In conclusion, thoracoscopic sympathectomy is a valuable procedure to cure erythrophobia.

Training

Quo vadis, chirurgia?

M. Gergely, *Magyar Imre Hospital, Ajka, Hungary*

In 1982, long before the worldwide advent of the era of laparoscopic surgery, James D. Hardy, famous for the first lung transplantation (1963), asked the question. 'Will the general surgeon become extinct?' and suggested that among threatened species this one was worth saving. He drew attention to the danger of overspecialization, but the recent desirable spread of minimally invasive surgery is not an interdisciplinary, but more an intradisciplinary, problem The benefits are counterbalanced by many drawbacks, the largest of which is believed to be the inefficient training of young surgeons in open abdominal surgery Even before the advent of laparoscopic surgery the education of young surgeons became unsettled. partial gastrectomy was first to disappear, then vagotomy became rare, followed by choledochotomy If surgeons are undertrained how will they safely convert a laparoscopic procedure to an open one?

The new era of laparoscopic intervention opens up new vistas, but the light is linked with shadow Repeated references in Presidential Addresses on both sides of the Atlantic warn about problems with surgical training and it is an obligation of us all, the large surgical associations and the leading national surgical boards, to prepare an effective and long-term strategy for a solution to this problem

Demands on surgeons in Spain

M. Limones, J.M. Jover, J.C Ruiz de Adana, J. Lopez Herrero, J.L. Ramos, P. Artunedo and M. Moreno Azcoita, *Hospital Universitario de Getafe. Madrid, Spain*

Demands and legal procedures are rising drastically in Spain for surgeons To ascertain the main causes for this, a study has been performed which is based on surgeons' experience and the registry of the National Health System (NHS)

First, a study of the register of demands on surgeons located in the NHS in public practice since 1978 was carried out Second, a questionnaire with 14 specific questions (the same items that were the cause of demands to the NHS) was sent to 13 026 surgeons all over Spain (13 surgical specialities) The questionnaire had nine open and fifteen closed questions. Of the 13 026, 900 were sent to private practitioners

Both sets of data were analysed and compared The main causes in the NHS register were surgical delay (26·6 per cent), inappropriate follow-up (25·0 per cent) and unclear indications (21·1 per cent)

The data obtained show a similarity between public and private practice. Up to now, although demands for surgical omissions or malpractice are increasing, these are not the main causes in our country.

Comparative interspecialty operative audit

P.G. Murphy, N.H. Qureshi, D. Raj and A.C Macey, *Sligo General Hospital, Sligo, Ireland*

All operative cases during normal working hours and 'out of hours' over 1 year were subjected to a detailed retrospective comparative audit 'Working day' cases were defined as those operated on between 09.00 and 17 00 hours Monday to Friday and 'out of hours' cases as those between 17.00 and 09.00 hours during weekdays and 24 h per day during weekends and bank holidays All hospital operating specialties were reviewed. The number of cases taken to theatre was the caseload. Workload was calculated from the British United Provident Association (BUPA) schedule of procedures with allocation of intermediate equivalent values to each case. Timeload was calculated using the Voluntary Health Insurance Schedule of Procedures Interspecialty caseload, workload and timeload results are shown.

It is concluded that orthopaedic surgeons have the greatest caseload and timeload. Specific guidelines for orthopaedic workload are required Orthopaedic surgeons failed to have the greatest workload due to biases inherent in the BUPA scales, which favour general surgical operations with more detailed listing of grades. No account is taken for extra time required at orthopaedic operations.

Specialty	Caseload	Workload	Timeload
Orthopaedic	2525 (40)	1905 (31)	2481 (34)
General surgery	1588 (25)	1999 (33)	1729 (24)
Obstetrics and gynaecology	795 (12)	795 (13)	961 (13)
Ear, nose and throat	1096 (17)	707 (11)	663 (9)
Ophthalmology	402 (6)	746 (12)	1470 (20)
Total	6406 (100)	6152 (100)	7304 (100)

Value in parentheses are percentages

Meeting the standards for surgical training

N.H. Qureshi, P.G. Murphy, D. Raj and A.C. Macey, *Sligo General Hospital, Sligo, Ireland*

A 1-year retrospective audit of operative workload for surgical trainees to assess their operative exposure is presented. Operative caseload was recorded from the theatre logbooks for each consultant, registrar and senior house officer (SHO) within each specialty. Using the 1985 Wallace formula, service equivalent values (SEVs) were assigned to all surgical teams, where consultant = 1·0, registrar = 0·7 and SHO = 0·5 The workload and timeload for each grade were calculated using intermediate equivalent values (IEVs) as recommended by the British United Provident Association schedule of procedures and the Voluntary Health Insurance time scale values, respectively. Consultants undertook a mean of 55 per cent of the total operative workload, registrars 42 per cent and SHOs 3 per cent only The table shows the results for the orthopaedic specialty

	Consultant	Registrar	SHO
No. of cases	448 (55)	330 (41)	32 (4)
Workload (IEV)	428 (67)	206 (33)	1 (0)
Timeload (h)	557 (68)	253 (31)	8 (1)

Values in parentheses are percentages

Based on the Royal College of Surgeons of England 1990 recommendations for a standard general surgical team in a firm comprising one consultant, registrar and SHO (SEV 2·2), the consultant should do 45 per cent, registrar 32 per cent and SHO 23 per cent of the total workload It is concluded that the operative workload of SHOs must be increased Registrar operative workload was adequate, but was biased towards trauma Theatre logbooks should include information to assess surgical training and workload.

Scalpel-fax: the first customized hypermedia manual for surgical quality control and training

P.J. Trigwell and M.H Edwards, *Friarage Hospital, Northallerton, UK*

An educational–learning–training tool for operative surgery has been designed to satisfy the needs of a range of medical personnel from consultant surgeon to scrub nurse, from administrator to surgical equipment manufacturer For day-to-day surgery, for teaching. for reference and for quality assurance, Scalpel-fax is a user-friendly combination of well founded surgical expertise, established through years of experience, and software technology Operations (currently numbering 60) are structured in the form of concise, integral steps consisting of procedures and decisions, and are stored as ordinary text files in any word processor format. When a particular operation is selected using Scalpel-fax the corresponding file is loaded into the application and automatically converted into hypertext, each operation step being shown as a single

0007-1323/93/S096-02 © 1993 Butterworth-Heinemann Ltd

numbered card on the screen. Operations are therefore featured one step at a time, and are followed algorithmically. In this manner the user emulates a complete operation, from checking the equipment inventory to filling in a postoperation surgical report Scalpel-fax can be customized The user is able to easily modify both text and hypertext to comply with his or her own regimen No prior computer knowledge is necessary. Written in Smalltalk/v windows for use on personal computers, Scalpel-fax currently offers four main hypertext facilities: revealing explanatory notes, skipping irrelevant steps, switching operations and displaying colour diagrams and pictures Navigation of the interface is facilitated by clicking hypertext, icons and buttons with a 'mouse' Further developments will incorporate CD-ROM, sound, video and multimedia

Transplantation

Quantitative analysis of structural and ultrastructural ischaemic changes following preservation of rat liver in University of Wisconsin–Belzer and Ringer's solutions

D. Kreisel, B. Dippe, H. Petrowsky, O Richter, M. Schneider, S. Krueger, H. Frenk, U. Leuschner, H.J.C. Wenisch and A. Encke, *Departments of Surgery, Pathology and Internal Medicine, University of Frankfurt Medical Centre, Frankfurt-am-Main, Germany*

Morphological consequences of organ preservation on hepatocytes and subcellular organelles because of altered metabolism and gradual energy depletion have been quantified sequentially.

Rat livers from 60 male Lewis rats weighing 200–250 g were stored at 4°C in University of Wisconsin (UW)–Belzer and Ringer's solutions following initial perfusion. Biopsies were performed immediately after flushing and 6 h, 12 h, 24 h and 36 h after cold storage for histological and ultrastructural examinations The cellular and nuclear areas of the hepatocytes were determined using light microscopic specimens, while the extent of subcellular organelles was quantified stereologically on electron microscopic photographs (×24 000) .

Over a period of up to 36 h the size of the hepatocytes increased steadily by 20 per cent with Ringer's solution, while a reduction of 10 per cent was noted with UW–Belzer. The mean(s d) nuclear area remained unchanged at 42(5) µm^2 with UW–Belzer, while with Ringer's there was considerable swelling of up to 63(7) µm^2. This leads to significant alterations in the cytoplasmic–nuclear ratio for both solutions The cytoplasmic matrix increased by 30 per cent with Ringer's while with UW–Belzer it decreased by 20 per cent after 36 h. Steady mitochondrial swelling from 0·7 µm^2 after flushing to 1·1 µm^2 after 36 h was noted with Ringer's There was no initial (6 h, 12 h, 24 h) significant change in mitochondrial size with UW–Belzer; only after 36 h was a slight swelling to 0·8 µm^2 apparent The smooth endoplasmic reticulum showed an intense vacuolization with Ringer's; after 36 h, 9 per cent by volume of the hepatocyte count consisted of vacuolized smooth endoplasmic reticulum. In contrast to Ringer's, only 0·5 per cent by volume of the hepatocyte count in UW–Belzer was made up of vacuolized smooth endoplasmic reticulum. For both solutions there was lysosome activation, which was more substantial for UW–Belzer (7 per cent by volume after 36 h) than for Ringer's (3 per cent by volume after 36 h) Peroxisomes and Golgi complexes showed no alterations

Hypothermic ischaemia leads to cellular and subcellular alterations in the supravital liver, which are far more substantial in the case of Ringer's solution Quantitative morphological examinations seem to be appropriate in establishing assured correlations between cellular structure and function in the ischaemia–reperfusion damage within the scope of liver transplantation.

Reduction of venovenous bypass in the anhepatic phase of liver transplantation using the piggy-back technique

J.L. Lázaro, *Liver Transplantation Unit, Hospital General Universitari Vall d'Hebron, Barcelona, Spain*

Some patients do not tolerate vascular clamping during the anhepatic phase of liver transplantation and a venovenous bypass is required for haemodynamic stability Another possibility is the piggy-back technique with preservation of the inferior vena cava. The author's experience with this technique is described.

In the past 4 years, 92 adult patients underwent orthotopic liver transplantation· 31 patients with venovenous bypass, 23 without bypass and 38 with the piggy-back technique. This technique was introduced in June 1991.

Before the use of the piggy-back technique, venovenous bypass was used in 60 per cent of patients, however, bypass is necessary in only 12 per cent of cases. The length of operation and the blood transfusion requirements were significantly reduced with the piggy-back technique.

This experience indicates that the piggy-back technique decreases the need for venovenous bypass, reducing the operating time and blood transfusion.

Family liver transplantation in children: improvement in surgical technique

M. Maragakis, J. Schleef, A. Kolberg-Schwerdt, J.B. Otte, I. Kerremans, B de Hemptinne and G.H. Willital, *Paediatric Surgical University Clinic, Munster, Germany*

In the past 4 years liver transplantation has been managed by cooperation between three universities. For paediatric liver transplantation this management was successful in the following areas· collection of liver specimens, preoperative staging in children, the use of a common transplantation team, and improvement of postoperative therapy Complications and costs were thus significantly decreased

Liver transplantations were performed primarily for biliary atresia and metabolic liver diseases Liver transplantations were undertaken in 60 children using full size, split liver and a segmental technique A further two children underwent family liver transplantation (FLT), with parents the donors for left liver segments II/III Preoperative treatments, transplantation procedure and postoperative treatment were performed in cooperation with other European centres. Of 62 children, five died over a 4-year period In eight children a retransplantation had to be performed

A combined Euro-children liver transplantation team was. for safety and economic reasons, the recommended management The authors believe that in future liver transplantation in children will be by FLT using the laser, the Cusa and intraoperative duplex ultrasonography.

Orthotopic liver transplantation in the pig: the 27 first cases

P.S. Mira, E Barrosc and J R. Pena, *Hospital de Curry Cabral, Unidade de Transplantação, Lisbon, Portugal*

The first 27 cases of orthotopic liver transplantation in the pig, in which 55 animals were used, are analysed The first 19 transplants were performed with passive venovenous portojugular shunt; in the last eight an active portocaval jugular shunt with a Biomedical pump was used

Anaesthetic and surgical techniques emphasized the inherent problems to the animal's survival, water and electrolyte balance, transfusion support, organ harvesting, recipient operation, as well as anaesthetic and surgical complications during and after surgery

The outcome of the series was. two deaths during surgery, nine deaths in the first 6 h, eight deaths from 6 to 24 h, two deaths from 24 to 48 h and six pigs survived 48 h after surgery

---

Liver transplantation in patients with previous portocaval shunt

J.E. Murio Pujol, *Barcelona. Spain*

A total of 12 liver transplantations in patients with portasystemic shunts, either portacaval or distal splenorenal in one patient, have been performed in the past 2 years Orthotopic liver transplantation (OLT) was indicated for severe liver failure caused by hepatitis C postnecrotic liver cirrhosis in seven cases, hepatitis B virus liver cirrhosis in one, multifocal hepatocellular carcinoma in one, cryptogenetic liver cirrhosis with acute thrombosis of the portacaval shunt and liver failure in one, and alcoholic cirrhosis in two The mean interval between portacaval shunt and OLT was 78 (range 2–192) months. In nine cases, the piggy-back technique was used. A venovenous bypass was employed in the first case as well as when there was acute thrombosis of the portacaval shunt The portasystemic shunt made hepatectomy easier because of the absence of portal hypertension During dismantelling of the portacaval shunt, splanchnic congestion was noted, necessitating closure of the abdominal wall with a prosthetic mesh in one case The mean packed red cell transfusion was 11·3 units Transplantation in the patient with a thrombosed portacaval shunt was technically difficult, severe portal hypertension requiring a packed red cell transfusion of 51 units. There was no postoperative mortality. The clinical course was uneventful in eight cases. One patient presented with hyperacute rejection related to positive cross-match and had to be retransplanted The mean hospital stay was 35·9 (range 12–117) days. After a mean follow-up of 13·7 (range 7–23) months two patients died from recurrent viral hepatitis at 11 and 23 months respectively

0007–1323/93/S098–02 © 1993 Butterworth-Heinemann Ltd

The presence of a patent portasystemic shunt, whether central or selective, is not a contraindication to OLT and the authors are persuaded that the piggy-back technique is particularly useful in these cases.

Transplant nephrectomy: factors influencing morbidity and mortality

D.C. O'Sullivan, D.M. Murphy, P. McLean and M.G. Donovan, *Beaumont Hospital, Dublin, Ireland*

Of 1048 renal transplants performed between 1971 and 1990, transplant nephrectomies were performed in 86 recipients (8·2 per cent). Mean patient age was 33 (range 3·8–66 5) years. Postoperative complications occurred in 51 patients (59 per cent). The number and severity of complications were greater in patients with acute rejection. Four patients died: one from bowel ischaemia, two from disseminated intravascular coagulation and one from pulmonary embolism. The external iliac artery was ligated to control haemorrhage in four patients. The nephrectomy rate rose significantly ($P <$ 0 005) when cyclosporin A was initially introduced

Transplant nephrectomy is a hazardous operation. Most failed grafts can be left *in situ* without compromising patient well-being The introduction of new immunosuppressive regimens may temporarily increase indications for transplant nephrectomy.

Familial amyloidotic polyneuropathy: a new indication for orthotopic liver transplantation

P. Parrilla, P. Ramirez, F.L. Andreu, F.S. Bueno, B. Escribano, J.A. Pons, M. Miras, J.M. Rodriguez, F. Acosta and A. Munar, *Hospital Universitario V. Arrixaca, El Palmar, Murcia, Spain*

The objective of this paper is to present the long-term results of seven patients undergoing orthotopic liver transplantation (OLT) with a diagnosis of familial amyloidotic polyneuropathy (FAP) The FAP diagnosis was based in all cases on: (1) compatible neurological symptoms and electromyography, (2) family history, (3) location of amyloid in abdominal fat and sural nerve; and (4) presence of a biochemical marker of the disease in serum. The mean follow-up was 6·4 (range 4–18) months and the patient survival rate 100 per cent.

Results of the investigations showed that: (1) the biochemical marker of the disease disappeared from plasma in all cases; (2) the neurological situation was discretely improved in the two patients who had received a transplant more than 10 months previously, and (3) electromyography neither improved nor worsened in any of the cases

In conclusion, it is believed that, while a less aggressive solution is awaited, a liver transplant may be useful in the treatment of certain patients with FAP to halt the neurological deterioration of the disease.

Facultative sequential immunosuppression in renal transplantation

A. Ruddle, A.H. Davies, B. Webster, R McGonigle and J.F.L. Shaw, *Derriford Hospital, Plymouth, UK*

Cyclosporin toxicity can impair the results of renal transplantation. The use of a facultative sequential immunosuppression regimen may help to avoid this phenomenon.

Such a regimen used in a district general hospital has been prospectively reviewed At surgery the recipient receives 500 mg methylprednisolone and then cyclosporin depending on the urine output (UO) at 6 h If UO >250 ml, the patient is given cyclosporin 10 mg kg^{-1} day^{-1} orally plus prednisolone 10 mg day^{-1} orally. If UO <250 ml, the patient is given azathioprine 2 mg kg^{-1} day^{-1} orally plus prednisolone 30 mg day^{-1} orally. When UO >500 ml, cyclosporin 2 mg kg^{-1} day^{-1} orally is added and later increased as the urinary creatinine level falls

Over a 6-year period from 1986, 165 cadaveric renal transplants have been performed using the above regimen for recipient immunosuppression The cumulative 1- and 5-year graft survival rates are 92 and 84 per cent respectively. The cumulative 1- and 5-year patient survival rates are 94 and 86 per cent

In conclusion, the above protocol has been shown to be an effective method of immunosuppression, avoiding the problem of cyclosporin nephrotoxicity while the graft recovers from preservation damage.

Trauma

Injuries and their management in Australian aboriginals

D.D. Beard, *Modbury Hospital and Road Safety Advisory Council, Adelaide, South Australia*

The Australian aboriginals are not war-like. If they came originally from somewhere in south central Asia and migrated south-east across interconnecting land masses, they may have been escaping from more belligerent races There was never any large armed resistance to white settlement. When small tribes resisted they were easily overcome, particularly because of the dominance of white firearms. Within Australia there was little major intertribal fighting and most of it for protection of tribal areas Most fighting was personal and frequently related to insults or arguments relating to women.

The management of injuries in the Australian aboriginals is discussed The aboriginal medicine man was a man of high degree. He had specific training. His work was involved mainly in illnesses and problems of the mind The actual management of injuries was most often carried out by tribal elders. The work of the medicine man and the methods of management of injuries are discussed

Cervical spine injury in patients with facial fractures

J.C. Beirne, P.E.M Butler and F.A. Brady, *Departments of Maxillofacial and Plastic Surgery, St James's Hospital, Dublin, Ireland*

A prospective 1-year study was undertaken to document the incidence of concomitant fracture of the cervical spine with facial trauma A total of 582 consecutive patients with facial fractures referred to the National Referral Centre at St James's Hospital (from 1 January 1992 to 31 December 92) were included in the study Some 1 04 per cent (n = 6) of patients with facial fractures were found to have associated cervical spine injury All of the cervical injuries occurred in the subgroup of patients with facial trauma following road traffic accidents (n = 94), resulting in an incidence in this subgroup of 6 per cent. Five of the six patients had associated multiple injuries. All six had facial lacerations and five had mandibular fractures Each of the six patients complained of either neck stiffness or pain Only two of the six cervical fractures (two patients with fractures of C2) were observed on standard three-view plain cervical radiographs. Four of the fractures were seen on computed tomography (CT): the two patients with fractures of C2 and two patients, one with compression fracture of the vertebral body of C4 and the other with comminuted fracture of the vertebral body of C7 Two patients had fractures that were diagnosable only on stress views under radiographic screening (subluxation of C4/C5 and subluxation of C5/C6).

This study illustrates the need for a high index of suspicion of associated cervical injury in patients with facial fractures, especially after high velocity type injury It also illustrates that negative plain radiographs may require further radiographic investigation (CT or stress views) and it exposes the limitations of CT in the diagnosis of ligamentous injury of the cervical spine in which stress views under radiographic screening of the spine are of value.

Abdominal trauma

P.L.O. Broos, *University Hospital Gasthuisberg, Leuven, Belgium*

Unrecognized abdominal injury remains a frequent cause of preventable death. In penetrating trauma the diagnosis may be very clear when there is obvious damage to the abdominal wall and bowel is protruding Penetrating trauma to the chest, back, buttocks and perineum should also arouse suspicion that the peritoneal cavity has been breached. In gunshot wounds mandatory exploration is the preferred approach for diagnosis In stab wounds without other clear physical findings the wound is explored under local anaesthesia In cases of fascia penetration, peritoneal lavage is helpful.

In blunt trauma, the peritoneal signs are often subtle, overshadowed by pain from associated injury and masked by head trauma or intoxicants. Diagnostic peritoneal lavage remains the cornerstone of triage in patients with life-threatening blunt abdominal trauma. Routine ancillary tests for potentially occult injuries include nasogastric tube placement for ruptures of the left diaphragm, Gastrografin contrast study for duodenum perforation and pyelography for urological injury Ultrasonography may become a valuable tool in the initial assessment of the injured abdomen. Computed tomography is useful as a complementary diagnostic tool in selected patients and is the critical test for guidance of non-operative management of known intraperitoneal trauma

Ultimately, the most important principle in the management of blunt abdominal trauma is repeat physical examination by an experienced surgeon

Surgical treatment of brain injuries caused by firearms

Ž. Djordjevic, V. Antunović, B. Nestorović, B. Djurović and I. Jovanović, *Neurosurgical Department, University Clinical Centre, Belgrade, Serbia*

A total of 1401 patients have been examined in the University Clinical Centre in the period from the beginning of war in 1991 until 1 November 1992. In all, 1095 patients were admitted to the Emergency Centre and 139 of these were treated in the Neurosurgical Department. The age of the patients ranged from 18 to 76 years. Death occurred in 67 (48 per cent) patients Most of the patients (114) were aged between 18 and 40 years A Glasgow Coma Score (GCS) < 8 was seen in 78 patients, of whom 23 (30 per cent) survived. The group of patients with GCS ⩾ 8 comprised 61 patients, with a survival rate of 82 per cent (11 patients died).

The best prognosis may be given to the cases with tangential skull injuries (of 17 cases only two died).

Intracranial pressure monitoring in critically ill patients

O. Esch, G.W. Froeschle, J V. Wening, O. Moellenberg and X. Rogiers, *University of Hamburg, Germany*

Implantation of an intracranial epidural pressure sensor in patients with presumed increase in intracranial pressure (ICP) can be performed for documentation purposes to aid in treatment, and for monitoring of therapy

During the past 5 years, ICP monitoring was performed in 65 traumatized patients, and in 11 patients after liver transplantation After complete neurological evaluation and cranial computed tomography, the sensor was implanted under sterile conditions on the intensive care unit. Two types of sensor and monitoring system were used; each was studied for practicability of implantation and long-term monitoring as well as for reproducibility of results and correlation of ICP with clinical parameters

The procedure took ⩽ 35 (mean 23) min for completion. Complications were minimal. No infection was documented, but in one patient with acute hepatic failure intraoperative bleeding from the site of the sensor eventually led to its removal In 26 patients, increased ICP was found that did not correlate with clinical parameters, this led to therapeutic consequences (hyperventilation, barbiturate use, diuresis, osmodiuresis) In spite of modification of surgical technique and the use of other monitoring systems, in 19 patients increased ICP as recorded by the present system did not meet clinical standards or could not be reliably reproduced.

As a result, the use of a single system in the authors' institution was agreed, and the technique of implantation and monitoring standardized such that regular interdisciplinary training of all personnel involved can be performed This has led to reliable ICP monitoring over the past 14 months

Injuries of the small and large intestine

D. Gaidamonis, *Vilnius University Emergency Hospital, Vilnius, Lithuania*

A total of 261 patient were treated for injury to the small and large intestines. Most were young people aged 20–40 years The main reason for injuries were knife and crash wounds Overall, 175 patients had injured

0007–1323/93/S100–05 © 1993 Butterworth-Heinemann Ltd

small intestine, 92 penetrating and 83 blunt injuries. The jejunum was injured in two-thirds of cases. The stomach was injured in 47 patients After primary repair a special tube for enterodecompression was used Mortality rate from injuries of small intestines was 11·4 per cent With injuries of the large intestine were 86 patients. In one-third of cases the transverse colon was injured, less commonly the sigmoid or ascending colon In all, 167 patients (64 per cent) with damaged small and large intestine underwent primary repair, 27 (10 per cent) had resection and anastomosis, two had resection and exteriorization, 37 (14 per cent) resection with ileostomy or colostomy and 30 (11 per cent) only ileostomy or colostomy. Morbidity and mortality rates correlated with the severity of associated injuries and also the time interval between accident and operative treatment The most frequent complication was suppuration of the wound. Thirty-five patients died, a mortality rate of 13 4 per cent. The most frequent cause of death was peritonitis or shock

Unreamed nailing technique in compound tibial fractures: a comparison with external fixation

W. Knopp, P.A.W. Ostermann, J. Buchholz and G. Muhr,
Trauma Centre 'Bergmannsheil', University of Bochum, Bochum, Germany

This study aimed to determine the efficacy of an unreamed nailing technique compared with external fixation in open tibial shaft fractures. Between 1986 and 1992, 204 compound fractures of the tibial shaft were treated by either unreamed nailing or external fixation. Since June 1992 an unreamed titanium nail has been additionally implanted. In total, 165 fractures underwent external fixation, 22 were stabilized with the unreamed nail and 14 were treated by reamed nailing. Three fractures were managed conservatively

Of the fractures treated, 192 healed Three IIIC fractures required subsequent amputation. A deep bony infection was observed in seven cases (3 4 per cent); 35 received autogenous cancellous bone grafts. In three cases a transport corticotomy was performed owing to large bony defects. In 17 cases the procedure was changed: cases with external fixators were changed to plates in eight patients, to unreamed nails in two, and to reamed nails in four The unreamed nail was changed to a reamed nail in three patients due to either a varus or a valgus deformity. Breakage of the locking bolts occurred four times in regular unreamed nails. There was no effect on the bony consolidation

In distinction to the external fixator the unreamed nail is more comfortable for the patient. In addition there is no increased risk of infection, although the regular unreamed nail is a less stable implant that might require a change to a reamed nail after consolidation of the soft tissue The titanium unreamed nail offers more stability with primary fracture healing.

Mesenteric and bowel injuries after blunt abdominal trauma

J.P. Letoquart, N. Kunin, A. La Gamma and A. Mambrini,
Service de Chirurgie Générale A, CHU de Rennes, Rennes, France

This study aimed to analyse the distribution and severity of the lesions, the types of accident and the diagnostic and therapeutic aspects of patients with mesenteric or bowel injuries after blunt abdominal trauma. Twenty male and four female patients (mean age 39 years) were victims of 17 vehicle crashes (16 car occupants and one motorcyclist) and seven direct abdominal impacts in civilian life Twelve victims of car accidents were under 40 years of age. Fourteen patients occupied the driver's position and eight used a seat-belt

Thirteen patients developed hypotension and shock after injury. The average time between the accident and surgical exploration was 39 h The findings were 14 small bowel perforations, seven colonic perforations and 15 mesenteric ruptures. Twelve patients had an associated abdominal injury: six hepatic, five splenic and five pancreatic Fourteen patients had an associated thoracic injury

Nine small bowel resections, eight intestinal suturings and one Hartmann's operation were carried out There were two deaths (8·3 per cent) and 13 surviving patients had postoperative complications (59 per cent). Mean hospital stay was 24 days

In conclusion, the use of a seat-belt and the type of accident were not related to the type of abdominal injury. However, morbidity and mortality were closely related to the existence of an associated abdominal or thoracic injury.

GEMIS: a new acronym for polytrauma illness

F. Meneghini and L. Stellin, *'G D'Annunzio' University, Chieti, Italy*

Multiple and sequential organ failure after trauma or major surgery was described in the mid-1970s Up to now, denomination of this syndrome has been based on clinical signs and symptoms appearing only at the end stage of the illness. Manifestations of multiple organ failure (MOF) are the end result of anatomopathological damage produced by deregulation and loss of many homoeostatic and self-protecting mechanisms of the body, which are activated in an abnormal way by hypo-oxygenation, tissue disruption and necrosis

Oedema is the first step in such pathological change, and it arises from microcirculatory damage. Studies performed by the authors with multiple trauma patients demonstrated that oedema occurs in different organs at the same time, instead of taking place in one organ after another in a step-by-step pattern, as assumed by other workers. Specimens of tissues and organs were taken at different times after the primary event. All tissues examined by light microscopy showed signs of inflammation and oedema shortly after trauma This is consistent with the hypothesis that microcirculatory damage arises immediately after major trauma, is widely and simultaneously distributed in all body tissues, and shows its effects in various organs at different times only because of dissimilar functional reserves of each organ The main pathological event in MOF, therefore, is the structural and functional damage to the microcirculation.

MOF, MSOF (multiple system organ failure) and multiple organ dysfunction are therefore incomplete names for the syndrome, because they refer only to late clinical events A new acronym has been coined – GEMIS (generalized endothelial microcirculation injury syndrome), highlighting the common early pathological event (generalized endothelial damage) present, even if latently, from the beginning in patients developing MOF Therefore acute respiratory distress syndrome, hepatic, renal, intestinal, cardiac and cerebral failures have to be considered as 'symptoms' of GEMIS instead of distinct clinical syndromes. Respiratory function is always the first to fail, because of the delicate alveolar capillary structure.

Haemorrhage from pelvic fracture

M.C. Moss, N. Pinto and M.D. Bircher, *St George's Hospital, London, UK*

Haemorrhage is the leading cause of mortality in patients with pelvic fracture The pelvis provides a large 'hidden' space into which haemorrhage can occur. To date there has been no reported correlation between pelvic fracture displacement and pelvic volume However, anecdote suggests that a small displacement leads to a relatively large increase in pelvic volume. Ten skeleton pelves were sealed with elastic membranes, and the volume of the true pelvis measured by filling a polythene balloon with water. Fixed-width blocks of progressive 1-cm increments were inserted at the pubic symphysis to simulate diastasis, and the volume measurements repeated. Further groups of measurements were made to simulate both disruption at the sacroiliac joints, and combined separations of both the symphysis and sacroiliac joints. For each 1-cm widening at the pubic symphysis there is a 4·6 per cent increase in the volume of the true pelvis; for each 1-cm displacement at the sacroiliac joint there is a 3·1 per cent increase.

These results demonstrate that a wildly displaced fracture that, for example, widens the symphysis by 10 cm and opens a sacroiliac joint by 3 cm, increases the pelvic volume by only 55 per cent. There is therefore a relatively small increase in pelvic volume with fracture displacement The increase in blood loss is accounted for by the associated soft tissue damage to the pelvis, which occurs during maximal displacement at the time of injury Haemorrhage occurs both into the pelvis and through the disrupted soft tissue envelope, out of the pelvis. Restoration of bony stability is therefore important for stabilization of the soft tissues to allow tamponade and clotting, and to prevent subsequent clot displacement External fixation of the acutely injured pelvis does have the effect of reducing pelvic volume but, probably more importantly, it helps the pelvic basin to stop leaking.

Operative treatment of fracture of the os calcis

D. O'Farrell, J. McCabe, J. O'Byrne and M. Stephens, *Mater Misericordiae Hospital, Dublin, Ireland*

A prospective study of 24 patients with displaced intra-articular fractures of the os calcis was performed to compare operative with non-operative management of these problematic injuries. Twelve patients underwent internal fixation of the calcaneus followed by early mobilization and 12 were managed non-operatively, also with early mobilization. All patients were reviewed 15 months later using eight parameters to assess outcome.

Of the 12 patients who had internal fixation, eight had returned to work. Pain-free ambulation distance was significantly longer (mean 4 km) in this group and only one patient complained of footwear problems, a unilateral change in shoe size. Of the 12 patients who were managed conservatively, only three had returned to work and eight had a unilateral increase in shoe size, while the mean pain-free walking distance in this group was only 1 km. The mean range of subtalar movement was 24° in the operated group but only 12° in the conservatively treated group ($P < 0{\cdot}05$). Radiological follow-up demonstrated partial or full restoration of Bohler's angle in the patients who underwent internal fixation. Plating of calcaneal fractures through a lateral approach for optimal results is recommended when managing displaced intra-articular fractures in patients under 40 years old.

Ankle ligament tears in sport: the role of magnetic resonance imaging

D. O'Farrell, J. McCabe, W. Curtin, J. Stack and M. Stephens, *Mater Misericordiae Hospital, Dublin, Ireland*

The purpose of this study was to ascertain the precise benefits of magnetic resonance imaging (MRI) in lateral ankle ligament tears and to establish whether this method bears any advantage over conventional diagnostic modalities when assessing these injuries. A total of 54 patients, all of whom had acute lateral ligament tears with positive stress radiographs, were reviewed by an orthopaedic surgeon. All patients then underwent a technetium isotope scan to screen for the presence of osteochondral fractures or additional soft tissue injury. Patients demonstrating marked uptake of isotope were further assessed using ankle MRI. Of 54 bone scans, 17 were normal and 16 showed minimal isotope uptake. The remaining 21 had increased uptake which suggested post-traumatic synovitis in 16 and deltoid ligament injury in 12. MR images in these 21 individuals confirmed anatomical lateral ligament tears in only seven patients, and deltoid ligament tears in nine. MRI detected otherwise undetected joint effusions in four patients. There were five osteochondral fractures in the whole series (three talus, one lateral and one medial malleolus), all of which were suggested on bone scan, but only three of which were shown on MRI.

We recommend screening with plain stress radiographs and scintigraphy to improve diagnostic accuracy in ankle ligament injuries and propose that MRI be reserved for patients whose radiograph or bone scan suggests a more severe injury or fracture.

Scene or emergency room thoracotomy for patients with severe trauma

S.F. Purkiss, A.J. Wood, F.W. Cross and T.R. Graham, *Department of Surgery, The Royal London Hospital, London, UK*

Resuscitative thoracotomy (RT) for trauma is only occasionally successful. In previous reports RT has been delayed by the time for transfer from the scene to the emergency department. In the London area the Helicopter Emergency Medical Service (HEMS) provides early medical attention at the scene, so widening the scope of field resuscitation procedures available; this has included RT for severe and blunt trauma.

During the period from 1990 to 1991, RT was performed by non-thoracic surgeons on 16 patients (15 men and one woman of median (range) age 25 (9–38) years) from a total of 1084 HEMS missions. Nine procedures were performed at the scene and seven in the casualty department. Medical attention was administered a median(s.i.r.) 16·2(4·0) min from the initial call to the ambulance service. The median(s.i.r.) Injury Severity Score was 29·9(11·8) for all patients and was not statistically different between patients having RT at the scene or in casualty. The time spent at the scene was significantly greater for those patients undergoing RT (35·1 *versus* 16·2 min, $P < 0{\cdot}01$). No patient survived RT but temporary improvements occurred more frequently in patients with penetrating injuries.

These results demonstrate that RT has limited efficacy and lend support to the concept that a 'swoop and scoop' policy should be adopted for patients at the scene after initial simple resuscitation techniques have been implemented. Thoracic surgical expertise should be sought early in the management of these patients when they arrive in the casualty department.

Hepatic injuries

I. Rodriguez, J. Cruz, J. Otero, J. Druet, R. Garrido and N. Gonzalez, *Hospital Ntra Sra del Prado, Talavera, Spain*

From January 1984 to December 1990, 1326 injured patients were admitted. The most frequent cause of admission was head injury. Some 265 (20·0 per cent) needed surgical treatment and 164 (12·4 per cent) underwent emergency laparotomy. Of these 164 patients, 57 (34·8 per cent) had liver injuries, 47 of whom were male with a mean age of 32 years. The most common cause of hepatic injury was motor vehicle accident (43), and 49 patients suffered from blunt trauma. Peritoneal lavage is the best diagnostic method. A total of 23 patients had hypovolaemic shock in the emergency department. Hepatic injuries were frequently associated with injuries in others areas of the body, such as the thorax (28) and head (23).

All patients had laparotomy. Some 62 lesions were found in 57 patients. The right lobe was more frequently injured, especially segments VI–VII. A total of 65 per cent had Moore grades I–IV. Liver injuries were frequently associated with other lesions, for instance retroperitoneal haematoma (14) and splenic injury (12). Of the 62 lesions, 57 were treated conservatively: 43 had hepatic sutures, seven haemostasis (direct compression, electrocautery or haemostatic substances) and seven no procedure. Partial hepatectomy was performed in five patients, of whom three also needed gauze packing to control bleeding. Twenty-seven patients were admitted to the intensive care unit after operation. Eight patients suffered complications. Reoperation was rare – six cases plus three to remove hepatic packing. The mortality rate was 9 per cent (five patients, two of whom died during surgery).

Motor vehicle accident is the major cause of injury. Liver trauma is the most common intra-abdominal injury in multiple trauma patients. Resection surgery is rarely required. Mortality and morbidity rates are low.

Management of isolated large bowel gunshot injuries

L. Roostar and M. Murruste, *Tartu University, Tartu, Estonia*

This retrospective study reports the treatment of 384 unselected patients with isolated large bowel or large and small bowel gunshot injuries (56 per cent of the total number of patients with large bowel injuries). Rectal injuries have been excluded from this study. Most of the wounds were in the ascending colon (116 cases) and transverse colon (122 cases).

The surgical technique chosen depended on the general condition of the patient and the size and severity of the damage. Bowel injuries with a diameter of < 2 cm with intact mesenteric blood supply (27 cases) were sutured. The wound was sutured followed by exteriorization of the bowel in 76 cases, extraperitonealization in 47 cases and proximal colostomy in 106 cases. The bowel was exteriorized in 50 cases.

Resection was indicated for major wounds, multiple injuries in a segment, partial or total rupture of the bowel and mesenteric injuries. Ascending hemicolectomy was performed in five cases and ascending colon resection with colostomy and ileotransverse anastomosis in 23 cases. Transverse colon resection with proximal and distal colostomy was performed in nine cases and with total proximal colostomy in 41 cases. The mortality rate was 30·5 per cent.

A systematic approach to the surgical treatment of traumatic enophthalmos

J.M. Ryan, M. McGurk and T.G. Arayathinal, *Maxillofacial Surgery Department, Guy's Hospital, London, UK*

Enophthalmos describes the backward displacement of the globe owing to traumatic disruption of the bony orbit. It leads to diplopia and cosmetic defect. The surgical treatment of enophthalmos has historically been empirical and unpredictable. This paper describes a systematic approach for the management of traumatic enophthalmos. Enophthalmos is measured before operation using an exophthalmometer The orbital volume is assessed radiologically using a low-dose computed tomographic scanning technique, utilizing 10 per cent of the conventional radiation dose. The surgeon can therefore identify before operation the implosion sites and quantify volume changes Bone grafts are harvested by a trephine technique from the iliac crest, and can then be modelled to the appropriate volume and shape using a purpose-built steel bone press This systematic approach has been used in ten cases with satisfactory results in nine.

Traumatic hip dislocation

J.-P. Stahl, K. Kunze, J. Buhr, Th. Zimmermann and K. Flechsenhar, *Department of Trauma and Emergency, Justus Liebig University, Giessen, Germany*

Between January 1990 and April 1992, 13 patients with traumatic hip dislocation were treated in the authors' surgical department. In two cases, dislocation of the hip occurred alone, without any bony injury. In two other cases, the hip dislocation was accompanied by fracture of the upper femur. In three of the 13 patients, Pipkin dislocation fractures were seen, while in six the traumatic hip dislocation was combined with fracture of the acetabulum. Traumatic hip dislocation is an injury that affects almost exclusively younger patients

Follow-up was carried out in seven patients Clinical examination included radiography and sonographic procedures Patients in whom no metal had been implanted had additional magnetic resonance imaging (MRI) studies A large variation was seen in the amount of periarticular calcification. MRI revealed no damage to the cartilage in patients with pure dislocation The overall range of motion at follow-up was 64–100 per cent, compared with the healthy side

When treating traumatic hip dislocation we emphasize the importance of physiotherapy and early mobilization without weight-bearing within 12 weeks of trauma The best results were seen in patients with a pure hip dislocation without associated fracture of the hip.

Primary arthroscopy and transarthroscopic treatment of fractures

St. Sundermann, U. Schutz and W.-R. Dingels, *Sana-Krankenhaus, Cologne, Germany*

Since 1990, 254 cases of primary arthroscopy have been performed in injuries of the ankle joint Indications for arthroscopy are determined by the presence of haemarthrosis, for the exclusion of concomitant osteochondrial fractures, the graduation of lateral ligament ruptures on video-screening, post-traumatic locking of the joint except for osteochondritic lesions, loose bodies, hypertrophic synovitis and radiological evidence of arthrosis Arthroscopy is performed under local or general anaesthesia and using a 5-mm arthroscope with 30° telescope The findings are filmed for documentation In all, 89 per cent of patients presented a haemarthrosis with different forms of lateral ligament rupture, 32 per cent showed additional osteochondral fractures and loose bone flakes, of which 9 per cent had to be operated on transarthroscopically or by arthrotomy Lateral ligament ruptures are only treated operatively by 'held' radiograms in anaesthesia with a subluxation of the foot more than 20°. Currently, fractures of the lateral and medial malleolus are treated by transarthroscopic osteosynthesis After operation there was one case of persistent irritation of the superficial peroneal nerve It is believed that arthroscopy should be extended to the ankle joint

Prognostic indicators of multiple organ system failure and mortality in a surgical intensive care unit

D.D. Tran, *Free University Hospital, Amsterdam, The Netherlands*

Multiple organ system failure (MOSF) is a complex syndrome with many known inter-related risk factors To account for such inter-relation, multivariate statistical methods were used to study factors related to the extent of MOSF and mortality in a large group of critically ill patients from a surgical intensive care unit (ICU). Criteria for chronic disease, malnutrition and infection were defined according to the literature A previously defined MOSF score, varying from 0 to 14, was used to quantify the extent of MOSF.

During a 1-year period (1987), 538 patients were consecutively admitted to an ICU. Mean(s.d.) age was 55 5(19 1) years Mean(s d) Acute Physiology and Chronic Health Evaluation (APACHE II) score was 5·9(5·6) Malnutrition and infection occurred in 33 per cent and 19 per cent of patients respectively Enterobacteriaceae were found in 60 per cent of infected patients. Infection was associated with an increasing MOSF score ($P < 0{\cdot}001$) Multiple linear regression selected advancing age, malnutrition, APACHE II score, shock and coma on admission, number of blood transfusions in the first 48 h, use of H_2-receptor antagonists (H_2-RA) and antacids, bacteraemia and intra-abdominal infection as independent factors related to the MOSF score Overall mortality rate was 11 per cent Mortality rate increased with rising age, malnutrition, and with the APACHE II score (all $P < 0{\cdot}001$) Furthermore, mortality was not only associated with the MOSF score, but also with the degree of malfunction within each individual organ system (both $P < 0\,001$). Multiple logistic regression selected advancing age, malnutrition, coma on admission, number of blood transfusions in the first 48 h, bacteraemia, APACHE II and MOSF score as major predictors of mortality

In conclusion, APACHE II score is positively correlated with the extent of MOSF Advancing age, malnutrition, shock and coma on admission, number of blood transfusions in the first 48 h, use of H_2-RA and antacids may impair host defences of the gastrointestinal tract and predispose to invasive infection, thereby aggravating the severity of existing MOSF These findings, together with the predominance of Enterobacteriaceae in infected patients, suggest that translocation of intestinal bacteria and endotoxin may be important in initiating and perpetuating the MOSF septic state in surgical patients with critical illness

Subtrochanteric fracture of the femur: results of treatment with the 95° condylar Blate plate, Gamma nail and dynamic condylar screw

P. Vanderschot, L. Verheyen and P.L.O. Broos, *University Hospital Gasthuisberg, Leuven, The Netherlands*

During a 10-year period 214 subtrochanteric fractures of the femur were treated at the Katholic University Hospital of Leuven Of these, 153 fractures were treated either with the 95° condylar Blate plate, a dynamic condylar screw (DCS), or a Gamma nail Retrospective analysis of the results was made.

A total of 77 men and 76 women were treated (mean age 64 years). Of these, 36 men and 14 women were injured in road traffic accidents. In almost all the other patients a simple fall or a fall from a height was the cause of injury The Injury Severity Score (ISS) ranged from 13 to 57 The mean ISS in men was 20, compared with 16 in women.

Of the fractures, 105 were treated with a 95° condylar Blate plate. There were six cases of delayed union (> 6 months), seven malunions and three non-unions Reoperation was necessary in four cases (three pseudarthrosis and one fracture of the Blate plate) Twenty-eight fractures were treated with a DCS Delayed union occurred in two cases, malunion in five and a reoperation was carried out twice (one cutting out and one loosening of the screws) The Gamma nail was used in 20 patients· malunion occurred in six cases and in five patients a second operation was necessary (two fractures at the tip of the Gamma nail, one Gamma nail was badly positioned and two cutting-out problems). Subtrochanteric fracture treated with a condylar Blate plate yielded better radiographically proven end results and the failure rate with this technique was less than with the DCS or Gamma nail. However, with a DCS or Gamma nail rapid mobilization is possible

Amputee sports

R.J. Watts, *Prosthetist to the British Paralympic Team 1992*

This paper covers two sporting events involving amputees, the IXth Paralympic Games held last year in Barcelona and the forthcoming sixth Whitbread round-the-world yacht race

Last year saw a spectacle that any athlete would have been proud to have participated in, the IXth Paralympic Games in Barcelona. The British Broadcasting Corporation screened a 1-h programme on the Paralympics on Christmas Eve The 1992 Paralympic Games slogan 'Sport without limits' was designed to bring two significant points into focus. the efforts made to bring about the full integration of disabled or physically challenged people through sport and the great numbers of teams and athletes participating.

The second event, the Dolphin Challenge, highlights the determination of the disabled to convert disadvantage into advantage The Dolphin project's boat was designed by Rob Humphries and built by Vision Yachts on the Isle of Wight, UK. It will be crewed completely by the disabled, blind, deaf and limb deficient. The Whitbread round-the-world yacht race will start on 25 September 1993. An estimated 30 boats will travel 32000 nautical miles in 9 months.

Outcome of patients with head injuries rescued by a helicopter emergency service in a metropolis

J.N. Wilden, J.C. Sutcliffe, R. McAvinchey, C.J.C. Kirk, H. Hetherington, S.E. Turvey, A. Wilson, I.G Wylie and E S. Watkins, *Departments of Neurosurgery, Neuroradiology and Helicopter Emergency Medical Service, Royal London Hospital, London, UK*

This study was undertaken to demonstrate that early management of head injuries reduces disability

Head-injured patients are resuscitated at the scene by a doctor and transported to the Royal London Hospital by helicopter. Severity, type and outcome of head injury are measured using the Glasgow Coma Score, Traumatic Coma Data Bank computed tomography brain scan classification and Glasgow Outcome Scale at 6 months.

A total of 112 patients sustaining head injuries with Abbreviated Injury Score ≥ 1 were recorded between September 1990 and December 1991. At the accident scene, the mean Glasgow Coma Score was 7, pulse oximetry was reduced in 35 per cent of cases and 60 per cent of patients were ventilated Average time from injury to helicopter arrival was 24 min. Average time to remove intracranial haematomas was 189 min Some 90 per cent of patients sustaining a diffuse I head injury and 60 per cent a diffuse II injury achieved 'independence' compared with 61 per cent and 35 per cent respectively in the Traumatic Coma Data Bank ($\chi^2 = 18\ 05$, 2 d.f., $P < 0\ 001$).

Reasons for these significantly different results will be discussed in relation to the methods of measuring head injuries and achieving 'rapid resuscitation' and 'early definitive neurosurgical care'

Urology

Role of the ipsilateral testis in the contralateral biochemical changes seen after unilateral spermatic cord torsion

F.M. Akgur, K. Kilinç* and T. Aktuğ, *Department of Paediatric Surgery, Dokuz Eylül University Medical Faculty, Izmir and *Department of Biochemistry, Hacettepe University Medical Faculty, Ankara, Turkey*

Unilateral testicular torsion has been shown to cause a decrease in contralateral testicular blood flow. The stimulus triggering this contralateral change may be transmitted either neurally or humorally. An experimental study was conducted to investigate whether the presence of the ipsilateral testis is necessary for the transmission of changes in contralateral testicular perfusion seen during unilateral spermatic cord torsion. Adult male albino rats were divided into four groups, each containing ten rats. In group 1 rats, basal values of biochemical parameters were determined Group 2 rats were subjected to unilateral spermatic cord torsion in the presence of the ipsilateral testis. Rats in group 3 underwent unilateral spermatic cord torsion after ipsilateral orchidectomy. Orchidectomy was performed by transecting the gubernaculum inferiorly and the efferent ductules superiorly Testicular artery and vein were ligated at the proximal pole of the testis. The testis was excised leaving intact epididymis attached to the spermatic cord. Rats in group 4 underwent unilateral orchidectomy without torsion.

Both testes and the right kidney were harvested at the end of experiments Levels of lactic acid, hypoxanthine and thiobarbituric-reactive products of lipid peroxidation were determined in testicular tissues and kidneys. Values of these three parameters obtained from rats in the orchidectomy alone group (group 4) did not differ significantly from basal values ($P > 0\cdot05$) Lactic acid, hypoxanthine and lipid peroxide levels all increased significantly in the contralateral testis but not in the kidney after unilateral spermatic cord torsion in the presence of the ipsilateral testis (group 2 animals) compared with basal values ($P < 0\cdot05$) Unilateral spermatic cord torsion in the absence of the ipsilateral testis (group 3) also produced significant increase in the values of intratesticular biochemical parameters in the contralateral testis compared with basal values ($P < 0\cdot05$) but, again, changes in the kidney were not significant ($P > 0\cdot05$).

It is concluded that the ipsilateral testis does not play a role in transmitting these contralateral changes

Morbidity of urinary diversion in patients undergoing pelvic exenteration for gynaecological malignancy

F. Bladou, G. Houvenaeghel, J R. Delpero, F. Granger and G. Guerinel, *Institut J. Paoli–I. Calmettes, Marseille, France*

A total of 97 patients undergoing pelvic exenteration for gynaecological malignancies (anterior 36, posterior 26, total 25, atypical ten) from 1980 to 1992 are reported. Of these, 69 patients had undergone previous radiotherapy Sixty-three urinary diversions were performed, 15 direct cutaneous ureterostomies, four digestive conduits, one enterocystoplasty, and one wet colostomy. Altogether, 112 surgical procedures associated with pelvic exenteration were performed, including six nephrectomies, seven ureteric reimplantations and seven partial cystectomies.

There were seven (7 per cent) short-term urinary complications (three urinary fistulas and four urinary and digestive fistulas on irradiated bowel). There were 37 surgical complications in 29 patients The majority of short-term surgical complications occurred in patients with previous radiotherapy > 45 Gy ($P < 0\cdot05$), total pelvectomy ($P < 0\cdot01$) and ileal conduit used for urinary diversion ($P < 0\cdot05$). There were ten long-term urinary complications· stenosis of cutaneous ureterostomy in five, stenosis of ureteroileal anastomosis on ileal conduit in two, and urinary fistula in three

Direct cutaneous ureterostomy is the simplest procedure for urinary diversion, but necessitates two stomas and has a high rate of stomal stenosis Ileal conduit requires only one stoma but has a high rate of fistula in irradiated patients. The use of a segment of unirradiated bowel (jejunum or transverse colon) constitutes the preferred method of urinary diversion in patients undergoing pelvic exenteration after previous radiotherapy Improved perioperative support and surgical technique have decreased postoperative mortality and morbidity rates. We propose pelvic reconstruction (i e. coloanal anastomosis, vaginal reconstruction and continent urinary diversion) after pelvic exenteration in young patients with gynaecological malignancy

Prostate thermotherapy: subjective and objective outcomes correlated in 6-month follow-up study of treatment *versus* sham groups

G.P.C. Dawkins, N.W. Harrison, M.G. Royle and M.S. Fletcher, *Department of Urology, Brighton General Hospital, Brighton, UK*

The technique of prostate thermotherapy has been fiercely criticized as a treatment for benign prostatic hypertrophy (BPH) bladder outflow obstruction on account of the insignificant improvement in urinary flow rate. Enthusiasts of the technique point to clinical response and a uroflow increase of 30 per cent which withstands statistical testing but compares poorly with increase after endoscopic resection Uroflow alone cannot be used to quantify outflow obstruction.

A total of 118 patients were entered into a randomized trial of active *versus* sham treatment. The effects of thermotherapy with the Thermex II system, 48°C for 3 h, were assessed by fill-void cystometry. Measurements were made before treatment and 6 months after treatment

In the treatment group ($n = 99$), 93 per cent of patients had a useful improvement. Of the sham group ($n = 19$), 6 per cent had a useful improvement ($P < 0\cdot005$) After analysis of the first 79 patients in the good response group there was a fall in voiding pressure of 35 per cent (range 28–55 per cent) ($P < 0\cdot001$), and a 34 per cent increase in uroflow ($P = 0\cdot01$) indicating a definite reduction in outflow resistance. In the poor symptomatic responders and shams, there were no consistent changes in the measured parameters

In conclusion, this treatment not only affords symptomatic relief but also reduces outflow resistance in patients with BPH-associated outflow obstruction.

Magnetic resonance imaging of urinary calculi

C. Dawson, K. Aitken, Y. Ng, I.B. Nockler and H.N. Whitfield, *St Bartholomew's Hospital, London, UK*

Accurate prediction of the response of a calculus to lithotripsy is still not possible. Certain stones, particularly calcium oxalate monohydrate (brushite), cystine and uric acid, are known to be hard and consequently have a poor response to extracorporeal shockwave lithotripsy (ESWL) This study reports the use of magnetic resonance imaging (MRI) *in vitro* to distinguish between stones of varying chemical types

Sixty calculi were placed in a phantom in the head coil of a Siemens Magnetom 1·5-T MRI scanner. T1-weighted (TR 600 ms, TE 15 ms), T2-weighted (TR 2500 ms, TE 90 ms), and proton density (TR 2500 ms, TE 20 ms) images were taken. The chemical composition of the stones was determined by infra-red spectroscopy

Significant differences were noticed between calcium oxalate and uric acid stones ($P < 0\cdot002$) and uric acid and struvite stones ($P < 0\cdot04$) on T2-weighted images, and between uric acid and struvite stones on proton density images ($P < 0\cdot04$) Several other comparisons failed to reach statistical significance because of the small group sizes Further work is continuing on larger samples correlating the findings with results of ESWL, to determine whether MRI might be used as an *in vivo* predictive test for the success of lithotripsy.

Low-angle X-ray diffraction of urinary calculi

C. Dawson, J. Horrocks, R. Speller and H.N. Whitfield, *St Bartholomew's Hospital, London, UK*

X-ray diffraction is a well established and reproducible technique for analysing urinary calculi, capable of differentiating compounds present within mixtures of 2 mg or less The first use of low-angle X-ray diffraction (LAXD) for the analysis of intact urinary calculi is reported.

0007–1323/93/S105–03 © 1993 Butterworth-Heinemann Ltd

Sixty calculi were analysed using a 70 kV_P X-ray beam. Data were collected using a lead-shielded germanium photon detector and analysed using a multichannel analyser linked to a microcomputer. The chemical composition of the stones was determined by infra-red spectroscopy

	kV$_P$ of signal peaks			
Calcium oxalate		33	41	49
Uric acid	25	38		50
Struvite		39		
Apatite			42	
Ammonium urate		38		
Saline solution (standard)		38		

These preliminary results show that LAXD is capable of differentiating between the common types of calculi. Further work is being performed to characterize larger numbers of calculi The low energy of the beam used means that this technique may prove suitable for *in vivo* work, and further studies are in progress to correlate the results of LAXD with stone fragility after lithotripsy

Evaluation of effect of time on recollection of patient-perceived outcome in prostatectomy

M. Emberton and A. Challands, *Surgical Audit Unit, The Royal College of Surgeons of England, London, UK*

In excess of 4500 patients were recruited from 105 contributing surgeons into a multiregional audit of structure, process and patient-perceived outcome in men undergoing operative prostatic procedures over a 6-month period. The study is under the auspices of the British Association of Urological Surgeons and the Association of Surgeons of Great Britain and Ireland.

Patients were asked to recollect symptoms before and after an operative procedure on the prostate gland A validation study of recollected symptoms was undertaken in 100 consecutive men undergoing prostatic surgery in Chesterfield and North Derbyshire Hospitals Each patient was asked to complete a symptom profile of the American Urological Association (AUA-7), and both disease-specific and general quality-of-life score, Ware's Short Form (SF-36) in the preoperative phase and at a 3-month postoperative interval.

Analysis of stability of scores over time, together with an estimate of correlation between actual and recollected scores, has yet to be undertaken. It is hoped that the effects on symptom recollection of either a strongly positive or an adverse outcome will be evaluated by comparison with global measures of satisfaction.

The implications of a retrospective method of data collection for the estimation of post-discharge surgical outcome are significant Proven validity of this method of data collection enables post-discharge outcome to be determined using a preoperative baseline without identifying patients before the procedure. Resultant benefits are likely to include an analysis of only one data set, increased data capture, reduction in matching error, decrease in patient's time commitment, together with considerable cost savings The results of this study will have implications on the design of all future studies of post-discharge surgical outcome

p53 expression in urothelial cell cultures and tissues from healthy people and patients with bladder cancer

J. Harney, C. Mothersill, C.B. Seymour and D.M. Murphy, *Beaumont Hospital and Dublin Institute of Technology, Dublin, Ireland*

Expression of a stable form of p53 has been associated with many tumours and is thought to indicate loss of the tumour suppressor function associated with the wild-type protein The expression of p53 in paraffin-embedded bladder cancers and normal urothelial cell cultures derived from healthy individuals and patients with bladder cancer has been examined.

Using the p53-240 and p53-DO7 antibodies, 20 of 22 paraffin-embedded bladder cancer specimens were found to express p53 All normal urothelial specimens from both healthy and cancer-bearing patients were negative for p53 expression In urothelial cell cultures derived from healthy individuals >10 per cent of cells were observed to be positive in nine of 37 cases. In cultured normal urothelium derived from patients with bladder cancer, staining was positive in 11 of 11 cases

It is concluded that stable p53 protein is present in most bladder cancers and also in histologically normal areas of urothelium distant from the site of the disease Expression of this protein was not observed in paraffin-embedded material but was apparent on culturing the cells. The presence of a subgroup of normal patients whose urothelium expressed stable p53 on culturing requires further study

New tumour node metastasis classification for prostate cancer: pathological features of cancers detected by prostate-specific antigen alone

M. Ohori, T.M. Wheeler, E. Rogers and P.T. Scardino, *Baylor College of Medicine, Houston, Texas, USA*

In 1992 the tumour node metastasis (TNM) classification system for prostate cancer (Union Internacional Contra la Cancrum and American Joint Committee on Cancer) was revised in several important ways. The new system includes a category (T_{1c}) for patients with non-palpable cancer detected by systematic biopsy as a result of an elevated serum prostate-specific antigen (PSA) level. It includes in the T_2 category cancers visible by transrectal ultrasonography in addition to those palpable by digital rectal examination To assess the clinical and pathological features of cancers in each of these categories, an analysis was carried out of 318 patients with prostate cancer assessed as clinical stages T_{1-3} N_0 or N_X M_0 and treated by radical retropubic prostatectomy.

In general, tumour volume increased with increasing clinical stage ($P < 0.0001$) while the percentage with a tumour confined to the prostate decreased ($P < 0.0001$). Of particular interest were 15 patients with T_{1c} tumours. None of these cancers was palpable or visible by ultrasonography Although the tumours were relatively small (median volume 0·72 cm^3), seven (47 per cent) were > 1 cm^3, eight contained a primary or secondary component of poorly differentiated cancer and four extended outside the prostate Of 232 patients with a T_2 cancer, 16 had a non-palpable tumour that was visible using ultrasonography and 21 a palpable tumour not ultrasonographically visible. These tumours were similar in size and pathological features.

The new TNM staging system provides appropriate categories for the inclusion of non-palpable prostate cancers detected using new diagnostic tests and appears to reflect the extent of the cancer and the prognosis of the patient.

Inflatable penile prostheses in the management of erectile impotence

E. Rogers and D.M. Murphy, *Beaumont Hospital, Dublin, Ireland*

Inflatable prostheses restore voluntary erection while remaining cosmetically acceptable. Twenty patients with erectile impotence, aged 22–65 years, underwent implantation of an AMS inflatable penile prosthesis Nineteen had an organic aetiology, with diabetes mellitus the most common primary disorder Sixteen patients received the AMS 700 CX prosthesis and two the AMS 700 Ultrex. Devices were implanted through a transverse infrapubic incision Hydroflex prostheses were inserted in the other two patients through a penoscrotal approach Before operation all patients underwent rigorous local skin preparation with antiseptic solutions. Broad-spectrum antibiotics were used All patients were reviewed after operation and instructed in the use of the device Follow-up ranged from 7 to 93 months There were no mechanical complications Surgical complications including infection of the prosthesis, scrotal haematoma and cylinder erosion, were each seen in one patient Nineteen patients maintained long-term satisfaction with the prosthesis Insertion of an inflatable penile prosthesis restored satisfactory erectile function in 95 per cent of patients

Rome pouch: a preperitoneal continent ileal reservoir with hydraulic valve

G. Ronzoni and M. Cagossi, *Department of Urology, Catholic University, Rome, Italy*

A continent ileal reservoir using the terminal ileum in a preperitoneal position has been used in 18 urological patients after cystectomy. The ureters were implanted using the Le Duc–Camey technique; the Benchekroun valve was used as a continent mechanism

The mean(s.d.) postoperative neobladder capacity was 350(60) ml, which increased to 600(90) ml after 1 year. There was no ureteric reflux or fistula formation during a follow-up ranging from 12 months to 4 years No complications with the stoma occurred.

This technique of continent diversion is particularly recommended for patients undergoing cystectomy.

Vascular

Leg compression and microcirculation

A. Abu-Own, J.H. Scurr and P.D. Coleridge Smith, *Department of Surgery, University College and Middlesex School of Medicine, London, UK*

The reasons for the efficacy of compression treatment in venous disease are not clear. Laser Doppler fluxmetry has been used to assess the effects of external compression on skin microcirculation. Fifteen patients with lipodermatosclerosis (LDS) because of chronic venous insufficiency as proven by colour duplex scanning and 15 control subjects were studied in the supine position. The laser probe, installed in a polythene chamber, was applied to the lower leg underneath a blood pressure cuff. Pressures were applied in increments from 10 to 100 mmHg. Laser Doppler flux (LDF), blood cell velocity (BCV) and concentration of moving blood cells were recorded.

	Pressure (mmHg)		Percentage increase	Median difference (95% confidence interval)
	0	20		
LDF (arbitrary units)				
Control	33 (22–41)	41 (29–54)	17	10 (4–18)
LDS	50 (38–60)	65 (46–118)	33	13 (3–24)
BCV (arbitrary units)				
Control	21 (11–26)	28 (16–46)	40	11 (4–22)
LDS	9 (4–17)	21 (6–30)	79	7 (3–21)

Values are median (interquartile range)

Compression of the skin at 20 mmHg resulted in an increase in LDF and BCV in normal and liposclerotic skin. Higher levels of compression resulted in a progressive fall in LDF and BCV. This study suggests that compression treatment may achieve part of its effect by causing an increase in the microcirculatory flow velocity.

Acetylcholine sweat-spot test: an easy and effective method for selecting patients for lumbar sympathectomy

D.F. Altomare, G. Regina, V. Petruzzellis, M. Fullone, R. Lovreglio and V. Memeo, *Istituti di Clinica Chirurgica, Cattedra di Chirurgia Vascolare and Clinica Dermatologica Università degli Studi di Bari, Bari, Italy*

Lumbar sympathectomy is a useful low-risk procedure for treating patients with ischaemic limbs, but its efficacy is not easily predicted. A possible explanation for this may be pre-existing damage to the sympathetic fibres because of long-lasting diabetes or from the ischaemic disease itself. The acetylcholine sweat-spot test (SST) is an easy and inexpensive test for evaluating sympathetic integrity.

Sixteen patients selected for either surgical or chemical lumbar sympathectomy entered this preliminary study. The SST was performed before operation and 1 month after operation on the foot of the ischaemic leg. The results were evaluated clinically by a preoperative and postoperative questionnaire; in five patients, preoperative and postoperative photoplethysmography, capillaroscopy, laser Doppler, oximetry and Windsour index was used. Four patients had a normal SST, five had moderate denervation and seven had severe or complete denervation. At 1 month after the operation the SST indicated a complete denervation in all patients except two; one of these had undergone chemical sympathectomy. Apart from the latter two patients, whose sympathetic activity persisted and in whom the operation failed, clinical results in the first two groups were fairly good, whereas no result was obtained in those with pre-existing damage to the sympathetic system.

A good correlation was found between clinical data and those from the objective measurements with photoplethysmography, capillaroscopy, laser Doppler, oximetry and Windsour index. These preliminary results indicate that the SST may be a helpful method for selecting patients for lumbar sympathectomy.

Hyperamylasaemia in ruptured aortoiliac aneurysm: prevalence and prognostic implications

J.S. Bagley, M. Tyler and G.C. Cooper, *Aberdeen Royal Infirmary, Aberdeen, UK*

Serum amylase activity was measured at presentation in 25 consecutive patients with ruptured aortoiliac aneurysm. Twenty-three patients survived to have serum amylase activity measured. The aims of the study were to determine the prevalence of hyperamylasaemia (serum amylase level > 340 units l^{-1}) and its prognostic significance. The 30-day mortality rate and development of specific major postoperative complications were documented. Serum amylase was correlated with urea and creatinine concentration and length of stay in the intensive care unit (ITU).

Hyperamylasaemia occurred in ten (40 per cent) of the 25 patients and was present on admission in four of these. There were two perioperative deaths from haemorrhagic shock. Of the remaining 23 patients, 14 (group 1) made an uncomplicated recovery and nine (group 2), six of whom died, developed one or more complications. At all three times of sampling, serum amylase activity was significantly higher in group 2.

	Admission	Day 1	Day 2
Group 1 (n = 14)	212(12)	213(27)	182(28)
Group 2 (n = 9)	348(53)	631(145)	455(116)
P*	<0.025	<0.001	0.01

Values are mean(s.e.m.) serum amylase level expressed in units l^{-1} (laboratory normal is < 340 units l^{-1}). *Mann–Whitney U test

Hyperamylasaemia was significantly more prevalent in patients who developed complications (P = 0.0007, Fisher's exact test). In addition there was a significant positive correlation, independent of renal function, between serum amylase at presentation and ITU stay (r = 0.78). Hyperamylasaemia is common within 48 h of presentation with ruptured aortoiliac aneurysm. It is associated with a complicated postoperative course.

Intra-arterial thrombolysis for lower-limb ischaemia in a district general hospital

P. Bearn, J.B. Festenstein, A.J. Marcus and J.A. Fox, *Edgware General Hospital, Middlesex, UK*

Intra-arterial thrombolytic therapy is the treatment of choice for acute lower-limb ischaemia when the duration of therapy will not compromise limb viability.

A prospective study carried out at a district general hospital with basic radiology facilities is described. A total of 24 consecutive patients (median (interquartile range (i.q.r.)) age 75 (66–88) years) presenting with acute lower-limb ischaemia secondary to thrombotic arterial occlusion underwent urgent intra-arterial thrombolytic therapy using streptokinase (n = 23) or tissue plasminogen activator (n = 1). Thrombolysis was monitored daily by angiography. The median (i.q.r.) duration of intra-arterial thrombolytic therapy was 3 (2–4) days. Intra-arterial thrombolytic therapy alone was performed in 13 patients and an adjuvant angioplasty or thrombectomy in 11.

An improvement in ischaemic symptoms was observed in ten of 13 patients who received intra-arterial thrombolytic therapy alone, in six of seven who also underwent angioplasty and in three of four who also required thrombectomy. After treatment, the median (i.q.r.) ankle:brachial pressure index was increased to 0.5 (0–0.8) (n = 23) compared with 0 (0–0.4) (n=24) at presentation (P = 0.017, paired Wilcoxon test). The 30-day limb salvage and mortality rates were 65 and 17 per cent respectively.

Intra-arterial thrombolytic therapy, modified for use in a district general hospital, was effective in saving acutely ischaemic limbs used either on its own or to facilitate more established limb salvage procedures.

Rare causes for occlusion of the popliteal artery

T. Benhidjeb, K. Bürger and U. Hanack, *Surgical Clinic (Charité), Berlin, Germany*

If claudication appears in young athletic people without signs of generalized arteriosclerosis or evidence of other risk factors, then the popliteal artery compression syndrome should always be taken into consideration in the differential diagnosis. This is of great importance in view of early surgical treatment, because a delay in the operative procedure could result in complications such as an acute occlusion or distal embolization. Using five patients (one with an entrapment syndrome, one with a soleus syndrome, one with cystic adventitial degeneration of the popliteal artery and two with exostoses of the femur and the tibia), the clinical, diagnostic and surgical peculiarities of these rare conditions are reported. The diagnosis was confirmed by arteriography in all cases. The therapy and results are summarized, 1·5–4 years after operation all patients are symptom-free.

Patient no	Age (years)	Sex	Diagnosis	Surgery	Follow-up (years)
1	48	M	Entrapment syndrome	Resection, prosthesis interposition (PTFE)	3
2	25	F	Soleus syndrome	Tendon splitting	1·5
3	25	M	Cystic adventitial degeneration	Vein graft interposition	4
4	39	F	Exostosis (femur)	Exostosis excision, vein graft interposition	4
5	22	M	Exostoses (femur, tibia)	Exostosis excision, desobliteration, vein patch	3

PTFE, polytetrafluoroethylene

Thromboprophylaxis in elective abdominal surgery with a low molecular weight heparin (dalteparin): a multicentre double-blind trial in 2069 patients of two different doses started the evening before surgery

D. Berqvist, U.S. Burmark, P.A. Flordal, J. Frisell, T. Hallböok, M. Hedberg, A. Horn, P. Kvitting, A. Lindhagen, K.G. Ljungstrom, T. Mätzsch, B. Risberg, I. Syk, S. Törngren, E. Wellander and P Ortenwall, *Departments of Surgery, Malmo, Danderyd, Gothenburg, Halmstad, Skovde, Stockholm, Sweden and Bergen, Norway*

Low molecular weight heparin (LMWH) is effective for thromboprophylaxis and a convenient method is to start treatment the evening before surgery. The optimal dose in high-risk general surgery is not yet established.

The aim of this study was to compare doses of 2500 *versus* 5000 anti-Xa units of LMWH (dalteparin) in elective general abdominal surgery, starting the evening before surgery and then every evening for 1 week.

A prospective, randomized, double-blind multicentre trial was performed. Deep vein thrombosis (DVT) was detected with a fibrinogen uptake test. Bleeding complications were recorded and classified. Analysis was performed on an intention to treat basis.

A total of 2097 patients were randomized and 28 were excluded after randomization. Some 66 per cent were operated on for malignant disorders, DVT occurred in 12·6 per cent in the 2500 unit group and in 7·7 per cent in the 5000 unit group ($P < 0.001$). The 30-day mortality rate was 3·2 per cent, without difference between the groups. There was one fatal pulmonary embolism. Bleeding complications occurred in 2·7 per cent in the 2500 unit group and in 4·7 per cent in the 5000 unit group ($P = 0.02$). Bleeding was of minor clinical importance.

Dalteparin, in the dose of 5000 anti-Xa units commenced the evening before surgery, has a good thromboprophylactic effect in high-risk general surgery at a cost of small bleeding risk. A dose of 2500 units is too low. The overall frequency of fatal pulmonary embolism is extremely low.

Vascular access and its complications in patients with chronic renal failure undergoing haemodialysis

L. Bozatlı, F. Çelik, Y. Kiliç, L Eldem, O. Arikan, I. Tasbasi, I. Kuru, K. Güler and Ö Ekinci, *Göztepe Social Insurance Hospital, Istanbul, Turkey*

A total of 226 arteriovenous (AV) anastomosis operations and 49 arteriovenous polytetrafluoroethylene (PTFE) graft operations were performed on 221 patients with chronic renal failure admitted to the haemodialysis centre of Goztepe Social Insurance Hospital and the General Surgery Department of Kartal Hospital, in Istanbul. Ages of the patients ranged from 13 to 85 years, with 84 (38 per cent) female and 137 (62 per cent) male. A large number of patients were between 50 and 60 years of age.

Of the 226 AV anastomosis operations performed, 114 (50·4 per cent) were snuff-box (longitudinal), 52 (23·0 per cent) were on the wrist area and 60 (26·5 per cent) were in the antecubital fossa (brachiocephalic). Of the 49 PTFE graft operations, five (10 per cent) were between the femoral artery and the saphenous vein (loop) and 44 (90 per cent) were between the brachial artery and the axillary vein (straight).

In patients with AV anastomosis, 22 thrombectomy procedures, three repairs of a pseudoaneurysm and 12 fistula ligation procedures were performed for the management of complications. In patients with PTFE grafts, eight thrombectomy and five graft excision procedures had to be performed. At 1 year, the mean patency rate of AV anastomosis was 77 per cent and 63 per cent for PTFE graft operations.

In all patients, the flow rate in both early and late postoperative periods was measured by B-mode Doppler imaging. The mean flow rate was determined as 90 cm s^{-1}

Internal vessel occluders facilitate distal anastomosis

R.T.A. Chalmers, J.J. Hoballah, W.J. Sharp, T.F. Kresowik, A.L. Synn and J.D Corson, *University of Iowa Hospitals, Iowa City, Iowa, USA*

When performing an anastomosis at the infrageniculate level, blood flow is traditionally arrested using vascular clamps or tourniquet control after limb exsanguination. While placing 185 *in situ* saphenous vein bypasses to the tibial level for limb salvage, the 'Flo-Restor' internal vessel occluder was used to facilitate construction of each distal anastomosis. These silicone devices are manufactured in a range of sizes to accommodate different vessel calibres.

After surgery, all patients were monitored prospectively with colour flow duplex scanning. The authors were particularly interested in velocity changes at the distal anastomosis. Of ten revision operations performed in the first month, two were related to the distal anastomosis but involved only the graft hood. At late follow-up, seven bypasses had significant duplex velocity changes at the distal anastomosis. Arteriography showed apparent disease progression in the artery in one case only. In another patient, a distal anastomotic pseudoaneurysm was detected and corrected at 3 months. The cumulative 60-month primary and secondary patency rates in this series were 70 and 84 per cent respectively.

It is concluded that the Flo-Restor is a useful device. It reduces dissection, avoids clamp trauma to calcified vessels and controls blood flow satisfactorily. The data show that with the Flo-Restor distal anastomoses can be constructed safely and the incidence of arterial anastomotic narrowing is negligible.

Neuropathy in chronic venous insufficiency

P.D. Coleridge Smith, S.K. Shami and J.H. Scurr, *University College and Middlesex School of Medicine, London, UK*

There have been few studies on the peripheral nervous system in patients with chronic venous insufficiency. The aim of the present study was to determine whether patients with chronic venous insufficiency and lipodermatosclerosis have a higher prevalence of neuropathy than normal subjects.

Forty patients with lipodermatosclerosis and 35 age-matched normal controls were examined for neuropathy using three methods of testing. The threshold to warming was used to assess small unmyelinated C fibres. The threshold to cooling and vibration was used to assess larger myelinated fibres. The threshold to warming and cooling was measured on the sole of the foot using a purpose-built instrument controlled by computer with specially written software. The threshold to vibration was measured on the big toe using an Ohio biothesiometer. Results were analysed using the Mann–Whitney *U* test.

	Threshold to heating (°C)	Threshold to cooling (°C)	Threshold to vibration (arbitrary units)
Controls*	1·2 (0·2–3·5)	0·2 (0·1–0·3)	12·0 (8·5–27·5)
Lipodermatosclerosis*	5·3 (0·1–9·1)	0·2 (0·1–0·4)	22·0 (13·0–31·0)
P	0·005	0·9	0·03
95% c.i. of difference	−0·3 to −3·8	0·1 to −0·1	0·0 to −12·0

* Values are median (interquartile range). c.i., Confidence interval

These results show that there is a peripheral neuropathy in patients with lipodermatosclerosis, as indicated by an increase in the thresholds to warming and vibration. Neuropathy in patients with lipodermatosclerosis may explain the vulnerability of such patients to skin ulceration.

Granulocyte elastase release in chronic venous disease of the lower limb

P.D. Coleridge Smith, D.A. Shields, S. Andaz, S. Sarin and J.H. Scurr, *The Middlesex Hospital, London, UK*

It has been suggested that neutrophil trapping and activation may result in the pathogenesis of skin changes seen in longstanding venous disease. This study measured plasma elastase as a marker of neutrophil activation in blood taken from an arm vein in three groups of 15 patients with uncomplicated varicose veins, varicose veins associated with lipodermatosclerosis (LDS) and venous ulceration. Results were compared with values obtained from three groups of age- and sex-matched normal controls. Blood was also taken for full blood count, including neutrophil count.

	Control	Varicose veins	Control	LDS	Control	Venous ulcers
Elastase (ng ml^{-1})*	18·05 (12·6–30)	25·6 (20·4–39·8)	17·7 (12·6–21·2)	22·1 (19–33·9)	18·8 (12·4–34·3)	26·0 (22·3–39·5)
Difference between medians	8·0		7·0		8·5	
95 per cent confidence interval for difference	0·8–14·0		1·4–13·5		1·4–14·1	
P†	0·0344		0·007		0·0265	

*Values are median (interquartile range). †Mann–Whitney *U* test

There was a significantly raised circulating plasma elastase level in all three patient groups, with no correlation between elastase and neutrophil levels, suggesting that neutrophil activation had occurred. There was a correlation between plasma elastase and age in the control group ($P = 0{\cdot}045$), but not with sex or neutrophil count. This *in vivo* study suggests neutrophil activation in venous disease.

Thromboxane antagonism prevents hindlimb ischaemia–reperfusion-induced gut damage

R.J. Corson, M. Fisher, N.Y. Haboubi, R.A. Little and C.N. McCollum, *University of Manchester, Manchester, UK*

Abnormal intestinal permeability has been linked with postoperative multiple organ failure. Previous studies have demonstrated that hindlimb ischaemia and reperfusion leads to abnormal permeability. The aim of this study was to determine whether thromboxane receptor antagonism with ICI 192605 could prevent this abnormal permeability.

Anaesthetized male rats were randomized to three groups: group 1 had 3 h hindlimb ischaemia and 2 h reperfusion ($n = 6$), group 2 were as group 1 with an intravenous infusion of the solvent dimethyl sulphoxide (DMSO) ($n = 6$), and group 3 were as group 1 with an infusion of ICI 192605 in the solvent DMSO ($n = 6$). Intestinal permeability was assessed by electron microscopic penetration of the permeability marker horseradish peroxidase beyond the intracellular junction of terminal ileal enterocytes.

All six rats in group 1 demonstrated abnormal permeability after reperfusion, four of the six animals in group 2 demonstrated abnormal permeability after the infusion of DMSO alone (*P* not significant *versus* group 1); however, no animal in group 3 demonstrated abnormal permeability after the infusion of ICI 192605 ($P < 0{\cdot}05$ *versus* group 1, Fisher's exact test).

Thromboxane receptor antagonism prevents the abnormal permeability that follows hindlimb ischaemia and reperfusion. This study suggests a possible role for such agents in the field of vascular surgery where reperfusion injury occurs after aortic cross-clamp release.

Neutrophil and endothelial mediators in postischaemic alterations to skeletal muscle blood flow

J. Crinnion, S. Homer-Vanniasinkam, S. Parkin and M. Gough, *The General Infirmary, Leeds, UK*

Endothelial and neutrophil-derived thromboxane A_2, leukotriene B_4 and elastase are putative mediators of reperfusion injury but their relative roles are unknown. After 6 h of unilateral hindlimb ischaemia blood flow was measured in the gastrocnemius muscle of ten rats after 10, 120 and 240 min of reperfusion (perfusion index), and levels of thromboxane A_2, leukotriene B_4 and elastase were measured in the venous blood of reperfused limbs. The results (median (interquartile range)) were compared with values obtained in ten normal controls. Perfusion indices in normal rats at 10, 120 and 240 min were 1·05 (0·68–1·18), 0·97 (0·79–1·13) and 1·01 (0·73–1·16) respectively, and in rats that had undergone ischaemia–reperfusion 0·08 (0·01–0·13), 0·29 (0·09–0·59) and 0·05 (0·01–0·14) respectively. Thus the latter group demonstrated low reflow (10 min, $P < 0{\cdot}01$ *versus* controls), relative reperfusion (120 min, $P < 0{\cdot}05$ *versus* controls) and reperfusion injury (240 min, $P < 0{\cdot}01$ *versus* controls). Levels of thromboxane A_2, leukotriene B_4 and elastase in normal rats were 288 (187–300), 124 (75–172) and 13 (0–17) respectively. In reperfused rats elastase levels, reflecting neutrophil recruitment/activation, peaked at 240 min (25 (16–31), $P < 0{\cdot}01$ *versus* controls). Values measured at 10 and 120 min were 15 (0–34) and 0 (0–23) respectively, and were not significantly different from controls. Leukotriene B_4 levels, indicative of neutrophil chemotaxis, peaked earlier at 120 min (190 (138–203), $P < 0{\cdot}05$ *versus* controls). Concentrations at 10 and 240 min were 126 (103–183) (*P* not significant) and 195 (159–211) ($P < 0{\cdot}05$) respectively. In contrast, thromboxane A_2 levels were highest at 10 min (1758 (940–2175), $P < 0{\cdot}001$ *versus* controls) and then fell to 1150 (580–1550) and 733 (340–880) at 120 and 240 min respectively. These results suggest that neutrophil recruitment and activation is a late event, and that the vasoconstrictor thromboxane A_2 rather than the neutrophil initiates low reflow.

Effect of depletion of circulating neutrophils on reperfusion injury

J. Crinnion, S. Homer-Vanniasinkam, S. Parkin and M. Gough, *The General Infirmary, Leeds, UK*

Neutrophils have been implicated in the pathogenesis of reperfusion injury. The effect of neutrophil depletion on gastrocnemius muscle viability, oedema and myeloperoxidase activity was assessed in a rat model. Rats were subjected to unilateral hindlimb ischaemia for 6 h and reperfusion for 4 h. Ten normal (no ischaemia), ten control (6 h ischaemia plus 4 h reperfusion) and ten neutropenic (given antineutrophil serum) rats were studied. Indices of gastrocnemius muscle viability and oedema were calculated (study limb:contralateral normal limb). Antineutrophil serum reduced median (interquartile range) neutrophil counts from 825 (560–1355) mm^{-3} in controls to 55 (40–145) mm^{-3} ($P < 0{\cdot}001$, Mann–Whitney *U* test).

	Viability index	Oedema index	Myeloperoxidase activity
Normal	1·00 (1·00–1·00)	1·00 (0·98–1·01)	0·05 (0·00–0·10)
Control	0·53 (0·33–0·61)	1·61 (1·28–1·69)	2·95 (1·70–4·70)
Neutropenic	1·00 (1·00–1·00)	1·64 (1·37–1·73)	0·30 (0·10–0·50)

Values are median (interquartile range)

Ischaemia–reperfusion caused muscle infarction, oedema and neutrophil recruitment (control *versus* normal rats $P < 0{\cdot}001$, all parameters). In rats treated with antineutrophil serum muscle necrosis was prevented and neutrophil recruitment was markedly attenuated ($P < 0{\cdot}001$ *versus* controls). However, muscle oedema still occurred (P not significant *versus* controls). These results confirm a role for neutrophils in the pathogenesis of postischaemic muscle necrosis but suggest that disruption of the endothelial barrier occurs independently.

Vein graft adaptation

A.H. Davies, T.R. Magee, J.K. Hayward, R.N. Baird and M. Horrocks, *Vascular Studies, Bristol Royal Infirmary, Bristol, UK*

The diameter of the long saphenous vein has been shown to affect the outcome of femorodistal bypass Many surgeons regard a vein with a diameter of <3 mm as unsuitable. It is well documented that vein grafts dilate

The long saphenous vein was studied in 70 patients undergoing femorodistal bypass. Diameter measurements were performed using a duplex scanner at the groin, mid-thigh and knee At the latter two points, diameter measurements were performed with proximal venous occlusion at 1-min time intervals Diameter measurements were repeated 7 days and 6 months after surgery

The preoperative mean groin diameter was 4·9 (95 per cent confidence interval 3·1–6·8) mm. Diameter measurements at the other points are shown.

	Non-dilated (mm)	Dilated (mm)	7 days (mm)	6 months (mm)
Mid-thigh	4·2 (2·5–5·9)	5·1 (3·1–7·1)	5·4 (3·7–6·7)	5·4 (3·7–7·1)*
Knee	3·8 (2·2–5·6)	4·8 (3·4–6·2)	4·8 (4·1–6·5)	5·0 (3·0–7·0)*

Values in parentheses are 95 per cent confidence intervals. *$P < 0{\cdot}01$ (analysis of variance)

Dilatation occurred in eight of ten veins with a diameter < 3 mm, so that all became > 3 mm These results suggest that, by using a technique of venous occlusion at the time of preoperative vein mapping, the functional diameter of the vein can be predicted and vein utilization increased

Augmented Doppler evaluation of the distal run-off

A.H. Davies, T.R. Magee, R. Parry*, S.G.W Tennant, R.N. Baird and M. Horrocks, *Departments of Vascular Studies and *Radiology, Bristol Royal Infirmary, Bristol, UK*

The quality of the distal run-off is one of the most important factors in determining the outcome following femorodistal reconstruction.

Ninety patients undergoing femorodistal bypass had preoperative intra-arterial digital subtraction angiography (DSA) and Doppler evaluation with pulse-generated augmentation (PGR) The results were compared with postoperative DSA.

Underestimation of the distal run-off calf vessels by preoperative DSA occurred in 34 per cent of patients

	Preoperative DSA	PGR	Postoperative DSA
Artery identified at the calf ($n = 90$)			
Posterior tibial	61	73	71
Anterior tibial	39	62	62
Peroneal	33	63	57
Quality of arch			
Complete	11	15	14
Incomplete	59	67	68
Occluded	20	8	8

Grafts performed in a limb with a below-knee PGR score $\leqslant 3$ had a 12-month cumulative patency rate of 73 per cent compared with 85 per cent in those with a below-knee PGR score $\geqslant 4$ ($P = 0{\cdot}08$, log rank test, $P = 0{\cdot}06$, Wilcoxon test). The 12-month cumulative patency rate for grafts with complete, incomplete or occluded arches, as defined by PGR, was 78, 90 and 38 per cent respectively ($P < 0{\cdot}0001$, log rank and Wilcoxon tests)

Preoperative evaluation of the distal run-off before femorodistal bypass should not be based on DSA alone and can be predicted by PGR

Popliteal artery entrapment syndrome

L. di Marzo, A. Cavallaro, V. Sciacca, A. Mingoli, P. Allegrucci and S. Stipa, *University of Rome 'La Sapienza', Rome, Italy*

Popliteal artery entrapment is described with increasing frequency in the world literature. It is due to an anomalous inter-relationship of the popliteal artery and its surrounding structures. A total of 34 cases in 25 patients (21 men) of mean(s d.) age 34·2(14·7) years were treated surgically Symptoms reported before operation were classified into three groups mild (17 limbs), claudication > 100 m (nine limbs), other – severe claudication, rest pain and necrosis (eight limbs) Preoperative arteriography showed arterial occlusion in eight limbs, stenosis in eight and aneurysm in two In 14 limbs stenosis or occlusion was shown after manipulation In two limbs diagnosis was performed on the basis of venography showing popliteal vein entrapment. Ten different anatomical variants were seen In 76 per cent of cases the medial gastrocnemius muscle was involved. Surgical treatment consisted of division of the anomalous structure in 21 cases In 12 cases a vascular reconstruction was required, while one case was explored and not reconstructed. Optimal results were obtained in patients treated by musculotendinous sectioning (patency rate 95 per cent, mean follow-up 57 months) When grafting was required the primary patency rate was 58 per cent (mean follow-up 61 months) It is concluded that popliteal artery entrapment should be diagnosed and treated as soon as possible, to limit surgical treatment and avoid the need for vascular reconstruction.

Arterial insufficiency and large leg ulcers

P. Ghosh and J.G. Mosley, *Leigh Infirmary, Leigh, UK*

Arterial gangrene generally begins on pressure areas on the side of the foot or heel. However, in a small proportion of patients it commences over the leg and may be mistaken for venous ulceration.

Experience in the vascular investigation and treatment of a consecutive series of 42 patients who had large (surface area $> 100\,\text{cm}^2$) leg ulcers is reviewed. The 42 patients were studied prospectively, all had non-invasive vascular investigations. Seventeen patients had significant arterial disease and underwent arteriography Twelve patients had a superficial femoral artery occlusion, four popliteal aneurysm thrombosis and one an arteriovenous fistula Fourteen patients underwent arterial bypass graft. All patients had skin grafting Those with venous disease had compression bandaging

The 15 arterial ulcers healed in 28 days after a successful graft This was significantly more rapid than in the 25 venous ulcers (mean 37 days). In addition, 75 per cent were still healed after 2 years compared with 57 per cent of venous ulcers. Arterial insufficiency occurs in over 30 per cent of patients with large leg ulcers. If treated successfully, prompt healing of the ulcer can be expected

Videothoracoscopic sympathectomy for secondary Raynaud's syndrome

B. Helms, P. Schwanitz and H.-D. Czarnetzki, *Klinikum Rostock Suedstadt, Rostock, Germany*

Secondary Raynaud's syndrome is an indication for thoracic sympathectomy. Warm flushed hand and improvement of hyperhidrosis are useful effects and there is significant improvement of peripheral hand circulation on the operated side. Conventional operation via minithoracotomy is too invasive for resection of a 3-cm segment of the sympathetic trunk. Rib fractures and spreading of the intercostal space are disadvantages of minithoracotomy, which have left sympathectomy with a bad reputation in the past. Using thoracoscopy with laparoscopic instruments and working in a controlled pneumothorax, resection of only the rami of the stellate ganglion and not the ganglion itself is possible with an excellent endoscopic view. Three subaxillary ports give a good cosmetic result. The suction drain is removed after 24 h.

Twelve patients have been operated on in this way. One developed Horner's syndrome, showing the importance of resecting only the rami of the stellate ganglion. Wound pain had gone after 36 h. There were no deaths and only minor morbidity with superficial wound infection in one patient. The circulatory result is excellent up to 14 months, longer term results are awaited. Minimally invasive sympathectomy extends its indications without disadvantages to the patient.

Multicentre randomized double-blind trial of low molecular weight heparin and standard heparin for prevention of postoperative venous thromboembolism in major abdominal surgery

V.V. Kakkar, A.T. Cohen, R.A. Edmondson, M.J. Philips, D.J. Cooper, S.K. Das, K.I. Maher, R.M. Sanderson, V.P. Ward and S. Kakkar, on behalf of the Thromboprophylaxis Collaborative Group, *Thrombosis Research Institute, London, UK*

The efficacy and safety of low molecular weight heparin (LMWH) and standard heparin in preventing postoperative venous thromboembolism were compared in a prospective double-blind randomized trial involving 3809 patients undergoing major abdominal surgery. The heparins were given before surgery and continued for at least 5 days after operation. A total of 1894 patients received LMWH and 1915 standard heparin. No difference was found in the efficacy of the two heparins. Perioperative deaths occurred in 110 patients (2·9 per cent): 63 patients (3·3 per cent) treated with LMWH and 47 (2·5 per cent) standard heparin (relative risk 1·36 (95 per cent confidence interval (c.i.) 0·93–1·97). Pulmonary emboli were detected in 27 patients (0·7 per cent), 13 (0·7 per cent) of whom were treated with LMWH and 14 (0·7 per cent) standard heparin. Sudden death occurred in eight of these and at autopsy five (0·3 per cent) and three (0·2 per cent) patients treated with LMWH and standard heparin respectively were found to have died from acute massive pulmonary embolism. Deep vein thrombosis was diagnosed in 11 patients (0·6 per cent) in each group. The safety of the heparins was assessed using objective criteria. A total of 93 incidents of major bleeding occurred in 69 patients (3·6 per cent) given LMWH compared with 141 incidents in 91 patients (4·8 per cent) treated with standard heparin. Severe bleeding occurred less frequently in patients receiving LMWH, there being 18 (1·0 per cent) affected compared with 36 (1·9 per cent) given standard heparin (relative risk 0·51 (95 per cent c.i. 0·29–0·89), P = 0·02). Similarly, wound haematomas were less common in patients receiving LMWH (27 (1·4 per cent) *versus* 52 (2·7 per cent), relative risk 0·52 (95 per cent c.i. 0·33–0·83), P = 0·007). Twenty bleeding episodes in 18 patients (1·0 per cent) treated with LMWH and 38 episodes in 33 (1·7 per cent) receiving standard heparin required further surgery, either for evacuation of a haematoma or to control bleeding (relative risk 0·55 (95 per cent c.i. 0·31–1·98), P = 0·05).

Both heparins appear to be of equal efficacy but LMWH is safer, it causes less severe bleeding, fewer wound haematomas and a smaller number of patients require reoperation to control bleeding.

Prospective randomized trial of low molecular weight heparin *versus* Persantin in femoropopliteal bypass grafts

V.V. Kakkar, R.A. Edmondson, A.T. Cohen and M.J. Phillips, *Thrombosis Research Institute, London, UK*

Late graft failure, which occurs in 30–35 per cent of patients undergoing reconstructive surgery for critical lower-limb ischaemia, presents a major clinical problem. In the majority of cases, such failure is due to intimal hyperplasia, often at the anastomotic site. Low molecular weight heparin (LMWH) may have a beneficial effect in controlling such lesions because of its proven antithrombotic and antiproliferative properties. A prospective randomized trial was therefore designed to compare the efficacy of LMWH *versus* conventionally used therapy of aspirin and dipyridamole in the maintenance of graft patency.

A total of 206 patients over 40 years of age with radiographically proven occlusive arterial disease and suffering from critical lower-limb ischaemia were randomized to receive either LMWH, 2500 units daily subcutaneously, or aspirin 300 mg and Persantin (dipyridamole) 100 mg daily. Each patient was assessed 1, 3, 6 and 12 months after inclusion in the trial.

A standard technique was used for performing femoropopliteal bypass. All risk factors likely to be related to graft failure or bleeding were recorded throughout the observation. Follow-up observations included clinical assessment, ankle:brachial pressure index, duplex ultrasonography and magnetic resonance imaging, particularly for assessment of the anastomotic site.

In all, 200 patients have been followed, nine died, seven in the LMWH group and two in the Persantin group (P = 0·12). The results of graft patency analysed over 1, 3, 6 and 12 months were as follows. There was a marked trend in graft survival in the LMWH group throughout the trial. This difference reached statistical significance with a 20 per cent increase in the graft patency rate observed at 6 months (relative risk 1·20 (95 per cent confidence interval (c.i.) 1·03–1·10), P = 0·035). The difference was more marked in the limb salvage group, even at 12 months (relative risk 1·73 (95 per cent c.i. 1·22–2·47); P = 0·006).

LMWH is superior to aspirin and Persantin in maintaining graft patency. The beneficial effect of a 3-month course of LMWH appears to continue to enhance selective graft patency for at least 1 year after surgery.

Evaluation of the effects of single-dose prostaglandin E_1 on fibrinolytic activity during major surgery

V.V. Kakkar, M.J. Phillips, R.A. Edmondson, A.T. Cohen, E. Melissari, R.M. Sanderson and J.A. Skinner, *Thrombosis Research Institute, London, UK*

The incidence of venous thromboembolism may be influenced by a period of reduced fibrinolytic activity following major surgery. Prostaglandin E_1 (PGE_1) has been shown to enhance fibrinolysis by inhibiting the release of plasminogen activator inhibitor (PAI-1) and promoting the release of endogenous tissue plasminogen activator (tPA).

A group of 30 patients undergoing routine total knee replacement received PGE_1 as an intravenous (i.v.) infusion ($4\,\mathrm{ng\,kg^{-1}\,min^{-1}}$) during surgery (20 cases), or subcutaneously $0{\cdot}05\,\mathrm{\mu g\,kg^{-1}}$ 2 h before surgery (five cases); five patients acted as a control group. All patients were given routine heparin thromboprophylaxis in addition. Fibrinolytic parameters were measured before, during and immediately after surgery and on days 1 and 5 thereafter. PAI-1 was significantly suppressed immediately after operation ($P < 0{\cdot}05$) in both treatment groups and tPA activity enhanced by i.v. therapy (P = 0·0065) after surgery. There were no changes in global coagulation times in either group. No serious adverse events were noted.

In conclusion, i.v. PGE_1 may be a useful adjunct in preventing fibrinolytic shutdown after major surgery, and warrants further investigation.

Sleeve arteriovenous fistula for haemodialysis as the fistula of choice

A. Kapala, W. Szczesny and Z. Mackiewicz, *Department of General and Vascular Surgery, Medical Academy of Bydgoszcz, Poland*

The technique of creating an arteriovenous fistula for haemodialysis using end-to-end 'sleeve' anastomosis is presented. In all, 108 fistulas were made in this way, patients were followed for 5 years and the results analysed by life-tables. The 'sleeve' fistulas were compared with 72 fistulas made by Linton's method.

There were no early failures (within the first 24 h) in the sleeve group, and late results were good. Using Doppler ultrasonography (Bruel and Kjaer 3535), the flow of blood through the fistula was estimated and simultaneous visualization of the arteriovenous anastomosis was performed. Sleeve fistulas are considered to be the fistula of choice because of the ease of creation, and good early and late results.

Saphenous vein or polytetrafluoroethylene graft for access in haemodialysis

P.J.E.H.M Kitslaar, K.M.L. Leunissen and J.H.M. Tordoir, *University Hospital Maastricht, Maastricht, The Netherlands*

Some 20–30 per cent of patients on regular haemodialysis need secondary procedures for the maintenance of vascular access. A consensus about which graft material should be used for such access is absent.

In a prospective study, therefore, the primary and secondary patency rates and complications (infection, puncture bleeding and development of aneurysms and venous hypertension) of 23 saphenous vein and 40 polytetrafluoroethylene (PTFE) prostheses (31 reinforced; nine stretch GORE-TEX) implanted as loop arteriovenous fistulas in the forearms of 48 patients in the period 1990–1992 were investigated. All patients had preoperative duplex screening of the arm vessels.

Four grafts (three PTFE, one vein) occluded before dialysis started (primary failure). There were nine early postoperative (<30 days) complications with PTFE prostheses, compared with two involving vein grafts ($P<0{\cdot}05$). In four patients of the vein group complications occurred at the donor site. During the follow-up period (mean 9 months), 26 surgical interventions were necessary in 16 PTFE prostheses because of complications compared with 14 revisions in nine vein grafts. Some 43 per cent of the vein grafts remained without any complication *versus* 35 per cent of PTFE grafts. The cumulative secondary patency rates for the vein and PTFE grafts at 0·5, 1, 2 and 3 years were 68 *versus* 70 per cent, 68 *versus* 64 per cent, 59 *versus* 57 per cent and 47 *versus* 57 per cent. The primary patency rates, including primary failure in the analysis, were better for the vein grafts than for the PTFE fistulas (62 *versus* 31 per cent after 1 year).

In view of the equal secondary patency rates for vein and PTFE grafts and the problems inherent in vein harvesting against a higher occlusion tendency of PTFE prostheses, no clear preference for vein or PTFE loop fistulas in dialysis access surgery is justified.

Transcutaneous oximetry, laser Doppler fluxmetry and capillary microscopy: reproducibility in patients with advanced atherosclerotic disease of the lower extremity

H.M. Klomp, C.H.A. Wittens and H. Van Urk, *University Hospital Rotterdam–Dijkzigt, Rotterdam, The Netherlands*

Non-invasive methods of studying the microcirculation have been advocated in patients with advanced peripheral vascular disease to assess skin viability. A prerequisite for such tests is reproducibility of results within an individual patient and between patients. This study was performed to evaluate the reproducibility of three methods: transcutaneous oxygen tension (*P*tco$_2$) measurement, diode laser Doppler fluxmetry (dLDF) and capillary microscopy (CM).

Repeated measurements were performed in 20 patients with rest pain or severe disabling intermittent claudication (ankle:brachial pressure index $<0{\cdot}5$). *P*tco$_2$ was measured on the dorsum of the foot, and measured under baseline conditions, during 4 min of oxygen inhalation and after 3 min of tourniquet occlusion. dLDF was performed on the palmar skin of the hallux, at rest and after 3 min of occlusion. CM was performed at the nailfold of the hallux: capillary density, morphological changes of the capillaries and perfusion with fluorescein were studied.

The *P*tco$_2$ results after oxygen inhalation were reproducible and allowed for differentiation in the severity of disease. Resting *P*tco$_2$ seemed less valuable. Some dLDF results are highly reproducible, but only resting flux and the flux increase rate after tourniquet occlusion discriminated between the severity of skin ischaemia in both diabetics and non-diabetics. CM was very reliable as performed by one observer. Capillary morphology score allowed for severity grading, whereas capillary density seemed to be influenced by the presence or absence of diabetes. Only those tests with adequate reproducibility and discriminatory ability should be used to evaluate surgical procedures or to determine amputation levels.

Stapler technique for establishment of arteriovenous fistula

E.V. Kolesov and E.I. Zemljansky, *Regional Hospital, Dnepropetrovsk, Ukraine*

Arteriovenous forearm fistulas (AVFs) for maintaining chronic blood dialysis are usually made by a suture technique. In the authors' clinic this procedure takes about 15–20 min. In a comparative study in 92 patients the routine suture technique was used in 44 procedures and a stapler in 104 for creation of AVF.

The tiny stapler devices with vacuum fixation of the vessels are now produced in the Ukraine. The usual time for fistula creation was <2 min.

While the patency rate was 100 per cent in the stapled group, thromboses did occur in the hand-sutured group, the difference being statistically significant ($P<0{\cdot}05$). The stapler technique can also be used for internal mammary artery coronary bypasses. The use of staplers could be worthwhile in many microvascular procedures where it is more rapid than hand-sewn anastomotic techniques.

Peripheral venous disorders in vascular symptom-free patients with Behçet's disease

A. Kuzu, C. Köksoy, C. Ozaslan, A. Gurler, A. Tüzüner and A.U. Ibn-i, *Sina Hospital, Ankara, Turkey*

The aim of this study was to investigate venous system involvement in patients with Behçet's disease who were free of vascular symptoms. Two groups of patients were assessed with non-invasive venous techniques. Assessment consisted of venous Doppler and photoplethysmographic (PPG) venous reflux examination of veins of the lower extremities. The first group included 34 patients with Behçet's disease who were free of vascular symptoms and the control group consisted of 26 healthy individuals. Doppler ultrasonography was used to determine venous obstruction and insufficiency. After pneumatic calf compression, the venous return time of the blood content of the leg skin to the baseline level was defined as the prebaseline time (PBT) by PPG. Patients with PBT under 20 s was considered as having venous insufficiency. Venous insufficiency was detected in 22 of 68 legs in the Behçet's group and in seven of the 52 legs in the control group using Doppler ($P<0{\cdot}01$). Twenty of the Behçet's disease group and six of the controls had a PBT lower than 20 s ($P<0{\cdot}01$). PBT in the Behçet's disease and the control groups for the right leg was 23·6 *versus* 30·6 s ($P<0{\cdot}03$) and 27·7 *versus* 30·6 s for the left leg, respectively (*P* not significant). Deep vein thrombosis was detected in three patients with Behçet's disease, whereas none of the controls was shown by Doppler to have disease (*P* not significant).

We conclude that vascular symptom-free patients with Behçet's disease have a higher incidence of silent venous disorders than the healthy population.

Non-invasive peripheral arterial system assessment of vascular symptom-free Behçet's disease

A. Kuzu, C. Koksoy, C. Ozaslan, A. Gurler, A. Tüzuner and A.U. Ibn-i, *Sina Hospital, Ankara, Turkey*

The aim of the present study was to determine the incidence of peripheral arterial disorders in vascular symptom-free Behçet's disease. Two groups of patients were studied. The first group consisted of 29 patients with the condition and the second group of 26 healthy individuals as a control group. Both groups underwent non-invasive peripheral arterial examinations consisting of Doppler, segmental pressure measurements and the determination of ankle brachial pressure index (ABPI) and femorobrachial pressure index (FBPI). The ABPI for the dorsalis pedis artery was $<1{\cdot}00$ in 26 legs of Behçet's group compared with nine legs in the control group ($P<0{\cdot}01$). The ABPI for the posterior tibial artery was $<1{\cdot}00$ in 12 legs in Behçet's group and in none of the controls ($P<0{\cdot}01$). The FBPI was significantly higher in the control group compared with the Behçet's disease group (1·32 *versus* 1·23 for the right leg, $P<0{\cdot}05$, 1·30 *versus* 1·22 for the left leg, $P<0{\cdot}03$).

It is concluded that the vascular symptom-free Behçet's disease has a significant incidence of arterial involvement. This patient group might benefit from screening on a routine basis.

Long-term results of the treatment of postphlebitic syndrome with the Felder operation

Z. Mackiewicz, St. Molski and P Flisiński, *Department of General and Vascular Surgery, Medical Academy of Bydgoszcz, Poland*

The postphlebitic syndrome is an important social problem, because of the frequency of the disease and difficulties of treatment Some 3 per cent of the Polish population suffer from this disease Many operative methods are used in the treatment of grade I postphlebitic syndrome In the authors' opinion the most useful procedure is the Linton operation with Felder modification. From 1983 to 1991, 93 patients with postphlebitic syndrome were operated on In three cases both limbs were treated In each case a Linton operation with Felder modification was performed. The patients' ages ranged from 28 to 77 (mean 47) years Duration of the disease was from 1 to 33 years. Ulcerations were present in 63 cases before operation The complications in the perioperative period were: deep vein thrombosis, two patients, marginal necrosis of the skin, five, wound infection, 11. Recurrent ulceration, smaller and less trouble, was observed in ten cases. In patients with recurrent ulceration descending venography was performed. In five patients incompetent valves were present in the deep venous trunk. Four of this group underwent transplantation of a segment of brachial vein with sufficient valves, in the other transposition of a vein trunk was done. It is necessary to consider coexisting insufficiency of valves in the iliac and femoral trunk when the Felder operation is unsuccessful.

Strategy for arteriovenous fistulas as vascular access in haemodialysis

A. Marx, L Gurke, M. Heberer, F Harder and J. Landmann, *Department of Surgery, University Hospital, Basel, Switzerland*

Diligent use of the patient's own blood vessels and a clear distal-to-proximal strategy in establishing arteriovenous (AV) fistulas are key points in vascular access surgery for haemodialysis The snuff-box fistula should be the access of first choice, followed by the Brescia–Cimino fistula Proximal upper-extremity fistulas (brachiocephalic or brachiobasilic) should be established only if these peripheral fistulas fail Graft fistulas should be reserved for patients in whom all autologous veins have been used.

The authors' experience pertains to 487 AV fistulas performed over a period of 17 years. In all, 86·7 per cent of patients referred for primary vascular access surgery were suitable for the creation of a peripheral direct AV fistula. After one or several additional fistulas in cases where the primary access failed, 73·6 per cent of all unselected patients are still on maintenance haemodialysis with one of these peripheral AV fistulas

	No.	Patency rate (%)		
		1 year	2 years	3 years
Peripheral fistula				
Snuff-box	216	74	67	64
Brescia–Cimino	148	65	61	60
Upper-extremity fistula				
Brachiobasilic	55	78	74	
Brachiocephalic	25	70	60	
Interposition graft	43	74	57	

These results seem to support this step-by-step strategy Use of the native vessels progressing from the snuff-box fistula to use of the upper-extremity veins should be preferred to implantation of interposition grafts.

Heterogeneous growth responses of human vascular smooth muscle: an insight into restenosis

E Munro*, P. Chan*, M. Patel, L. Betteridge, K. Gallagher, M. Schachter, P. Sever and J. Wolfe*, *Departments of *Vascular Surgery and Clinical Pharmacology, St Mary's Hospital and Medical School, London, UK*

Variation between individuals modelled in vascular smooth muscle cell (VSMC) hyperplasia *in vitro* may provide insights into the reasons why some, but not all, patients develop restenosis. In response to a standard 15 per cent fetal calf serum-stimulated 14-day cell growth assay, a 42 per cent coefficient of variation in growth rates is noted between different human VSMC lines from patients with restenosis and controls (n = 120) However, there was no correlation between increased growth rate and restenosis Heterogeneity is also prominent in the response of VSMC lines to growth inhibition

Inhibitor	No.	Median (range) inhibition	Coefficient of variation
Heparin (100 μg ml^{-1})	47	14·9 (0–90)	22·3
Fenofibrate (100 μM)	18	53·0 (30–68)	4·5
Amlodipine (10 μM)	16	29·0 (21–40)	5·2

Values are percentages

Cell lines varied most in response to heparin, cell lines from patients with restenosis were relatively resistant to heparin inhibition (median 8 per cent (95 per cent confidence interval 2–25 per cent)) in comparison to patients undergoing primary bypass (median 22 per cent (95 per cent confidence interval 15–44 per cent); P < 0·001, Mann–Whitney U test).

Heterogeneity in growth response of human VSMC to inhibitors *in vitro* may reflect the variable propensities to restenosis observed in patients *in vivo*, and may account for variable responses to agents in clinical trials aimed at preventing restenosis

Protection against no reflow after ischaemia

D. O'Farrell, L.E. Chen, A.V. Seaber and J.R. Urbaniak, *Duke University Medical Center, Durham, North Carolina, USA*

The aim of this study was to demonstrate no reflow in skeletal muscle and to assess the benefit of allopurinol and manganese superoxide dismutase (MNSOD) The cremaster of 40 Sprague–Dawley rats was isolated the right was used for experimental manipulation and the left as a control The rats were separated into five groups: group 1 were subjected to 5 h ischaemia, group 2 had 5 h ischaemia and then 90 min reperfusion, groups 3–5 had 5 h ischaemia followed by 90 min reperfusion, but group 3 had 0·9 per cent saline, group 4 had allopurinol and group 5 had MNSOD after the period of ischaemia but before reperfusion. Responses to electrical field stimulation and postischaemic fluorescein dye perfusion were used to assess muscle injury in the treatment and control groups. Isometric tension in equivalent muscle strips was measured in an organ bath system The contractile force developed, expressed as a percentage of control, is shown

	Group 1	Group 2	Group 3	Group 4	Group 5
Potassium chloride	72(13)	31(13)*	28(9)	74(10)†	72(12)†
Twitch	57(13)	15(8)*	15(5)	48(15)†	56(9)†
Tetanus	68(15)	23(7)*	23(7)	55(17)	66(10)†

Values are mean(s.e.m.). *P < 0·05 *versus* group 1, †P < 0·05 *versus* group 2 (Mann–Whitney U test)

This study demonstrates that 5 h ischaemia produces a 50 per cent reduction in skeletal muscle function and further deterioration occurs (85 per cent functional loss) after 90 min reperfusion However, treatment with MNSOD before restoration of flow protects function and circulation Allopurinol shows a similar but lesser effect.

Preventing reperfusion injury in skeletal muscle

D. O'Farrell, L.E. Chen, A.V. Seaber and J.R. Urbaniak, *Duke University Medical Center, Durham, North Carolina, USA*

The aim of this study was to reduce skeletal muscle reperfusion injury using tumour necrosis factor alpha (TNF-α), D-factor and manganese superoxide dismutase (MNSOD). The protective effects of each agent were compared by measuring muscle function and blood vessel diameter (*in vivo* videomicroscopy) in treatment and control groups.

The right cremaster muscle was isolated in 40 Sprague–Dawley rats and ischaemia induced for 5 h; this was followed by 90 min reperfusion. Arteriolar diameters were measured before and during ischaemia and reperfusion.

Isometric tension in response to electrical field stimulation and potassium chloride was measured in an organ bath

	Saline	MNSOD before	MNSOD after	TNF-α	D-factor
Tetanus	23(7)	102(18)*	66(10)*	35(10)	28(19)
Twitch	15(5)	102(24)*	56(9)*	34(11)	15(7)
Potassium chloride	32(8)	120(22)*	72(12)	38(15)	21(11)

Values are mean(s e m.) maximal tension of right cremaster as a percentage of the control (left cremaster) $*P < 0\ 05$ *versus* saline group (Mann–Whitney *U* test)

In conclusion, MNSOD confers significant protection from reperfusion injury on skeletal muscle, particularly if given before the ischaemic insult, but TNF-α and D-factor do not have such an effect in this model

Surgical treatment of the post-thrombotic syndrome: improvement of the Linton operation by use of piracetam

J.-P. Puts and J.A. Gruwez, *Catholic University Hospitals, Brussels, Belgium*

In 1938, Linton proposed a technique for the treatment of patients affected by the post-thrombotic syndrome (PTS). However, more than 50 per cent of the patients developed some degree of postoperative cutaneous complications skin necrosis or epidermolysis A total of 176 Linton operations were performed at this centre during the past 8 years. The first group (1) of 60 Linton procedures was performed without protection from a low molecular weight heparin (LMWH). Of these patients 17 (28 per cent) developed cutaneous complications and one had a pulmonary embolism. A LMWH was then used systematically in a second series of patients (group 2) There was an increase in cutaneous complications, 31 of these 70 patients (44 per cent) developed skin necrosis (group 2 *versus* 1· $\chi^2 = 3{\cdot}53$, $P < 0\ 07$) However, 58 per cent of a subgroup of 40 patients with venous ulcerations had postoperative skin necrosis ($\chi^2 = 4{\cdot}24$, $P < 0\ 04$) Finally, a combination of piracetam and LMWH was used in group 3 of 46 patients undergoing Linton operations Four (9 per cent) had postoperative skin necrosis (group 3 *versus* 2. $\chi^2 = 16\ 69$, $P < 0\ 0001$) Piracetam decreased the incidence of skin necrosis 6 7 times in the absence of venous ulceration ($\chi^2 = 5{\cdot}12$, $P < 0\ 03$) and 4·1 times in the presence of ulceration ($\chi^2 = 10\ 51$, $P < 0\ 002$). It is suggested that a standardized Linton operation is a satisfactory surgical treatment of PTS. Venous ulcerations heal quickly The high cutaneous complication rate reported in the literature can be reduced by using a combination of piracetam and LMWH

Negative angiography in subarachnoid haemorrhage

S. E. Refsum*, C. McKinstry, N. Pathirana and K.E. Bell, *Department of Neuroradiology, Royal Victoria Hospital and *Department of Surgery, Queen's University of Belfast, Belfast, UK*

Between 10 and 20 per cent of patients with a proven subarachnoid haemorrhage (SAH) will have a normal cerebral angiogram. The prognosis is believed to be good. Given the risks of rebleeding from an undetected aneurysm, it is important to ensure that the arteriogram is truly negative before assigning a patient to this group The aim of this study was to review experience with repeat arteriography over a 2-year period

All patients with proven SAH had their case notes and radiological investigations reviewed between 1 January 1990 and 1 April 1992. SAHs secondary to a brain tumour, trauma or primary intracerebral bleed were excluded. Patients with an initial negative or equivocal angiogram were classified according to the original report and the repeat angiograms then reviewed without knowledge of the original report.

There were 216 proven SAH cases of which 172 (79 6 per cent) had an aneurysm identified, while 44 (20·3 per cent) cases were either normal or equivocal for the presence of an aneurysm Thirty of these patients underwent repeat arteriography and an aneurysm was demonstrated in ten. Three of these were from the initial entirely normal group

In conclusion, repeat arteriography is recommended in proven SAH even when the initial study is normal.

Central venous miniport implanted with a new surgical technique on the distal upper arm

K. Ridwelski, W. Berdel* and H. Lippert, *Surgical Clinic (Charité) and *University Clinic Steglitz, Berlin, Germany*

A new miniport system was used for central venous access in a prospective study including 61 patients Fifteen patients had the port positioned on their forearm and 22 on the chest wall The remaining 24 patients had miniports implanted by a new technique on the distal upper arm. The basal or brachial veins were dissected and the catheter implanted under local anaesthetic Using a new electromagnetic catheter tracking system, the catheter tip was positioned in the superior vena cava. When compared with radiographic detection the system predicted the position of the catheter tip accurately in 22 patients and changed surgical procedure by predicting incorrectly in two patients The miniports were used for chemotherapy and supportive treatment, including parenteral nutrition and transfusion Complications were observed in seven of the 15 patients with a proximal forearm port and four of the 22 patients with the chest wall port No complications were observed in patients who had implantation of the port into the distal upper arm.

As a result of this prospective study, implantation of miniports was carried out in the distal upper arm in 82 patients With a mean expected system function of 152 (range 35–485) days the complication rate was 4 per cent (two infections, one paravasation, and one incurable pain). As a consequence only three miniports had to be removed

Intravenous digital subtraction angiography *versus* computed tomography in assessment of abdominal aortic aneurysm

R.A. Salaman, A. Shandall, R.H. Morgan, L. Fligelstone, W.T. Davies and I.F. Lane, *Cardiff Vascular Unit, University Hospital of Wales, Cardiff, UK*

The aim of this study was to compare the accuracy of intravenous digital subtraction angiography (DSA) and computed tomography (CT) in the preoperative assessment of abdominal aortic aneurysm (AAA)

Patients who had undergone elective AAA repair within the past 3 years were identified and their case notes and preoperative radiology reviewed. A total of 127 patients were identified: 103 had had preoperative DSA, 118 CT and 94 had had both Preoperative radiology reports were compared with operative findings and the sensitivity and specificity of the two investigations compared

	Renal artery involvement		Iliac artery involvement	
	DSA	CT	DSA	CT
Involvement	98 of 103 (95)	105 of 118 (89)	158 of 202 (78)	178 of 222 (80)
Sensitivity	0·60	0·83	0·75	0 56
Specificity	0·99	0·90	0 79	0·88
False positive	1 (4)	11 (52)	32 (47)	20 (40)
False negative	4 (14)	2 (2)	12 (9)	24 (14)

Values in parentheses are percentages

DSA and CT are both useful investigations in the preoperative assessment of aortic aneurysms. This study showed CT to have a higher sensitivity than DSA in the prediction of renal artery involvement This, however, was at the expense of a very high false-positive rate. DSA was far more specific than CT, though less sensitive, and missed 40 per cent of suprarenal aneurysms

Neither investigation is a good predictor of iliac involvement, both having high false-positive rates This is possibly because of underestimation of aneurysm extent by the surgeon, and the reporting of ectatic arteries as aneurysmal by the radiologist DSA gave additional information about distal occlusive disease and run-off which was not available with CT Both DSA and CT are useful investigations, but both have their limitations. Vascular surgeons should be aware of these when interpreting their results

Abdominal aortic aneurysm: 10-year population study in Glasgow

A.K. Samy and G. MacBain, *Southern General Hospital, Glasgow, UK*

A total of 2936 cases of aortic aneurysm admitted to Glasgow hospitals between January 1980 and December 1989 were studied. Information was obtained first from Scottish Morbidity Records 1, Scottish Hospital Inpatients Statistics, and the accuracy assessed by detailed inspection of 500 case notes evenly distributed throughout the study period. The data from 489 of these matched the Scottish Morbidity Records data which were therefore accurate in 97·8 per cent of these cases.

Of the 2936 patients, 852 (29·0 per cent) had more than one admission with the same diagnosis in the same year and of the remaining 2084, 169 (8·1 per cent) had thoracic aneurysm. After correction for these findings, the remaining 1915 patients with abdominal aortic aneurysm (AAA) were further studied Of these, 618 (32·3 per cent) were women, giving a male to female ratio of approximately 2·1, which remained constant for each year of the study The mean(s.d , s e m) age of the study population increased from 70·3(9·0, 0·74) years in 1980 to 72·3(9·2, 0·53) years in 1989. There was a significant increase in the percentage of patients over the age of 75 years (from 17·4 per cent (25 of 144) in 1980 to 28·8 per cent (86 of 299) in 1989) Some 27·1 per cent of the patients (519 of 1915) had ruptured aneurysm. Hospital mortality rate for all patients with AAA was 25·4 per cent (486 of 1915) 15·2 per cent (211 of 1389) for intact and 53·2 per cent (275 of 517) for ruptured AAA, including unoperated cases This mortality rate for patients at Glasgow Royal Infirmary, the location of the only full-time vascular unit in the city which accounted for 713 patients (37·2 per cent) of the whole study population, was lower for both ruptured and intact AAA compared with the other Glasgow hospitals The figures were 40·5 per cent (64 of 158) for ruptured and 7·9 per cent (44 of 555) for intact AAA in the Royal Infirmary compared with 58·8 per cent (211 of 359) and 19·7 per cent (166 of 843) in the other hospitals.

Allowing for improved diagnostic techniques and clinical awareness of the disease, there seems to be an increase in the incidence of AAA in Glasgow, and more women with the condition than expected The figures support the claim that vascular surgery should where possible be managed by fully trained vascular surgeons.

Vacuum compression therapy to ischaemic lower limbs

A.K. Samy, G. MacBain and A. Hutchison, *Southern General Hospital, Glasgow, UK*

A vacuum compression therapy device exerting alternating negative and positive pressures was used on 13 consecutive patients with chronic lower-limb ischaemia Lack of rest pain was used to assess the effects on the limb's venous blood quality and capillary flow Toe pulse oximetry and measurements of femoral venous blood gases and lactate were performed at three points. before, immediately after and 15 min after a short session of vacuum compression therapy There was evidence of initial deterioration in levels of blood gases and lactate immediately after the end of the session followed by significant improvement 15 min later

Mean(s.e.m) values before and 15 min after were compared: oxygen saturation in the toes increased from 94·3(0·52) to 97·8(0·36) per cent ($P = 0·002$); venous partial pressure of oxygen increased from 4·1(0·13) to 4·6(0·18) kPa ($P = 0·003$), venous partial pressure of carbon dioxide was hardly altered from 6·57(0·15) to 6·61(0·17) kPa ($P = 0·003$), venous hydrogen ion concentration decreased from 41·6(0·68) to 40·2(0·63) ($P = 0·003$), and venous lactate concentration decreased from 1·0(0·08) to 0·91(0·1) mmol l^{-1} ($P = 0·004$). No patient developed complications and eight experienced warmer feet for a mean(s e m) of 5·5(0·53) h following the therapy It is therefore suggested that vacuum compression therapy may improve capillary circulation of ischaemic limbs. The initial asymptomatic biochemical deterioration of the local venous blood quality may be attributed to a capillary washout phenomenon and/or a tourniquet effect of the device's rubber cuff over the patient's thigh. Further studies monitoring clinical criteria may be essential to establish the objective benefits of vacuum compression therapy in peripheral vascular disease.

Efficacy of rifampicin-impregnated graft in reducing methicillin-resistant *Staphylococcus aureus* vascular graft infection in a sheep model

F. Sardelic, P.Y. Ao and J.P. Fletcher, *Westmead Hospital, Sydney, Australia*

Methicillin-resistant *Staphylococcus aureus* (MRSA) is the most common infecting organism in the authors' experience of vascular graft infection The aim was to study the efficacy of rifampicin-impregnated Dacron in preventing vascular graft infection after a topical inoculum of MRSA. A left carotid artery interposition graft (length 2 cm and diameter 5 mm) was placed in 20 Merino sheep under general anaesthesia. Either a standard gelatin-sealed Dacron graft (control group, $n = 10$) or a rifampicin-soaked gelatin-sealed Dacron graft (treatment group, $n = 10$) was used At the completion of operation a topical inoculum of 108 colony-forming units of MRSA was applied After 3 weeks the sheep were reanaesthetized and the grafts were harvested in a sterile fashion. Cultures were taken of the perigraft tissues, external surface and internal washings of the graft and of a graft segment In the control group 38 of 40 cultures were positive, while only 19 of 32 cultures were positive in the treatment group ($P < 0·001$) All grafts were infected on at least one culture There was a significant decrease in abscess formation in the treatment group ($P < 0·003$) There was no difference in patency rates or anastomotic disruption. None of the MRSA retrieved from the grafts had developed resistance to rifampicin

Long-term outcome of critical limb ischaemia

R. Sayers, M. Thompson, A. Naylor, J. Budd, N. London, D. Ratliff and P.R F. Bell, *University of Leicester, Leicester, UK*

Factors affecting the outcome of critical leg ischaemia need to be defined to formulate appropriate treatment options. During a 42-month period 232 critically ischaemic limbs were treated in 209 patients (median age 71 (range 42–92) years), of whom 76 (36 per cent) had diabetes mellitus Tissue necrosis was the presenting feature in 123 limbs (53 per cent) and rest pain alone in 109 (47 per cent) Overall, although the cumulative 2-year limb salvage rate was 71 per cent with a corresponding mortality rate of 27 per cent, only 36 per cent of patients remained symptom-free after 12-month follow-up Univariate analysis of pretreatment risk factors showed that advanced age, sex, diabetes mellitus, tissue necrosis or the preoperative ankle pressure did not affect limb salvage, mortality, or symptom recurrence rates Although it is possible to achieve high limb salvage rates by pursuing an aggressive approach to revascularization in critical limb ischaemia, recurrence of symptoms is common The outcome of treatment, however, is not influenced by preoperative risk factors and these should not be considered to be contraindications to revascularization.

Analysis of critical risk factors for elective aortic replacement for abdominal aortic aneurysm

D.M Shah, R.P. Leather, B B Chang and R.C. Darling III, *Albany Medical College, Albany, New York, USA*

Complications and causes of mortality in 768 consecutive patients who underwent elective aortic replacement (EAR) for abdominal aortic aneurysm (AAA) during the past 12 years were analysed Age ranged from 37 to 92 years, and the male female ratio was 3:1. EAR was performed using either transperitoneal endoaneurysmorrhaphy or a retroperitoneal approach A total of 20 patients had severe chronic obstructive pulmonary disease and 1·5 per cent were on home oxygen. Some 33 per cent of patients had preoperative creatine levels above 1 3 mg dl^{-1}, 15 patients were dialysis dependent and six had had a renal transplant The perioperative mortality rate was 2·3 per cent and did not change significantly with either time or operative technique. The majority of deaths were the result of cardiac complications (56 per cent) In addition, 8 7 per cent of patients had non-fatal complications, which were equally distributed among renal, pulmonary and cardiac causes.

Cardiovascular, pulmonary and renal risk factors, complications and mortality in the last 50 consecutive patients were prospectively evaluated. Some 40 per cent had moderate to restricted pulmonary function and 50 per cent a serum creatine level greater than 1·3 mg dl^{-1} The mortality rate, causes of death and complication rate remained similar. These data show that pulmonary and renal impairment did not pose significant risks for EAR. Cardiac risk was the same, in spite of detailed cardiac evaluation by history, electrocardiogram, stress tests and selective cardiac catheterization. It is suggested, therefore that, except for significant coronary artery disease, no other risk factors should deter EAR for AAA.

Autotransfusion in aortic surgery using a new membrane cell separator

Z.A. Varga, J.F. Thompson, J.C. Locke-Edmunds, R.N. Baird, P.M. Lamont and J.R. Farndon, *University Department of Surgery, Bristol Royal Infirmary, Bristol, UK*

To date, centrifugal cell separators have been used in intraoperative autotransfusion An alternative is to use filtration. The Haemocell 350 system, which employs pulsed flow and a high surface area quadruple sandwich filter, has undergone investigation.

A 0·2-μm pore size filter was studied first (n = 8). This yielded high heparin (3·2 units) levels and a low packed cell volume (PCV) (0·19, 0 16) in the reinfusate; electron micrographs revealed filter blockage. In the second phase a 0 6-μm pore size filter was used Collected blood was either washed (n = 5) or unwashed (n = 5) with saline. Filter efficiency was judged by PCV, plasma haemoglobin (Hb), D-dimer and heparin washout. Two units of collected blood were processed with each filter.

	Washed		Unwashed	
	Unit 1	Unit 2	Unit 1	Unit 2
PCV	0 20	0 13	0 25	0 22
	(0 20–0 26)	(0 12–0 17)	(0 24–0 35)	(0 15–0 23)
Hb	230	180	528	286
(mg dl^{-1})	(42–337)	(75–320)	(230–1390)	(216–841)
D-dimer	4	8	32	32
(μg ml^{-1})	(4–16)	(4–16)	(16–64)	(16–64)
Heparin	1 6	2 4	3 0	3 0
concentration (units ml^{-1})	(1 2–5 1)	(1 3–6 8)	(2 0–5 2)	(1 2–5 0)
Amount of	464	1039	462	882
heparin (units)	(342–1775)	(651–3230)	(242–775)	(458–1345)
Processed	550	580	540	545
volume (ml)	(480–570)	(470–620)	(490–654)	(480–620)
Reinfused	356	540	196	446
volume (ml)	(346–446)	(496–626)	(186–206)	(336–488)

Values are median (range)

Filtration and saline washing reduced heparin, D-dimer and haemoglobin concentrations, but increased the quantity of reinfusate and decreased its PCV In both groups a considerable amount of heparin was present in the reinfusate. Clinical application of this system should be confined to cardiovascular surgery where the effect of heparin can be reversed with protamine.

Ne–He laser radiation in treatment of crural ulcerations in patients with post-thrombotic syndrome and diabetic angiopathy

J. Wasiak, L. Wolf, M. Sopiński, R. Markert, U. Mikulska, P. Janczak, W. Olejniczak and K. Kotodziejczyk, *Department of Surgery, University of Medicine and Institute of Physics, Lodz, Poland*

Crural ulcerations resulting from post-thrombotic syndrome and diabetic angiopathy were treated with 0·25 per cent silver nitrate solution and moist applications of antibiotics effective against cultured microflora In addition, crural ulcerations were irradiated in randomized patients with a Ne–He laser The field of ulcerations was planimetrically measured by contact copies on sterile foil strips. Comparison of epithelialization times of ulceration enabled the determination of the effectiveness of the procedure. No patient showed arterial disorders in the lower extremities, 90 limbs were treated, including 70 with post-thrombotic syndrome and 22 with diabetic angiopathy Differences were not found between healing rates of irradiated and non-irradiated ulcerations in patients with post-thrombotic syndrome Healing time of ulcerations in diabetic patients was shorter than in those with post-thrombotic syndrome Healing time of irradiated ulcerations in the limbs of diabetic patients was statistically shorter The results obtained encourage the use of the Ne–He laser in the treatment of diabetic legs.

Lipid peroxidation in spinal cord ischaemia and reperfusion injury

Z. Yi, L.Y. Bing, L.W. Hong, L.L. Sheng and Z. Min, *Research Institute of Surgery, Daping, Chongqing, China*

Changes in lipid peroxidation in a rabbit model of typical spinal cord injury are reported Secondary paraplegia was induced by abdominal aortic occlusion. After 40 min of occlusion, the malonyldialdehyde (MDA) level and water content in the T7–T8 and L3–L4 regions increased, while superoxide dismutase (SOD) decreased. After 30 min, and 2, 4 and 24 h of reperfusion, the MDA level and water content continued to increase ($P <$ 0·001), MDA reached a peak after 4 h of reperfusion, while SOD decreased (compared with normal control levels and those measured during the period of ischaemia, $P <$ 0·001) The changes in SOD and MDA levels in the spinal cord correlated negatively (T7–T8. $r = -0·7$, $P <$ 0 01; L3–L4, $r = -0·98$. $P <$ 0 001). The MDA levels and water content correlated with each other positively (T7–T8 r = 0 94, $P <$ 0 01; L3–L4. r = 0 76, $P <$ 0 05) It may be inferred that lipid peroxidation played an important role in the deterioration of hindlimb function and pathological changes of the cord after spinal ischaemia and reperfusion, furthermore, suppressing the production of free radicals and enhancing antioxidant activity in local tissues might be of benefit in preventing secondary injury

Accelerated peripheral thrombolysis with a pulse-spray technique

S.W. Yusuf, S.C. Whitaker, R.H.S. Gregson, J. Astil, P.W. Wenham, B.R. Hopkinson and G.S. Makin, *University Hospital, Nottingham, UK*

Pulse-spray thrombolysis (PST) is a new technique of accelerated thrombolysis. This study presents experience of 23 consecutive patients, 20 with native peripheral arterial thrombosis and three with peripheral bypass graft thrombosis. The median age of the patients was 74·5 (range 35–89) years and the median duration of symptoms 6 (range 1–60) days. Severe ischaemia with sensory and motor deficit was present in 11 of 23 patients. Recombinant tissue plasminogen activator (rtPA) was used in a concentration of 0·33 mg ml^{-1} in boluses of 0·2 ml with a median total dose of 18 (range 10–35) mg. The median length of occlusion was 23 (range 4–55) cm. Complete radiological lysis was achieved in 22 of 23 cases and the median duration of lysis was 135 (range 50–1125) min which is a nine-fold reduction in the lysis time compared with results of conventional therapy with rtPA. The median ankle.brachial pressure index improved significantly (P = 0·002, Mann–Whitney U test) from a prelysis value of 0 to a value after lysis of 0 8. PST rapidly restores vascular patency and therefore may become the treatment of choice in acute limb ischaemia including those at immediate risk of irreversible ischaemic damage, which would conventionally be treated with emergency surgical reconstruction.

Journal of the Royal College of Surgeons of Edinburgh

Edited by **Alfred Cuschieri**

Published for the Royal College of Surgeons of Edinburgh

The ***Journal of the Royal College of Surgeons of Edinburgh*** covers clinical advances in management within general surgery and other surgical specialities. Each issue of the journal is comprised of a balance between original peer-reviewed publications and state-of-the-art commissioned reviews on major current topics. It also incorporates an Operative and Technology Section with special reference to Minimal Access Surgery.

Journal of the Royal College of Surgeons of Edinburgh is published bimonthly. Subscription prices for 1993 are as follows: £88.50 (Europe), US$170.00 (USA & Canada), and £97.00 (elsewhere).

The official journal of the Society for Minimally Invasive Therapy

Minimally Invasive Therapy

Editor: John Wickham

Assistant Editors: M J Coptcoat, A Adam, E vanSonnenberg, J M Fitzpatrick

Since the founding of the Society for Minimally Invasive Therapy in 1989, the subject has gained rapidly in prominence and importance. A large number of surgeons, radiologists and clinicians are now just beginning to appreciate the benefits, both to patients and practitioners, of minimally invasive techniques. *Minimally Invasive Therapy* includes innovative research papers, expert review articles, topical leading articles, instrumental studies and correspondence. *Minimally Invasive Therapy* is a prestigious base from which workers in any speciality may present their experience for the benefit of their colleagues and patients.

Minimally Invasive Therapy is published bimonthly. Subscription prices for Volume 2, 1993, are as follows: Individual £80.00 (Europe), £88.00 (Overseas), US$173.00 (USA & Canada); Institutional £133.00 (Europe), £146.50 (Overseas), US$258.00 (USA & Canada).

All members of the Society for Minimally Invasive Therapy will receive the journal as part of their annual dues. Further details regarding the Society can be obtained from: Miss Fay Harrison, Minimally Invasive Therapy Unit, 2nd Floor New Guy's House, Guy's Hospital, St Thomas Street, London SE1 9RT, UK
